The inverse satellite model allows the computation of the motor currents for a given trajectory of the satellite in a way that the elasticity of the powertrains and flexible solar panels is taken into account and compensated. Using the inverse model, optimal re-orientation maneuvers have been computed for energy and time optimality. The use of inverse satellite models in this optimization greatly improves the optimization process by simplifying the problem considerably.

As part of a two degree of freedom control system, the inverse satellite model can be used as a feed-forward controller to compensate elastic effects and other modeled nonlinear effects that act on the satellite.

## Abstract

Stage separation dynamics modeling is a critical capability of future launchers preparatory studies. The development of stage separation frameworks integrable in end-to-end launch vehicle trajectory simulations have been presented in the relevant literature but none profiting from the object-oriented and equation-based acausal modeling properties of MODELICA. The objective of this paper is therefore to present such an approach to this problematic. Based on the *Constraint Force Equation* (CFE) methodology, two case studies to evaluate the proposed approach are considered. Results demonstrate that the approach corresponds very well with the physics behind separation. In addition, we found easiness of implementation of the method within a single environment such as DYMOLA, demonstrating the benefits of an integrated approach.

## 1 Introduction

Stage separation dynamics modeling is a very challenging task and a critical capability that must be considered in the preparatory studies and development of next generation launchers [14, 16, 17]. The integration of such stage separation modeling into a single environment capable of end-to-end launch vehicle trajectory simulation is also a key technology to aim for.

The importance of such capability arises from the fact that after separation, the integrity of each stage must be kept in order to guarantee overall success of the space mission pursued. In this sense, the development of an integrated framework for analysis and simulation of stage separation is desired.

Early efforts on the subject of multi stage launch vehicle separation from the 60's and 70's are mainly

from NASA studies [1, 2, 4] and their *Program to Optimize Simulated Trajectories (POST)* as a generalized trajectory simulation and optimization software [5], developed in partnership with the (then) Martin Marietta Corporation. Renewed interest in the subject in the 2000's led NASA's development of a stage separation conceptual separation tool, *ConSep* [11, 12, 13, 14]; which is a MATLAB-based wrapper to the commercially available ADAMS solver, as its predecessor *SepSim*. However, being *SepSim* and *ConSep* dependent on the commercial software ADAMS, they have the disadvantage of not being easily integrable in a generic trajectory simulation software. This in turn eludes the capability of performing efficient end-to-end launch vehicle trajectory simulations. As a result, a generalized approach to stage separation problems of launch vehicles was developed [16]. The approach, coined as the *Constraint Force Equation* (CFE) methodology, was implemented into the *Program to Optimize Simulated Trajectories II (POST2)*, the *POST* follow-up. Separation studies applied to real platforms such as the Hyper-X or the Space Shuttle can be found in [18, 10]. The thesis [15] studies launcher separation analysis with OPENMODELICA but results in a tool (*OMSep*) which is only capable of input-output analyses at separation time, and not for generic launch vehicle trajectories.

As yet, an object-oriented and equation-based acausal modeling approach to stage separation dynamics integrable in end-to-end launch vehicle trajectory simulations is still missing. Such approach could potentially facilitate the integration of this and other capabilities within a single multi-physics environment such as DYMOLA.

The objective of this paper is therefore to present such an alternate approach to stage separation dynam-

ics based on the CFE methodology using MODELICA [7, 8]. We do this by means of the following sub-objectives: We study first the modeling challenges of multi-stage launcher separation dynamics; then we present an approach based on CFE implemented in MODELICA; following, we provide two case studies for which we apply the method; and finally we present some results and discussion, outlining benefits and disadvantages.

## 2 Modeling

For the simulation of launch vehicle stage separation dynamics, it is necessary being able to model two bodies connected together according to properly-selected constraints prior to their physical separation; and at the release command of such constraints, their subsequent and independent flight motion must continue. This section presents the separation dynamics and the separation mechanisms modeling aspects.

### 2.1 Separation dynamics

We refer to separation dynamics in this paper the study of the effects of forces and torques of a two-body system during their physical separation.

Such separation dynamics modeling clearly exhibits discontinuities similar to those described by other phenomena such as switching, limiting, friction, etc. Modeling must deal with these problems in special ways since this kind of behavior is sensitive to numerical solution errors, initial condition calculation/propagation, and integration in general.

MODELICA offers the possibility to implement a.o. several methods for such phenomena:

- *Stop and restart*: The complete system is simulated as a single body until separation time. Then the system is splitted into two bodies with independent states, and initial conditions are propagated accordingly. This solution however requires the split of two (or more) events.
- *Regularization*: This methodology consists on applying the constraint between the two bodies during their connected motion with a smooth but very stiff spring-damper system. This avoids the use of strict discrete or event behaviors. Such methodology is commonly used for simulation of friction, stiction, and other similar nonlinear behavior.

- *Hybrid*: This methodology consists on treating the simulation as a hybrid state machine where continuous and discontinuous behaviors are conditioned with data flows and proper transitions. This hybrid state machine framework is however complex to integrate in generic form for launch vehicle trajectory simulations.
- *Constraint Force Equation (CFE) Methodology*: The CFE methodology [16, 17, 18] consists on computing internal constraint forces and moments on two bodies during their connected motion and their application as external forces and torques to each of them separately. On separation command, these internal forces are set to zero, and then each body carries their own flight motion separately.

Of these methods, particular interest due to its applicability and easiness of implementation is given to the CFE methodology, which is selected as the primary method for the follow up of this study.

#### 2.1.1 Constraint Force Equation Methodology

The *Constraint Force Equation* (CFE) methodology [16, 17, 18] is a highly intuitive method consisting in the computation of joint loads, namely internal forces and torques, caused by joint constraints; along with their application as external forces and torques on each body independently, see Figure 1.

The joint loads which constrain one body’s motion relative to the other are dependent upon the external forces acting on each body as well as the type of joint. The net forces and torques on each body are therefore the sum of the usual external forces and torques *plus* the joint loads applied to each body as additional external forces and torques. In consequence, the CFE joint model simply augments the external loads of the system [17]. Quoting step by step [16, 17], the equa-

Figure 1: CFE diagram. Illustration credits: [16].

tions of constrained motion of two rigid bodies ( $A$  and  $B$ ) connected by a single joint (point  $\bar{A}$  in body  $A$  and point  $\bar{B}$  in body  $B$ ) are as follows:

$$\mathbf{F}_A^{(ext)} + \mathbf{F}_A^{(con)} = m_A \ddot{\mathbf{x}}_A, \quad (1)$$

$$\mathbf{T}_A^{(ext)} + \rho_A \mathbf{F}_A^{(con)} + \mathbf{T}_A^{(con)} = \mathbf{I}_A \dot{\boldsymbol{\omega}}_A + \boldsymbol{\omega}_A \times \mathbf{I}_A \boldsymbol{\omega}_A \quad (2)$$

where  $\rho_A$  is the position vector from the mass center of  $A$  to point  $\bar{A}$  of  $A$  at which the constraint force is applied. Similarly for  $B$ :

$$\mathbf{F}_B^{(ext)} + \mathbf{F}_B^{(con)} = m_B \ddot{\mathbf{x}}_B, \quad (3)$$

$$\mathbf{T}_B^{(ext)} + \rho_B \mathbf{F}_B^{(con)} + \mathbf{T}_B^{(con)} = \mathbf{I}_B \dot{\boldsymbol{\omega}}_B + \boldsymbol{\omega}_B \times \mathbf{I}_B \boldsymbol{\omega}_B. \quad (4)$$

There are so far 24 unknowns and 12 equations. Another set of six equations can be obtained from the law of action and reaction:

$$\mathbf{F}_A^{(con)} + \mathbf{F}_B^{(con)} = \mathbf{0} \quad (5)$$

$$\mathbf{T}_A^{(con)} + \mathbf{T}_B^{(con)} + (\mathbf{r}_B - \mathbf{r}_A) \times \mathbf{F}_B^{(con)} = \mathbf{0} \quad (6)$$

where  $\mathbf{r}_A = \mathbf{x}_A + \rho_A$  and  $\mathbf{r}_B = \mathbf{x}_B + \rho_B$ .

Six equations are missing. Worth noticing at this point, we only consider a *single joint* which constrain all six remaining degrees of freedom between the two bodies. This is because our focus is towards trajectory simulations and having multiple connections is not necessary unless when considering actuator sizing, sensitivity analyses, etc. In general, the CFE methodology allows to consider any type of joint which allows or not any specific relative motion between bodies; and redundancy of joints when necessary.

In this sense, for relative translation constraints and  $\mathbf{e}$  being unit-vectors of the corresponding ( $A$  or  $B$ ) body-frame, it is required that:

$$(\mathbf{r}_B - \mathbf{r}_A) \cdot \mathbf{e}_A = 0 \quad (7)$$

meaning that the distance between the two points of a particular direction remain fixed. And finally, for relative rotations constraints, it is required that:

$$\mathbf{e}_A \cdot \mathbf{e}_B = 0 \quad (8)$$

meaning that three properly selected two-unit-vector sets must remain perpendicular.

Eqs. (7)-(8) would have to be differentiated twice with respect to time so that the resulting relationships involve the unknown accelerations and angular accelerations, thus finally being able to couple them with the

equations of motion. In other words, the six missing equations are given by the following generalized constraint equations of the joint:

$$\ddot{g} = 0 \quad (9)$$

where  $g$  represents either of the nondifferentiated constraints in Eqs. (7) and (8). As it will be demonstrated in the next section, the manual differentiation of Eqs. (7)-(8) and their coupling with the equations of motion can be avoided altogether by the MODELICA implementation since this is done automatically. The last important aspect of the CFE methodology relevant to this work is the accuracy of the joint loads solution, which is sensitive to computational error and initial joint misalignment [17]. To handle such concern, the CFE algorithm could feature a.o. a stabilization technique known as Baumgarte stabilization [3, 6, 16]. This particular stabilization technique consists on replacing the ODE given by Eq. (9) which allows perturbations to grow linearly with time, by the following asymptotically stable ODE ( $\eta > 0$ ) involving terms of the once differentiated and nondifferentiated forms of  $g$ :

$$\ddot{g} + 2\eta \dot{g} + \eta^2 g = 0 \quad (10)$$

however at the expense of more computational effort. Many other stabilization techniques [6] could be implemented; these other methods, and a guidance for selecting  $\eta$  are however out of the scope of this paper.

## 2.2 Physical modeling of multi-stage separation mechanisms

Separation mechanism refers in this proposal to a mechanical model (or device) that makes separation possible in simulation (or reality). Physical modeling refers in this context on the capability to model separation behaviour by considering first principles (kinematics, dynamics, mechanics, physics, etc.); and being able to get realistic insight from such models for other purposes such as actuator sizing, sensitivity analyses, control, optimization, etc.

Based on our internal *DLR Space Systems Library*, separation mechanism physical models of different complexity levels can be studied. Simplified models for preliminary and conceptual studies; and more detailed ones for engineering validation aspects. These varying degrees of complexity would be helpful in order to perform separation mechanics analyses and

to assess the performance of the overall separation.

Configuration details of the separation mechanisms as well as their physical specifications must be provided to achieve more detailed and realistic models. Concerning the simple models, four variants have been studied:

- *Linear charge (release device)*: The linear charge model performs ideal or benchmark separation between two bodies. This mechanism “cuts” the two-body system on command. It simulates (ideal) explosive release devices, clamps, diaphragms, or point-release devices such as explosive bolts.
- *Bushing (separation impulse device)*: This model performs an impulsive reaction due to the release of a smooth but very stiff spring-damper system which keeps the two body system connected until separation command.
- *Kick-off spring (separation impulse device)*: Same as before, the impulsive reaction due to the release of a spring-damper system simulates the proper transmission of forces and moments of the two-body system during separation. This model is implemented with the *Constraint Force Equation* (CFE) methodology. This element is combined with a release device to simulate a realistic kick-off spring mechanism.
- *Generic (auxiliary devices)*: Other generic devices can be modeled in combination with the previous models, or with any other physical model from the library.

### 3 MODELICA implementation

In this section, the MODELICA implementation of separation mechanism models is presented. The challenges of this implementation strongly depends on the method selected as outlined in Section 2. Since the separation models in this work relies on a proper combination of the CFE methodology with physically-relevant elements, the implementation is not a straightforward application of existing MODELICA libraries; other aspects such as proper setup of initial conditions, state selection, modularity, and extendability are also challenging.

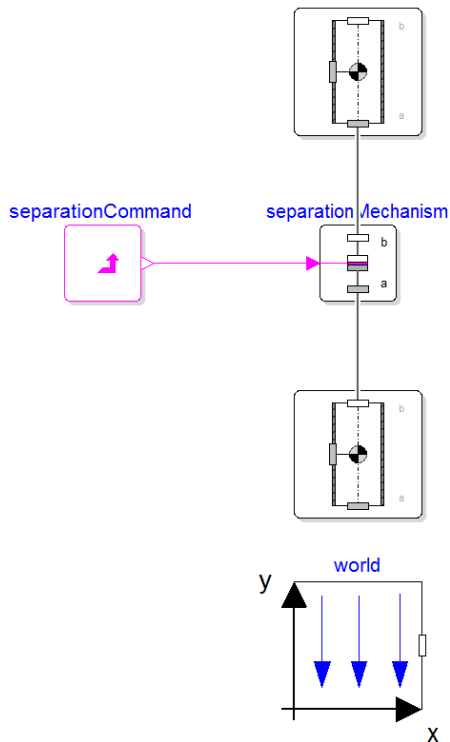

Figure 2: DYMOLA simulation layout consisting on a world model, two instances of rigid bodies, the separation mechanism model, and a boolean input for the separation command.

The baseline for the development of separation dynamics and separation mechanisms is the following partial mechanism model:

```

partial model PartialMechanism
  "Partial separation mechanism model"
  Interfaces.Frame_a frame_a
  "Joint frame a";
  Interfaces.Frame_b frame_b
  "Joint frame b";
  Interfaces.BooleanInput u;
end PartialMechanism;
    
```

As shown in the code, the partial mechanism interface model consists of two frames to connect a two-body system, and a boolean input for the ignition or separation command. Such interface allows the use of several separation models depending on the desired level of complexity by using replaceable instances. The approach here is bottom-up design, where the basis of separation dynamics simulation comes first from a single instance of a ‘release device’ mechanism.

In this work, a release mechanism model is implemented to simulate both a linear charge device com-

monly used in launcher stage separation, where the forces and moments at separation are zero; and as a base model for the next level of complexity. In other words, for the implementation of a separation impulsive device, an instance of a release device providing the capabilities of joint motion until separation is required on top of another physical model providing the corresponding impulsive forces or moments at the time of separation. Therefore, increasing the functionality to the separation model will consist on adding impulsive devices or simply improving the physics behind the device in question.

```

model SeparationMechanism
  "Separation mechanism model"
  Interfaces.Frame_a frame_a
    "Mechanism frame a";
  Interfaces.Frame_b frame_b
    "Mechanism frame b";
  Interfaces.BooleanInput u;
  replaceable Interfaces.PartialMechanism
end SeparationMechanism;

```

The implementation of the CFE procedure in MODELICA is as follows. The generalized constraint equations of the joint (9) have to be differentiated twice as explained before. Translational and rotational constraints at the joint are hence implemented as:

```

equation
  // generalized constraints
  g_con = frame_a.r_0 - frame_b.r_0;
  G_con = Frames.relativeRotation(frame_a.R
    , frame_b.R);

  // generalized velocity constraints
  g_con_dot = der(g_con);
  G_con_dot = Frames.angularVelocity2(G_con
    );

  // generalized acceleration constraints
  g_con_ddot = der(g_con_dot);
  G_con_ddot = der(G_con_dot);

  // CFE generalized joint constraints
  g_con_ddot = {0,0,0};
  G_con_ddot = {0,0,0};

```

In short, we present briefly two of the main models developed in this work:

- *Linear charge (separation release device)*: A release device is modeled by an instance of the *SeparationMechanism* model, called for instance **linearCharge**, which contains the partial interface outlined before, plus a switching mechanism between the CFE methodology and free body mo-

tion.

- *Kick-off spring (separation impulse device)*: An impulsive device is modeled by an instance of the *SeparationMechanism* model, called for instance **kickOffSpring**, which contains a **linearCharge** instance, plus a replaceable **separationMechanism** instance simulating the physics behind the impulsive device, such as a spring-damper system.

For a practical scenario to study, consider the trajectory phase of a generic launcher where the payload (Body *B* - the satellite to be placed in orbit) is to be separated from the remaining launcher upper stage (Body *A* - assuming a multi stage launcher). In this case, the problem consists of two bodies flying together under the effect of gravity in joint motion (the composite) up until separation is commanded. The separation command is usually given immediately after the shut down of the upper stage main engine. In this study however, we provide the separation command at any specified time. Figure 2 shows the DYMOLA simulation layout while Figure 3 shows a simulation of the physical setup of the case studies.

Initial conditions with respect to Earth-Centered-Inertial (ECI) frame of the composite are given to Body *A* as follows:

$$\mathbf{x}_A(t=0) = \begin{bmatrix} 1.1378 \times 10^7 \\ 0 \\ 0 \end{bmatrix} \text{ m,}$$

$$\mathbf{v}_A(t=0) = \begin{bmatrix} 0 \\ 5.9188 \times 10^3 \\ 0 \end{bmatrix} \text{ m/s}$$

and their translational and rotational dynamics are obtained from the rigid body model of the *Modelica Multibody Library* [9]. In the following section, we will study the separation dynamics implementation in MODELICA by means of two case studies: the first one considers the upper stage and payload (the composite) joint motion, while the second study considers the separation phase. For both cases, the forces due to gravity acceleration are obtained from the EGM96 model implemented in our internal *DLR Space Systems Library*. Both case studies are implemented in DYMOLA and the solution is computed using the DASSL solver with a tolerance of  $1e-7$ . A smaller tolerance of this solver would increase significantly the resulting chattering when Baumgarte stabilization is used.

**equation**

```

...
// CFE generalized joint constraints with Baumgarte stabilization
g_con_ddot + 2*eta*g_con_dot + eta*eta*g_con = {0,0,0};
G_con_ddot + 2*eta*G_con_dot + Frames.Orientation.equalityConstraint ( frame_a.R ,
frame_b.R ) = {0,0,0};
    
```

Figure 3: Simulation of the physical setup of the case studies.

Table 1: Mechanical properties of the two-body system.

Property	Body A	Body B	Units
Mass	6000	1000	Kg
$I_{11}$	23000	800	Kg·m <sup>2</sup>
$I_{22}$	23000	800	Kg·m <sup>2</sup>
$I_{33}$	18000	600	Kg·m <sup>2</sup>
$I_{21} = I_{31} = I_{32}$	0	0	Kg·m <sup>2</sup>

### 3.1 Case study I: upper stage and payload (composite) joint motion

The joint motion of the composite (Bodies A and B, the upper stage and the payload respectively) is simulated for a total time of 2000 s. During such motion, the MODELICA implementation of the CFE methodology is expected to derive automatically the joint constraint forces and torques such that the two-body system stays properly connected, with relative zero displacement. This case study therefore accounts for the validity of such implementation.

### 3.2 Case study II: upper stage payload separation dynamics

The upper stage payload separation is simulated in a practical scenario setup. It consists of a simulation of 20 s, half of which is in connected or joint motion, and then at  $t = 10$  s, the ignition command for separation is

given. At this point, a kick-off spring separation mechanism model is in charge of the dynamical separation between the bodies. The subsequent independent motion of each body is then expected. This case study therefore accounts for the applicability of the physical models of separation mechanisms implemented.

## 4 Results and discussion

As outlined in the last section, **Case Study I** accounts for the study of internal forces and torques of the composite joint motion during a given portion of its trajectory by means of the *Constraint Force Methodology* implemented in MODELICA. During such joint motion, an important metric to assess the proposed method is the relative joint displacement between the two bodies when they are supposed to stay connected, as proposed and suggested by [17].

In this respect, Figure 4 presents the resulting constraint forces  $\mathbf{f}[i]$  and torques  $\boldsymbol{\tau}[i]$  at the joint during the connected motion, in all ECI directions  $i = x, y, z$ , respectively; while Figure 5 presents the resulting *relative* joint position  $\mathbf{rrel}[i]$  and the *relative* joint velocity  $\mathbf{vrel}[i]$ , in all ECI directions  $i = x, y, z$ , respectively.

Results shows that the corresponding joint constraint forces and torques, obtained automatically by MODELICA in order to satisfy the CFE methodology constraints successfully keeps the bodies properly connected (hence, the composite) during their connected flight motion. Such result is evidenced looking at the relative joint position and relative joint velocity between the two bodies, which are supposed to be zero during the connected flight. A clear disadvantage for long simulation periods of joint composite motion is the necessity to keep the drift within physical boundaries, hence requiring a stabilization method. Stability and accuracy of the solution, especially for large simulation times, are improved with the addition of the *Baumgarte stabilization*. Nevertheless at the expense of chattering as shown in Figures 4-(b), 4-

(a) Constraint forces at joint during connected motion with CFE methodology, in all ECI directions  $i = x, y, z$ .

(b) Constraint forces at joint during connected motion with CFE methodology plus Baumgarte stabilization with  $\eta = 2$ , in all ECI directions  $i = x, y, z$ .

(c) Constraint torques at joint during connected motion with CFE methodology, in all ECI directions  $i = x, y, z$ .

(d) Constraint torques at joint during connected motion with CFE methodology plus Baumgarte stabilization with  $\eta = 2$ , in all ECI directions  $i = x, y, z$ .

Figure 4: Case Study A results: constraint forces and torques at joint during connected motion.

(d), 5-(b), 5-(d), meaning more computational time and effort.

**Case Study II**, as outlined in the last section, accounts for the study of absolute– and relative– position, velocity, and acceleration, respectively, between the two bodies from a multi-stage separation dynamics practical scenario. In here, the ‘release device’ simulated by a linear charge model has been augmented with an ‘impulsive device’ in parallel simulated by a kick-off spring model in order to simulate such a separation mechanism between the two bodies at their

time of release from each other.

In this respect, Figure 6 presents the bodies’ *relative* position  $\mathbf{rrel}[i]$ , velocity  $\mathbf{vrel}[i]$ , and acceleration  $\mathbf{arel}[i]$  along the ECI orbital flight direction  $i = y$  (which is valid only for such a very small time frame) during the connected motion (first 10 seconds), and during their subsequent separation (last 10 seconds). Figure 6 also presents a zoom of the small time window just around the separation command.

Results of this separation scenario shows the corre-

(a) Relative joint position during connected motion with CFE methodology, in all ECI directions  $i = x, y, z$ .

sponding relative states of the composite up until separation command and then their subsequent independent flight. Once again, the benefit and ease of use of the MODELICA implementation of the CFE methodology is evidenced during the connected flight of the composite, since constraint forces and torques are automatically computed and applied to the system. At separation, the relative states suggest an impulsive behaviour due to the kick-off spring separation mechanism model. This model releases a pre-compressed force stored in a replaceable spring-damper model, ev-

identing good correspondence with the physics behind separation. Such devices result in impulsive forces applied to the two-body system. This in turn causes a change in relative velocity and therefore, a successful physical separation of the system.

## 5 Conclusion

The objective of this paper was to present an object-oriented and equation-based acausal modeling approach to launch vehicle stage separation dynamics

with MODELICA. The aim is to develop an integrated approach for end-to-end launch vehicle trajectory simulation within a single environment.

Based on the *Constraint Force Equation* (CFE) methodology, two case studies to evaluate the proposed approach were considered. The scenario under study consisted of two bodies –representing a generic launcher stage and its payload– prior, during, and after their separation in orbital flight motion.

Results demonstrated that the approach, mainly thanks to the acausal and equation-based modeling features of the MODELICA language, corresponds very well with the physics behind separation while providing easiness of implementation within a single environment such as DYMOLA. The method computes and applies constraint loads automatically during joint motion and removes them accordingly at separation time, all in consistency with the CFE methodology.

A disadvantage for long simulation periods of joint body motion is the necessity to keep the drift within physical boundaries, hence requiring a stabilization method. This in turn increases chattering and computational time and effort, thus resulting in a trade-off to consider for the task at hand. Validation studies are left to future work.

# A Modelica Library for Scalable Modelling of Aircraft Environmental Control Systems

Philip Jordan    Gerhard Schmitz

Hamburg University of Technology, Institute of Thermo-Fluid Dynamics  
Denickestr. 17, 21075 Hamburg

## Abstract

In the design process of complex technical systems such as environmental control and cooling systems for modern commercial aircraft, modelling and simulation is widely used. Simulation can provide viable insight during all phases of the system design cycle, but the questions to be answered by a simulation activity vary along the advancement of the design process. In this paper, the Modelica library developed in the Clean Sky project TEMPO is presented. The aim of the library is to support scalable system models which can be modified in detail and characteristic to be used during different phases of the design cycle without the need of rebuilding the system model or switching to another software tool. The library structure and the approach to integrate different detail levels is outlined and demonstrated at the example of a generic aircraft environmental control system architecture.

*Keywords: Environmental control system, scalable detail, object-oriented modelling, library*

## 1 Introduction

The competitive environment and the challenge to limit environmental impact while air traffic demand is increasing, aircraft manufacturers and suppliers are under continuous pressure to improve the performance of their products. Since it becomes increasingly difficult to improve the global system performance by independent optimization of subsystems, the need to instead aim for an optimized global system performance during development has been identified [1]. New and unconventional aircraft systems architectures such as the “More Electric Aircraft” (MEA) are the subject of past and ongoing European research programmes [2, 3].

The design process of complex technical systems such as aircraft environmental control and cooling systems can be broken down into characteristic design

phases. During all phases, modelling and simulation can be used to support the design process. However, each phase may pose different questions with regard to the physical phenomena of interest, the accuracy, or the simulation speed for example. Specialized tools can be used to meet the requirements for each simulation task. The library presented in this paper aims at using the object-oriented features of the Modelica language to integrate multiple layers of models. Each layer corresponds to a set of models designed for a specific simulation task and is subsequently referred to as “Detail Level”. The Detail Levels are integrated such that a single system model that has been assembled from available library component models can be “scaled”, i.e. reused, for a simulation activity of a different phase of the system design cycle.

The ability to create polymorphic models is a core feature of the Modelica language and it is used to create flexible and configurable models in many published Modelica libraries. An example are the variable dynamics settings and exchangeable heat transfer models in the `Dynami cPipe` Model of the Modelica Standard Library. Several libraries which pick up the concept and focus the design of the library more on scalable models have been presented.

In [4] structuring a Modelica library with scalable models for building simulation with the need for different models along the temporal evolution of a project in mind is discussed. A library for power plant simulation currently under development uses the idea of detail levels as group of models with similar complexity and incorporates the concept to organize the models within the library structure [5].

A somewhat different approach towards the concept of a “Detail Level” is taken in the library subject to this paper. Rather than a specific parametrization of a polymorphic model, a “Detail Level” represents the required characteristics of a model designed for a specific simulation task. This task is to be carried out at a certain point or in the system development process.

Switching a system model between two “Detail Levels” can therefore be seen as switching between different use cases where the information about the existing system structure is kept. The advantage of this is that the user does not have to rebuild the same system with another set of specialized models even though the actual model equations for each detail level may not have much in common.

The library discussed in this paper is developed within the scope of the TEMPO project (Thermal Exchange Modelling and Power Optimization). TEMPO is a research project in the Systems for Green Operations (SGO) technology demonstrator of the Clean Sky Joint Technology Initiative. The focus of the SGO demonstrator is to mature technologies which were developed during the MOET (More Open Electrical Technologies) project [2], and demonstrate architectural integration of thermal management technologies such as the electrically driven air system which was developed in MOET. In order to optimize and validate such architectures, extensive modelling studies are carried out. The presented library supplies the models for the environmental control system for the SGO demonstrator.

## 2 Models for Different Stages in the System Design Process

The process of designing and implementing a technical system is characterized by distinctive phases. In each phase design decisions have to be made and predefined milestones have to be reached before the development can proceed to the next phase [6]. The V-Diagram shown in figure 1 is a graphical representation of the system development process.

Figure 1: System design process displayed in the form of a V-Diagram

In this case, the process has been broken down into

four characteristic phases, System Design, Component Design, Component Test and System Test. Based on the tasks associated to the design phase, requirements for the models in the respective phase have to be formulated. The following section describes the characteristics of the Detail Levels of the TEMPO library. Table 1 gives a brief overview over characteristic differences of the main components for different Detail Level settings.

### 2.1 Phase 1: System Design

The system development process begins with the conceptual design of the system followed by preliminary system design. Based on customer need, system requirements have to be developed. From the overall system-level requirements, design requirements for the subsystem level are deducted. The phase covers feasibility assessments and leads to the decision on a system architecture. Simulation during this phase is used to support decisions on a system architecture and to deduct performance requirements for the components of the system.

The models designated for use during this phase are collected in the Detail Level 1 of the library. The Detail Level 1 models do not include dynamic effects. Performance characteristics are modelled by parameter setting. Turbomachinery components for example allow user defined efficiency settings, heat exchanger models are effectiveness based where the effectiveness can be a user defined parameter. The simple modelling assumptions aim for very fast and robust models for initial requirements estimation. The effects of a parameter variation on the system behaviour in this setting is limited by the constraints imposed on the remaining components.

### 2.2 Phases 2 and 3: Component Design and Component Testing

In the detailed design and development phase of the system development cycle, subcomponents and subsystems are brought into realization. As the design of the component progresses, more reliable performance predictions become available. These component performance predictions can be fed back into the system model, for example to check for compliance with overall system performance requirements. In parallel to the development of the actual components and their thermodynamic performance validation, the development of a control strategy is started. Models for control

Table 1: Overview of main component model characteristics for different Detail Level settings

Component	Detail Level 1	Detail Level 2	Detail Level 3	Detail Level 4
Turbine	Fixed operating point (parameter)	Map based, input filtering	Map based, input filtering	Simplified flow model, forward computation
Compressor	Fixed operating point (parameter)	Map based	Map based	Map based
Heat Exchangers	Static balance eqns, fixed effectiveness, optional local over/under determination	Static balance eqns, map based heat transfer, optional local over/under determination	Dynamic balance eqns, dynamic wall, geometric parametrization, discretization	Surrogate function for outlet temperatures calculation
Valves	Optional local under determination	Optional local under determination, input filtering, flow reversal supported	Input filtering	Input filtering, forward computation
Reservoir (tank) models	Pressure boundary, optional local over/under determination	Map based, optional local over/under determination	Map based, dynamic balances equations, global mass control	Map based, dynamic balances equations, global mass control

developments focus on the dynamic behaviour of the components.

When component prototypes have been produced or acquired, they are tested and additional performance data becomes available. In the form of performance maps, this information can be fed back into the system model, both for thermodynamic performance models and models for control development.

The Detail Level 2 Models of the library are designed to be used for thermodynamic performance simulations during these phases of the development process. The components are static models, performance characteristics are typically calculated from performance maps. Turbomachinery components use efficiency and flow characteristic maps, heat exchangers use effectiveness maps.

In the library, the models for control development activities during these phases are collected in Detail Level 3. These models use a more physical modelling approach. The heat exchanger models now include dynamic mass and energy balances on the fluid side and dynamic energy balances for the core material. Heat exchangers with connection to the incompressible liquid fluid domain also have the option to activate a dynamic momentum balance. The balance equations are discretized into finite volume elements. To somewhat limit computational effort and to improve robustness, the heat exchangers use lumped momentum balances and flow reversal is not supported. The parametrization of the heat exchangers is geometry based and can be modified to change surface geometries and flow patterns.

### 2.3 Phase 4: System Test

After the components and sub-systems have been designed and the prototypes have been manufactured and tested, they are integrated into the final system prototype. Simulation activities may include analysis of component behaviour with integration effects taken into account or hardware in the loop simulations to validate the developed control system.

Models for this kind of activity make up the Detail Level 4 in the library. The models used include dynamic behaviour, but the models are simplified in favour of faster simulation speed. The models are designed towards the use of fixed step solvers, while actual hardware-in-the-loop capabilities have not been implemented within the scope of TEMPO. A heat exchanger model of this Detail Level calculates outlet temperatures based on transfer functions. Fast states such as pressures in air components have to be removed to allow the usage of a sufficiently large step size with a fixed step solver.

## 3 Integration of Detail Levels

Two aspects regarding model structure for scalable models are discussed in this paper. This section treats how the detail level specific models are combined to achieve the model switching capability on the system level. Section 4 contains a description of the organisation of the models within the library structure.

The different available Detail Levels are collected on

the component level. Components in this context are units such as heat exchangers, valves or compressors. To create a system model, scalable components from the library are used to build up the desired architecture. As a sum of its components, the system model is also scalable. Scaling the system model is done by switching all components to a different Detail Level using a global parameter, while the system architecture information is kept.

In order to change the Detail Level setting of a system model, the `inner/outer` construct is used. The system model contains an `inner`-object of the class `SystemState`, in which the Detail Level setting is stored. In the library, the default instance name of the `SystemState` instance is “system”. All component models inherit from a `PartialComponent`-class which provides the interface to the `inner`-object “system” on the system level. In this class, the user can access the Detail Level setting from the graphical user interface.

### 3.1 Component Level Integration of Detail Levels

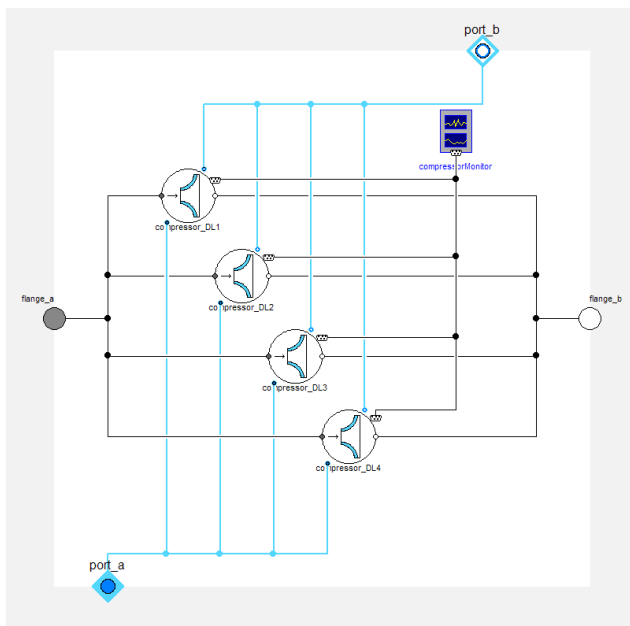

Figure 2: Container model structure seen as in the diagram layer view of a scalable component model

Polymorphism in Modelica is usually achieved by using the `redeclare` and `replaceable` language elements. Variations of encapsulated elements of the model can be exchanged in order to create the desired variant of the component. However, the Modelica language does not support parameter-based redeclaration. As a consequence, it is not possible to invoke a series of

redeclarations by one central parameter setting. Therefore `redeclare` and `replaceable` constructs can not be used to achieve the Detail Level switching behaviour needed for this application.

Instead the container method of class parametrization is applied to build scalable components from the Detail Level specific models. The container approach is a very basic parametrization method, where the scalable component model contains a set of conditionally declared variants of the component. Figure 2 shows the diagram layer of a scalable compressor model. Depending on the Detail Level parameter setting, only the desired model is instantiated. An advantage of this approach is the complete encapsulation of the Detail Level specific code. Model equations and class structure (internal class hierarchy levels for example) of a component may vary greatly between Detail Levels. The encapsulation allows task-oriented modelling independent of requirements for other Detail Levels, as long as the interfaces are compatible.

By default, the components are configured to follow the global Detail Level setting. This global Detail Level setting can be manually overridden individually for each component.

### 3.2 System Level Integration of Detail Levels

Figure 3: High pressure water extraction loop model with Detail Level dependent decoupling modules

A system model expressed in the equations of different Detail Levels can not always naturally be decomposed in the same manner. By building up a scalable system model from of scalable component models, at least one layer of decomposition is fixed and the library

has to address this issue. A common example of such a decomposition issue is a closed loop fluid system like the vapour cycle included in the application example in section 5. With dynamic mass and energy balances on the fluid side, the system is well-posed if it is made by connection of balanced component models according to the Modelica specification. A purely static variant of the same system on the other hand can not be created the same way. The connect-statement closing the loop introduces a redundant mass balance while the overall system lacks a “grounding”-equation.

A well-posed static model made from locally balanced components could be achieved by removing the connect statement and manually adding a pressure or total mass constraint. To be able to scale a system model without the need to modify the system topology, the option to add or remove equations has been shifted to the component models. The consequence is that individual components can now be configured to be locally over- or under-determined. With reference to the application example, this means that for the Detail Level 1 version of the vapour cycle, that the valve is configured to act as a loop breaker while the refrigerant reservoir is locally overdetermined and provides the necessary grounding. Local over- and under-determination is also used to adapt the causality of the overall system if required by the simulation task while the system level topology remains unmodified. In the presented vapour cycle system, the evaporator superheat is controlled by the expansion valve opening position. Be it that the control logic is not available and not to be simulated in the conceptual design phase (Detail Level 1). Instead, the evaporator superheat can be fixed. The additionally introduced equation in the evaporator model is compensated by configuring the valve coefficient as an unknown. This requires extra care by the user, since a globally balanced system is no longer guaranteed.

Another aspect which has to be considered for integrating the Detail Level specific models into a scalable system model are the constraints imposed by the system architecture information. When the Detail Level specific equations are incorporated into a scalable component model, the architecture of the system in which they will be used in is yet unknown. But the overall equation system which will have to be solved includes the constraints associated with the system architecture information. Unfavourable combinations of model equations and connections can lead to high index systems or non-linear algebraic loops. Such unfavourable equation system structure cannot always be avoided, but the modeller will generally try to adapt the system model and

the component configuration for improved robustness and performance. In thermo-fluid systems for example, complex networks of static components usually lead to large non-linear systems of equations. If the time scales of interest allow it, artificial dynamic states can be introduced to decouple the static components. In a scalable system model, it may occur that such measures are necessary for one Detail Level, but not for another. In a scalable system model, as it is presented here, multiple system models in fact “share” one set of system level constraints, i.e. the system architecture information. This means, that measures of which the necessity depends on Detail Level and system level constraints, need to be integrated into the Detail Level management. In the presented library, dynamic fluid states for decoupling large non-linear systems of equations are implemented in dedicated components.

The image in figure 3 shows the Modelica Diagram view of a model of the high pressure water extraction loop in air generation unit of an environmental control system (ECS). Such a system is installed on the Boeing 747-8 for example [7]. In a purely static configuration, the component equations together with the circular connections lead to a difficult to solve algebraic loop. The decoupling modules located between the components include the artificial state variables, but depending on the Detail Level setting, they are only activated when the Detail Level setting requires it.

## 4 Library Structure

The library structure is organized around component models such as valves or heat exchangers, which are ready to be connected in an executable system model after they have been parametrized. A general modelling philosophy is the aim for a flat inheritance structure for improved readability at the cost of possibly duplicate code elements. Where possible, the components contain no more than two inheritance levels. A common base class provides the component icons and common GUI elements like start value parameters.

The library covers three fluid domains: Air-, refrigerant- and incompressible liquid coolant domain. Thermofluidic components are by design permanently associated to a fluid domain. For example, there is a dedicated valve model for the air domain and a dedicated valve model for the incompressible liquid domain. The separation allows simpler—because more specialized—code for the components. The association of a component to a fluid domain is indicated by colour marking of the icon and connectors. The colour

of air domain components is blue, refrigerant domain components are identified by green coloured icons and connections and the incompressible liquid domain components are of orange colour.

### 4.1 Fluid Modelling

Within TEMPO, proprietary fluid property models provided by the SGO project partner are used. The data is accessed using external functions. The Modelica interface to the fluid data follows the Modelica.Media model structure for easy conversion to MSL fluid models. Each of the available fluid domain—air, refrigerant and incompressible liquid—have their own base package, fitted to the characteristics of the fluid type. The fluid connectors are identical to the Modelica.Fluid-connectors of the Standard Library. Currently, no distinction is made between total and static values for pressure and specific enthalpy.

Variants of the air type fluid model cover a range of dry and moist air models from simple and fast to more complex and accurate. Variants of the refrigerant and incompressible liquids cover several different fluids.

### 4.2 Component Organization

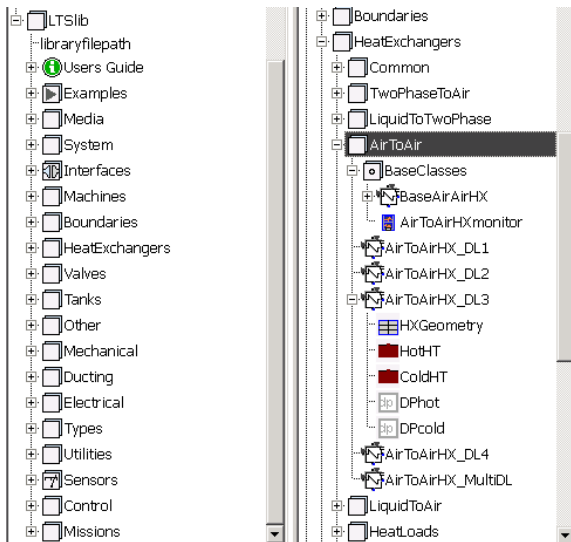

Figure 4: Package tree of the TEMPO library

Two main criteria are used to group the library elements in an efficient manner. The top level criterion is a generic functional classification of the type of component as shown on the left side of figure 4. Within each functional group, the components are classified according to the fluid domain they are associated with. On the right side of figure 4 it is illustrated for the HeatExchangers-package. All variants

of the Air-to-air heat exchanger model extend from a common base class. The scalable component model AirToAirHX\_MultiDL is the container model integrating all Detail Level specific models. The finite volume based dynamic heat exchanger model of Detail Level 3 is assembled from a set of subcomponents. These are located in the Common package.

## 5 Application to a System Model

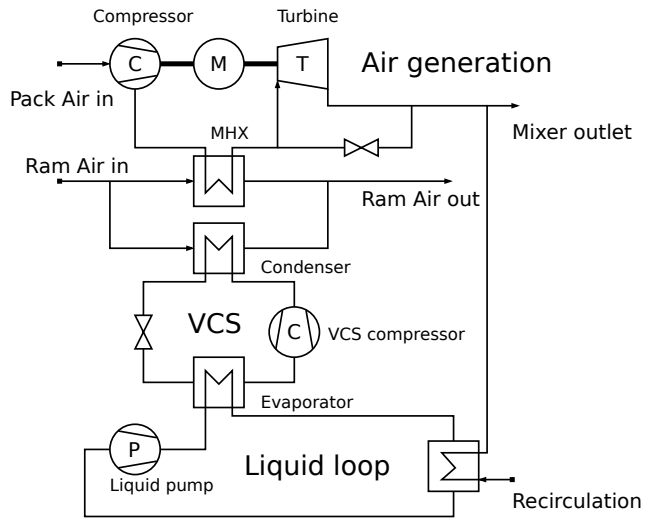

Figure 5: Reference architecture: Generic bootstrap cycle with motorized compressor, liquid cooling loop for cabin air recirculation cooling and vapour cycle

The application of the library is demonstrated on a generic ECS architecture. The architecture is modelled with the scalable components and simulated in different Detail Level settings. Fully real-time capable models which could be used in a real time environment are not yet supported by the library and are beyond the scope of TEMPO, therefore the simulated Detail Level settings cover the design phases 1–3 described in section 2.

The data used in the models such as performance maps and geometry information is proprietary, so that some the plotted results have been normalized.

### 5.1 Reference Architecture Description

The modelled ECS architecture is shown in figure 5. The system includes the air generation unit (pack) which provides pressurized air to the cabin. The presented system is based on a generic bootstrap cycle. Ambient air is pressurized in the compressor, excess heat is discharged in the main heat exchanger (MHX) using ram air as heat sink. The pack air is then cooled down

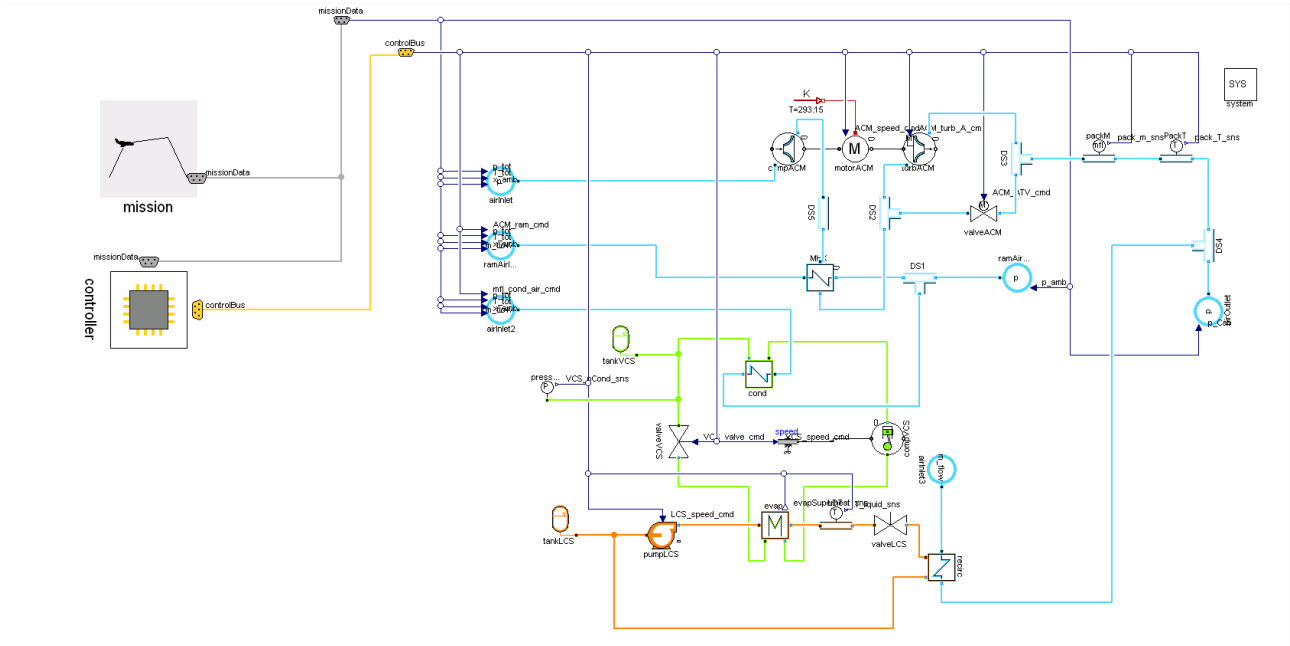

Figure 6: Diagram layer view of the ECS model

further in a turbine before it is released into the air distribution system. A liquid cooling loop is used to cool recirculation air from the cabin. A vapour cycle (VCS) is used to discharge the thermal load via ram air.

The diagram view of the reference architecture model is shown in figure 6. Boundary conditions and system control signals are provided by additional models. Mission (ambient conditions) and controller models are not integrated into the Detail Level management, i.e. the container model parametrization is not applied on them. The use of ambient data is independent from the Detail Level setting, therefore the data can be used in all Detail Levels. The controller model is assembled individually for a system as different controller models may be used on one ECS model.

In the model used for the simulations for the application example, the aircraft cabin is represented by an altitude dependent pressure boundary. The ram air mass flow control is simplified by directly imposing the mass flow rates and the cooling load from the recirculation air remains constant over time.

## 5.2 Detail Level 1 Use Case

All components of the system model are modelled statically. The model is intended for easy parametrization effects on the system and fast computation speed. This is reflected in simplified modelling assumptions and allowing to set properties as parameters that normally depend on the operating point. These proper-

ties are heat exchanger effectivenesses, superheating or subcooling temperature differences for vapour cycle heat exchangers, pressure ratios and efficiencies for turbomachinery or vapour cycle pressure levels for example.

For a simulation with the ECS model in Detail Level 1 configuration the ambient conditions for the model were set constant to represent a cruise flight at 38000 ft with Mach number  $Ma = 0.8$  at ISA conditions.

With the local over- and under-determination of the components, the degrees of freedom of the model can be changed. In the simulated example, the effectiveness as well as the superheat temperature difference of the VCS evaporator are fixed, so that the heat flow rate is determined twice. In return, the valve constant is set to be a free variable.

In figure 7 the evolution of the required condensation pressure and the power required is plotted for different settings of the condenser effectiveness. The pressure level has been normalized with a reference maximum pressure, the power demand has been normalized with a reference power.

## 5.3 Detail Level 2 Use Case

The Detail Level 2 configuration provides static models with more complex and accurate modelling assumptions. The components are mainly based on performance maps. Data available from detailed component design and prototype testing (Phases 2 and 3) can be

Figure 7: Evolution of required VCS high pressure level and VCS power demand for a given condenser effectiveness

used to verify the system performance. The additional variability of component performance properties allows to evaluate the effects of component interaction on the system level.

The ambient conditions for the Detail Level 2 simulation are unchanged and correspond to level flight at 38000 ft,  $Ma = 0.8$ . In this example, the vapour cycle superheat temperature is again set as a parameter. The ram air mass flow rate is reduced during the simulation. In figure 8 the output of the simulation is shown. From top to bottom, the curves show the evolution of the mass flow rates in the condenser, the normalized pressure levels of the VCS, evaporator liquid side outlet temperature deviation from target and the VCS power demand. The mass flow rates are normalized with respect to a reference mass flow rate, the pressure levels are shown in reference to a maximum allowed pressure. The result of the reduction of the ram air mass flow rate is an increase of the pressure levels. The change in evaporator pressure has an impact on the driving temperature difference and the evaporator heat flow rate decreases. As a result, the evaporator liquid outlet temperature increases. The result is presented in form of a deviation of a target temperature. In this case, the reduced ram air flow still provides enough cooling for the liquid cycle. However, the increased VCS power demand counteracts the reduced ram air flow.

Figure 8: Results of simulation in Detail Level 2 setting

### 5.4 Detail Level 3 Use Case

The system model in Detail Level 3 setting switches the underlying equations to a combination of dynamic and static components. Valve, pump, turbine and compressor models are static and use performance maps similar to the Detail Level 2 setting. System dynamics are captured by the heat exchanger models. The liquid cycle components dynamic momentum balance option have been switched off.

The system model is now used to test a control strategy. In the Detail Level 3 example, pack outlet temperature, pack mass flow rate and evaporator liquid side outlet temperature are controlled to maintain target values. The controller model used together with the

Figure 9: Dynamic mission simulation results

Figure 10: Mission altitude and Mach number profile for the dynamic Detail Level 3 use case

ECS model is assembled from has been implemented with elements from the Modelica Standard Library and the Modelica\_StateGraph2 library.

Figure 10 shows the mission profile which was used for the simulation. After an initial taxi-out period, a climb phase follows until a cruise altitude of 38 000 ft is reached. The descent begins after 30 min of cruise followed by a taxi-in phase on ground. The Mach profile is a function of the altitude, cruise speed is  $Ma = 0.8$ .

The top left graph in figure 9 displays the achieved pack outlet temperature, which matches the target output temperature except for two occasions. The bottom left graph shows the ram air mass flow rate in the main heat exchanger, which is modulated to control the pack outlet temperature. The mass flow rate shown is normalized by a reference mass flow rate. The controller tested in this simulation produces some overshoot and oscillation and should probably be revised and re-tested.

The control of the vapour cycle pressure levels however is successful in this simulation as it can be observed in the top right graph. The plotted data is normalized by the target condenser pressure. The bottom graph shows the condenser ram air flow which is used to maintain the condenser pressure. With increasing altitude, less ram air is needed due to the colder temperatures.

## 6 Conclusion and Future Work

In this paper, the Modelica library developed within the Clean Sky project TEMPO is presented. The library is designed for aircraft environmental control and cooling systems modelling. The focus of the library is the thermo-fluid domain, covering air, vapour cycle and liquid cooling systems. A key feature of the library is the integration of multiple levels of detail, where each Detail Level corresponds to a set of models specifically fitted to a certain simulation task. The detail levels are defined according to the simulation activities which are carried out along the process of developing

an environmental control system from the initial conceptual phase to the finished prototype. The library is organized around the Detail Level concept and allows to switch a system model from one Detail Level to another. The underlying model equations are thus exchanged to meet the requirements of another simulation task while preserving the information on the system architecture, freeing the developer of the need to entirely recreate the system model from scratch. As an application example, a scalable model of a basic aircraft environmental control system has been assembled and simulated for three different Detail Level settings. The development of the TEMPO library is ongoing work. A cabin model for commercial aircraft is currently under development. For the near future it is planned to make the library fully compatible to the recently extended Media-Library of the Modelica Standard library and to separate other protected intellectual property of the project partner from the core library. This version of the library will then be made available to the public.

## Abstract

The peak power consumption of multi-axis production machinery (e.g. industrial robots) is determined by the forces during acceleration phases of continuous movements. The required high electric currents represent a cost factor in terms of the mains power supply. In this paper a new Modelica-based method is presented to save the mechanical braking energy of production machinery into a local flywheel-based energy recuperation system (ERS) for later utilization. An ERS has twofold advantages: on the one side it reduces the apparent power peaks from the mains power system. On the other side the overall energy consumption can also be reduced therewith. However, a mechanical ERS with a flywheel needs to be controlled in advance, as its internal inertia and the switched magnetic field introduce some dead time in the process. Therefore, the here presented approach uses an interdisciplinary Modelica model of the machinery to compute future power requirements prior execution of new movements. It is assumed that the machine program is known upfront in a textual form. The movement commands must be carried out with the virtual machine model first. The simulation computes the energy demand, according to which the stored amount of energy within the ERS (i.e. the angular velocity of its flywheel) must be controlled. The here computed reference angular velocity signal is put later also to the real controller, where the physical ERS is attached to as an extra motor. This paper presents the methodology along an example of a 3-axis robotic manipulator that is installed in the VDTC building of the Fraunhofer IFF, Magdeburg. This specific example has been used to validate the concept: 12% less power-consumption and 10% less power peaks were achieved during the operation.

*Keywords:* production machine, power efficiency, energy recuperation, flywheel, Modelica simulation, virtual NC

## 1 Introduction

Energy efficiency is nowadays a crucial competitive factor within the production industry. Additionally, in order to reduce production time, cycle times must always become shorter. The power requirement of production machinery is mostly dominated by the acceleration and braking of mechanical loads (e.g. heavy chassis parts in a car production line). As a common power supply for their induction motors, multi-axis machines are utilizing a single intermediate DC circuit. The motors of the machine are usually able to generate electric current upon external driving forces. This generated current can be recovered by the frequency inverters into the capacitors of the intermediate circuit.

The aim of this research was to develop a new methodology to integrate an electromechanical energy storage unit here, thus larger amounts of recovered energy can be utilized later in the production process again.

### 1.1 Energy Recuperation System - ERS

Modern high-speed flywheel-based energy recuperation systems (ERS) have high durability and can store a large amount of energy in a relatively compact space. A mechanical ERS itself is equipped with an AC induction machine that can also accelerate and decelerate the flywheel, thus convert between electrical and mechanical energy.

There are multiple industrial application fields where electromechanical ERS are being used with utmost efficiency. In case of production machinery they can be used as an uninterruptible power supply to overcome blackouts enabling the machinery to enter a safe state without causing any damage of the product. A most recent application is to compensate power fluctuations in electric networks of city trams [5]. This very application suggested the idea of this study: the integration of an ERS into a production machine.

## 1.2 Storing Energy in a Rotating Flywheel

The following formula can be used to compute the stored mechanical energy of a rotating flywheel:

$$E = \frac{1}{2} \theta \omega^2 \quad (1)$$

where  $\theta$  is the rotational inertia and  $\omega$  is the angular velocity of the flywheel rotor. The bearings of the flywheel are utmost optimized, thus the idling short-term friction losses are negligible. At ultra-high speeds (>25000 rpm, carbon-fiber flywheel) there is a need of a vacuum chamber to reduce drag losses. Nevertheless, the power consumption of this extra vacuum pump lessens the efficiency of the ERS.

There is a hurdle at using mechanical energy storage units in multi-axis machines due to large differences in mechanical and electrical time constants. The speed of an inert flywheel must be controlled in advance to be able to supply energy to and from the process effectively.

As production machines are usually program-driven, the next movement command can be known a priori. Therefore, the proper flywheel speed can be pre-computed by utilizing a mechatronic model of the whole system. The flywheel speed must be decreased a short time earlier than the axes begin to accelerate, and vice versa: it must be accelerated upon recuperating mechanical energy via the machine axes.

## 1.3 The ERMA Project

The here presented work has been done in the *ERMA* project (Energy Recuperation for Multi-Axis Machines) funded by the German Federal Ministry of Education and Research under the project number 02PK2192. The consortium agreed to demonstrate the methodology with a simple, 3-axis robotic manipulator that can be used to transport alloy wheels.

Figure 1: CAD model of the ERMA demonstrator

As production machinery in general is targeted by the here presented concept, a Siemens *Sinumerik*

*840D sl* NC controller was chosen to control the demonstrator. Numeric control is very common in the production industry and basically does not differ much from other interpreted robot programming languages. However, conventional NC controllers give no access to their internal axis interpolator states prior execution. Therefore, a look-ahead in the interpreted program is not directly possible.

Fortunately, Siemens offers a virtual NC kernel (VNCK), which is a software service that covers the whole functionality of a real Sinumerik NC interpreter offline, under Windows. An NC program (G-code) can be interpreted with the VNCK the same way as if it would run on the real controller, thus the reference trajectories can be extracted for each axis in advance. Therefore, it is known how a given movement command will be executed. The commissioning of VNCK is quite straightforward: once the configuration of the real Sinumerik NC has been set up with the real machine axes and parameters, the exported settings can be used later on demand to simply boot the VNCK. The identical configurations ensure a consistency between the simulated trajectories and the real executed ones.

The *ERMA* demonstrator system has been equipped with a prototype, steel flywheel-based ERS from the partner company *rosseta Technik GmbH* [5]. The ERS is shown on Figure 2 and has the following main properties:

- Mass: 52 kg
- Dimensions: 410 x 190 mm
- Induction machine: 20A peak current
- Rated power: 10 kW
- Rated energy: 22.8 kW<sub>s</sub>
- Max. speed 25000 rpm

Figure 2: The flywheel-based ERS in the cabinet

The electrical cabinet including the four motor controllers (3 synchronous permanent-magnet drives of the manipulator + 1 asynchronous induction machine of the flywheel) have been developed by the partner company *aradex AG* [6].

## 2 Modeling in Modelica

In this chapter the modeling workflow is described along the example of the *ERMA* demonstrator system. It can be used to model a production machine conveniently in Modelica environment.

### 2.1 Mechanical Subsystem

In the recent years in the Fraunhofer IFF there has been a research focusing on automated translation of CAD information (geometry, physical properties and kinematic structure) into a parameterized Modelica multi-body description [1]. A plug-in was developed to generate MKS models directly from the Pro/Engineer CAD system. However, a lot of 3<sup>rd</sup> party Pro/Engineer assemblies could never be translated to a valid model without manual work. In a CAD environment the effort of defining the right constraints of a complex articulated mechanical system can be a troublesome work. In order to ease this task, designers usually circumvent the right definition of degrees-of-freedom between adjoined CAD assemblies and parts. Unfixed bodies or overdetermined constraints render the automated translation process erroneous. During the model conversion the constraints are normally mapped to Modelica joints automatically. Although the original constraints can be named, no meaningful joint names can be specified in Pro/Engineer. Therefore, the direct usability of a fully auto-generated model is questionable in model-in-the-loop scenarios.

Virtual commissioning of digital machine models with real controllers in the loop represents a new research focus in the Fraunhofer IFF. There must be a clear naming convention of joints to define the communication channels to and from simulated axes. Therefore, the solution of automated model translation had to be developed further. Using the *VINCENT* framework [2][7] the multi-body structure can be configured separately. The rigid bodies can be assembled together intuitively by using drag & drop from imported CAD assemblies and parts. The STEP interchange format is supported to let designers use various CAD systems that they have expertise in. Unfortunately there exists no widely-spread data exchange format yet, in which many CAD system developers would agree to include the constraints between the objects being designed. Therefore, the joints must be placed and connected with body elements in *VINCENT* manually, as well. However it seems to be a tedious work, after some practice a complete machine configuration can be defined with 40 bodies and 30 joints within a few hours. Once the structure has been configured, it can easily be reused

upon changing geometries or some other parameters. The Modelica model is directly generated out of the information in *VINCENT* using the same workflow as in [1]. Figure 3 shows the generated model according to the simple *ERMA* 3-axis robot. As long as the internal details are also modeled, the physical properties (mass, inertia, center of gravity) of rigid body elements with known uniform density can be simply derived from the fine-triangulated geometry models [3]. In case of simplified 3<sup>rd</sup> party CAD parts with no modeled interior the mass properties from datasheets of the manufacturer must be used instead.

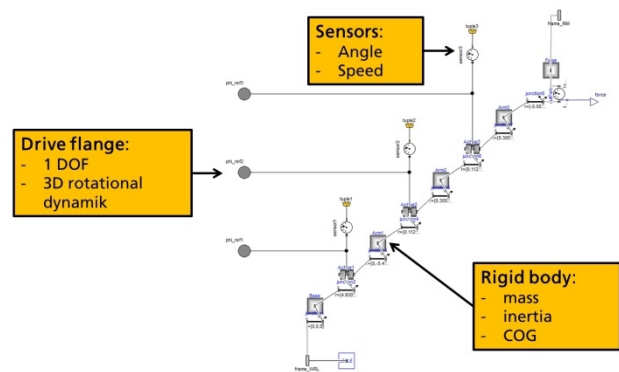

Figure 3: The generated multi-body model of the *ERMA* demonstrator

### 2.2 Usage of the Modelica Model during Sizing of the Drives

During its planned pick-and-place job of transporting alloy wheels the *ERMA* demonstrator must reach various points in space as fast as possible. At the early phase of the project the aforementioned multi-body model was used to compute acceleration limits. For this reason a new Modelica block was developed supporting point-to-point path interpolation of arbitrary goal positions within the workspace of a robot. Similar to the *KinematicPTP2* model in the standard Modelica library, this path interpolator allows the specification of kinematic constraints (maximum velocity and acceleration) of each output. Besides the start and end positions any number of intermediate locations can be given, too. As a result, time-optimal trajectories between adjacent goal positions are being computed.

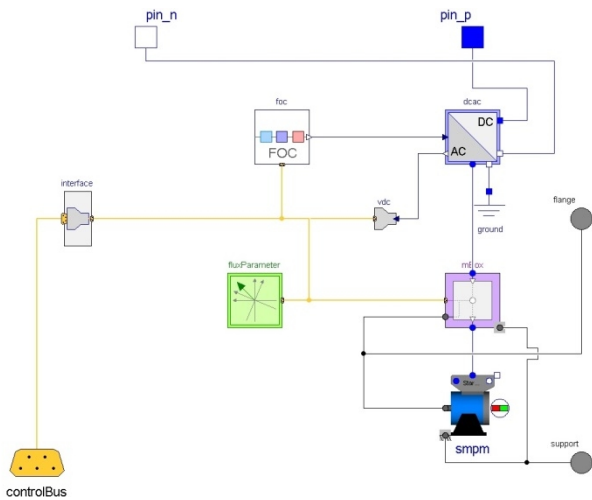

By using ideal position sources the simulator could compute the required torques during the sizing of the demonstrator. The simulated torque curves were taken to select the proper drive characteristics to be used. After multiple simulations involving iterative model updates using manufacturer data, a proper drive selection could be found. Table 1 summarizes the chosen drives including the gear ratios:

**Table 1:** Selection of Wittenstein-alpha permanent-magnet synchronous drives of the ERMA demonstrator

	Axis1	Axis2	Axis3
	TPM+	TPM+	TPM+
	power 110	power 110	high torque 025
Gear ratio (stages):	1:7 (1x)	1:35 (2x)	1:55 (2x)
Stall torque [Nm]:	(vertical)	878	214
Max. torque [Nm]:	600	1600	530

**2.3 Mechatronic Model of the Intermediate DC Circuit and the Electric Drive Subsystem**

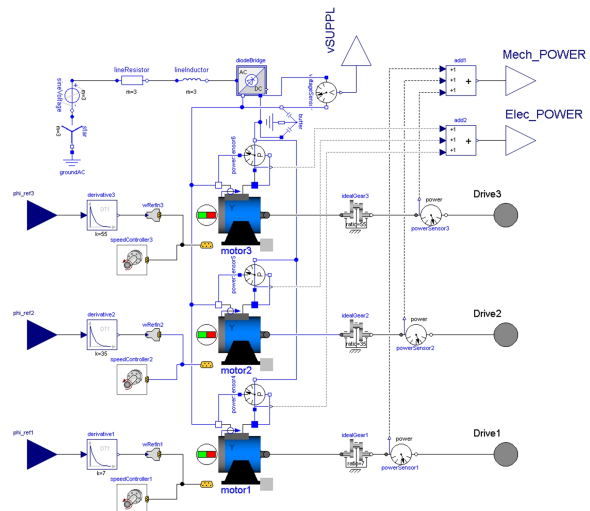

The prediction of future power requirements needs more than analyzing a pure mechanical model. Only an interdisciplinary model can compute the correct energy balance including the losses in other domains. The *Smart Electric Drives* Modelica Library has been developed at the *Austrian Institute of Technology* [8]. The SED library allows convenient modeling and simulation of an entire electric drive subsystem. It provides components of various electrical devices including motor models with power electronics and also energy storage modules. As both thermal and transient magnetic effects are taken into consideration, these models can fulfill the purpose of computing realistic power requirements. Figure 4 shows the diagram of a synchronous permanent magnet (SMPM) machine including field-oriented control and voltage and current limitations. A very similar control strategy is used in the real motor modules of the *ERMA* demonstrator.

**Figure 4:** Field-oriented controlled permanent magnet synchronous induction machine

This torque-controlled SMPM machine model from the SED library is to be connected to the intermediate DC supply circuit. It utilizes an internal DC/AC frequency converter and a three-phase synchronous induction machine model with permanent magnet excitation. The input torque is to be computed externally; a position controller can retrieve the required electrical state variables over a bus connector. The mechanical flange is connected to the respective revolutive joint in the mechanical model.

Based upon the specifications from the manufacturer the drive models were parameterized with real data. Measurements were carried out at the *aradex AG* to validate some model parameters such as winding resistances and inductances. The electric parameters of the AC/DC rectifier module were taken into account in a conventional three-phase diode bridge rectifier model from the SED library. It is extended with buffering capacitors to model the intermediate DC circuit that is built into the real electric cabinet. Figure 5 shows the diagram of the drive subsystem in Modelica:

**Figure 5:** Mechatronic model of the electric drive subsystem including the DC intermediate supply circuit

The drive subsystem model of the demonstrator includes a 400V three-phase AC power source, the DC circuit model and three synchronous permanent magnet motor blocks with an ideal gear and a position controller per each instance. The three-phase motor model uses space phasor formulation with d and q axes [4] and it considers thermal losses in the rotor bushing (mechanical friction) and electrical losses (eddy current, ohmic winding resistance), as well. Permanent magnet excitation is modeled by a constant equivalent excitation current feeding the d-axis:

$$I_e = \frac{1}{\sqrt{2}\pi} \frac{U_{OC}}{L_m a f_{nom}} \tag{2}$$

where  $U_{OC}$  is the RMS open circuit voltage at nominal speed,  $L_{md}$  is the main field inductance in d-axis and  $f_{nom}$  is the nominal frequency. These parameters could be found on the datasheet of the real motors. The here implemented flux-weakening control strategy weakens the magnetic rotor field so that the stator voltage is restrained to given voltage limitations even though the shaft speed rises.

The derivatives of the input axis position signals are fed to the proportional integral speed controllers. The internal gear ratio is taken here into consideration as a gain factor. The reference torque of each motor is computed according to the aforementioned field-oriented control. Feedback signals are available over the bus connector (see Figure 4).

The included standard Modelica power sensors allow measuring the momentary mechanical and electrical power consumption. The sums of those are the *POWER* outputs of this subsystem model. This way, after mathematical integration of the electric power signal, the energy consumption of arbitrary axis movements can be determined.

## 2.4 The Concept of the “Energy” Axis

In this work the energy demand of a production machine needs to be pre-computed with the presented mechatronic model according to original machine control programs. The energy demand within a small amount of time frame determines the next reference angular velocity of the flywheel in the ERS. For this reason an *ENERGY* spindle axis was defined in the Sinumerik controller of the *ERMA* demonstrator. This fourth axis represents the reference flywheel speed. Due to its inertia, the flywheel must accelerate earlier, in order to be able to recuperate the generated electric currents during a braking phase. However, the axes within the same channel of an NC controller are always controlled together as a bundle. There is no direct “predictive” way to let one of them move earlier than the others.

There is a solution to this problem by means of NC curve tables. A curve table is a way to look up and interpolate values of a *follower* machine axis based on the position of a *leader* axis. For this purpose there can be arbitrary pairs of leader-follower axis positions stored in the rows of a curve table. The only rule is that the leader positions must be increasing or decreasing monotonously. Upon moving the leader the NC controller interpolates a smooth movement of the follower. In the *ERMA* case the aforementioned *ENERGY* axis takes the role of the follower in each curve table definition. Upon each NC movement command there is at least one machine axis

involved. As the axis interpolation during movements is always monotonous, a leader machine axis can always be chosen respectively.

## 2.5 Coupling with the VNCK Service

As briefly introduced in chapter 1.2, there is a Windows service that emulates the core functionality of a real Sinumerik NC controller. The Virtual NC Kernel (VNCK) service registers a COM (Component-Object-Model) interface for easy integration into other Windows-based applications. Using this interface a Microsoft C# .NET-based GUI application called *IFF VNCK Manager* was developed. It can attach the Modelica simulation to the VNCK service and perform the transformation of an original NC program into a new form that includes the usage of curve tables to control the flywheel-based ERS.

Figure 6 shows the top-level view of the *ERMA* demonstrator model with VNCK coupling:

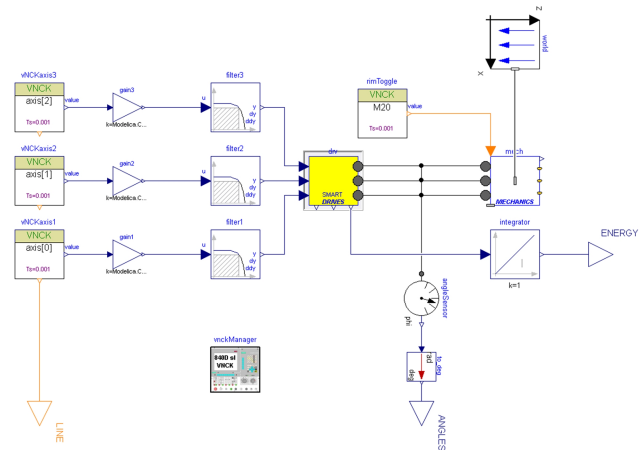

Figure 6: Top-level model of the *ERMA* demonstrator with VNCK binding

On the part of Modelica, a new *VNCK Library* has been created in the Fraunhofer IFF. It includes external C functions for binding, communicating with and finally stopping the VNCK service over a .NET/Managed C++ wrapper within the *ERMA* .NET solution. Modelica blocks were also developed for retrieving interpolated axis values and machine states at discrete time events. In the scenario of the demonstrator the latter way is used to detect commands for gripper control influencing the mass being transported. As the real gripper can programmatically get hold of or release a car wheel during the process, the load can vary over time. However, the virtual wheel body must always remain attached to the simulated robot’s gripper, because the model structure cannot be changed in Modelica during the simulation. Therefore a mass override input variable has been added to the standard Modelica rigid body

model. After a gripper release command is decoded by the VNCK, the mass of the wheel is set to zero immediately.

There is a single *VNCKManager* instance placed in this topmost Modelica model: the VNCK service is started during its initialization (in the initial equation section). The VNCK axis reader blocks are referencing this singleton instance over inner / outer Modelica constructs. During the processing of the original (textual) NC program, the VNCK is configured to report the source line positions, as well. This *LINE* integer output of the model is used to split the computed signals into multiple curve table definitions, as described later. According to an example NC program Figure 7 illustrates the splitting positions of the output signals (yielding six sections for six *G1* commands):

Figure 7: Splitting simulation signals according to NC statement blocks

The beginning of a new line with a movement command (in the example of Figure 7 those lines are labeled with *N1...N6*) is decoded by the VNCK and reported to the VNCK Manager.

The smallest step size of the VNCK service for axis-interpolation is 12 milliseconds. As only relatively coarse axis angles are being output therewith, filters must be applied in Modelica to smooth and reconstruct the continuous position reference signals. Each *VNCKaxis* block has a third-order Butterworth filter (10Hz cut-off frequency), and an additional first-order low-pass filter is applied in sequence, too. According to the smooth input signals the drive subsystem (Figure 5) can now compute the total power requirement at each simulation step (1ms). The smooth machine angles together with the integrated energy signal and the current NC source *LINE* signal are being output to the common simulation result file at equidistant intervals of 1ms.

The model of the machine being simulated can be arbitrary complex. There is no requirement of real-

time capability, because buffering mechanisms are used with semaphores within the .NET VNCK Manager application to synchronize the VNCK service and the Modelica simulation. The complete mechatronic model of the three-axis *ERMA* demonstrator is approximately 2 times slower than real-time. If the simulation would be faster and could overtake the VNCK process, it is forced to wait for the VNCK to yield the goal machine angles. For this reason the external C function call in each *VNCKaxis* can block the calling simulator thread until the buffer receives the next VNCK output (@ 83Hz / every 12msec) greater than or equal to the time step.

However, in case of *ERMA* the VNCK can compute three interpolated angles much faster than real-time. Therefore, the internal buffer of target angles is filled beforehand, thus buffer synchronization occurs only upon the beginning of the simulation.

The *VNCKManager* block shuts down the VNCK service and the simulation after receiving a *terminate* notification at the end of the interpreted NC program (*M30* command). After this event, the .NET application can start to process the simulation results.

## 2.6 Flywheel Control Strategy

Within the *ERMA* project a new strategy had to be developed to transform the computed energy levels to appropriate flywheel speeds, thus allow the ERS to reduce the power consumption of a production machine. There are multiple permanent consumers in the electric cabinet that cannot be eliminated: such as frequency inverters, decentralized peripherals (switched magnetic valves, limit switches, etc.) or the Sinumerik controller itself. Besides further thermal losses in the system their static power consumption could neither be modeled nor compensated with the flywheel strategy.

According to the *ERMA* concept the total sum of the flywheel energy in the ERS together with the potential and kinetic energy of the machine must be kept at a constant energy level. The range of the computed *ENERGY* signal can be determined after the simulation. This has to be transformed into a range of flywheel speed according the inverse of the formula (1) in chapter 1.1. Right at the moment where the energy signal has its maximum, the flywheel must rotate at its lowest (idle) speed. Similarly, the upper flywheel speed-limit must correspond to the lowest energy state of the machine during the process. Using higher flywheel speed as needed would increase the friction losses, thus an optimum had to be found. The ideal flywheel speed range is also influenced by the maximum amount of energy that can be recov-

ered during the whole process. In case of typical fast pick-and-place tasks in a production line the flywheel of the ERS never stops, because it has relatively high power consumption upon startup accelerations. In case of the *ERMA* demonstrator the range of 5400-6800 rpm has been determined experimentally. Within this range of 1400 rpm 1300J of process energy can be stored theoretically.

As mentioned earlier, the simulation result file contains data about the original NC program lines, too. The splitting of the result file occurs at each moment the *LINE* signal changes. The example of Figure 7 yields six individual sections after the simulation. A new curve table definition is then created out of each section. It is not to forget that the flywheel must be controlled in advance. Therefore, prior writing the corresponding leader-follower axis values into the output curve table, the section of the energy signal is shifted 54 milliseconds forwards in time (towards prediction). This amount of time was determined empirically, after exhaustive testing with the real energy recuperation system. Figure 8 shows the software tool chain that is used in this work. A .NET solution “*IFF VNCK Manager*” has been created to modify an existing main NC program (.mpf) with the incorporation of curve tables, thus the NC controller is able to control the energy axis of the ERS transparently during the real executed process.

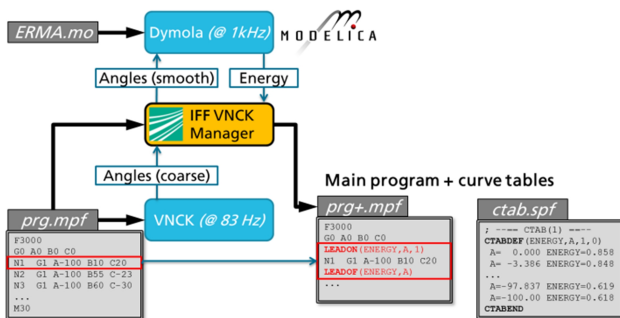

Figure 8: Software chain to create modified NC programs with ERS control capability

As there are usually multiple axes moving upon a single NC command, the leader axis of a curve table definition is chosen according to the biggest position difference being travelled. In the example of Figure 7 the role of the leader axis in the first three curve tables is A, B and C, respectively.

### 3 Summary

In this paper a new concept of including a flywheel-based energy recuperation system into production

machinery is presented. Based on a semi-automated workflow of creating a detailed, realistic mechatronic Modelica model of the system and coupling with a virtual controller, the movements to be executed can be assessed energetically in advance. This information can be used to control a mechanical energy storage unit earlier, overcoming its intrinsic flywheel inertia, which otherwise would hinder effective energy recuperation.

The demonstrator of the here presented *ERMA* project is located in the Virtual Development and Training Centre of the Fraunhofer IFF in Magdeburg, Germany. Using this methodology a 12% reduction of the machine’s energy consumption was achieved.

## 4 Acknowledgement

The here presented work has been funded by the German Federal Ministry of Education and Research within the Resource and Energy Efficiency Program under the project named “*ERMA - Energy Recuperation for Multi-Axis Machines*” (02PK2192).

## Abstract

This contribution presents a Modelica implementation of the generalized power-based modeling approach conforming to the bond graph methodology. The corresponding developed library BondGraph is discussed in detail. It allows graphical modeling according to the bond graph formalism, and contains common bond graph elements, as well as specific nonlinear elements, especially related to hydraulic effects. Furthermore, several composed models are provided, such as switching valves, pipes, cylinders, etc. A combination with blocks of the Modelica Standard Library is possible. The application of BondGraph to an industrial plant is described to demonstrate its capabilities.

**Keywords:** *power-based model, bond graph, library, Modelica, hydraulic*

## 1 Introduction

Since general purpose simulation environments enhance their capabilities, modelers attempt to take advantage of the offered possibilities completely. Hence, models become more comprehensive and cover the multidisciplinary of the considered systems. Therefore, domain specific modeling libraries are developed and offer possibilities to model the involved different physical effects separately as well as to interconnect them. The generalized power-based approach is an alternative efficient modeling formalism. Based on the generalized power definition, unified modeling elements are conceptualized applicable to the direct multidisciplinary modeling of complex systems. Consequently, the modeling procedure consists of the characterization of domain specific processes corresponding to their unified complements and interconnecting these complements to the model of complete sys-

tem according to its structure. For further advantages of generalized power-based modeling, see e.g. [1] and [2]. The Modelica language is particularly suitable for the development and representation of power-based models, primly because of the possibility of the acausal multiple signal connections definition.

The bond graph (BG) formalism provides a multidisciplinary, generalized power-based approach to the modeling and also graphical model representation of dynamic systems (cf. [3]). By the object-oriented nature, BG possess the according advantages. The graphical system representation by a BG can be translated automatically to a system of differential-algebraic equations, wherefore the implementation of the BG approach with an appropriate modeling language is necessary.

The Modelica language and the BG formalism are partly closely related modeling methodologies. Hence, an implementation of the BG formalism in Modelica is considered in this contribution. The proposed implementation attempts to take advantages of both modeling concepts. The developed open source library BondGraph is recommended to be used with Dymola 7 or later versions as this software supports completely included model definitions.

The introduced BondGraph library is available online at the official Modelica web page [4]. It contains common standard BG elements, as well as specific nonlinear elements. The included nonlinear models were designed especially for the modeling of hydraulic networks. For these, attention has been paid to their numerically stable computation. Further components provided by BondGraph include composed models of technical units, e.g. valves, and blocks for signal generation, e.g. to control valves.

A short introduction to the BG formalism is given in the Section 2. The implementation of a number of representative elements in the BondGraph library is

discussed in Section 3. In Section 3.1, the implementation of the standard BG elements, and in Section 3.2, the implementation of the hydraulic elements are presented. Section 4 introduces an industrial plant and the corresponding model developed using the BondGraph library. Several examples are provided to illustrate the described issues. A brief summary is given in Section 5. The used formula symbols are summarized in the Appendix.

## 2 Bond Graphs

Since its development, the BG approach has become a well-known technique for object-oriented graphical modeling (cf. [3]). This fact is based on the established definition of generalized power (cf. [5]) as the product of a conceptional effort  $e$  and a flow  $f$  variable:

$$P = f \cdot e. \quad (1)$$

This generalized specification provides the feasibility of multidisciplinary modeling with unified elements. The only prerequisite for this obviously advantageous modeling approach is an appropriate assignment of power variables i.e. effort and flow for considered domains.

For example, in the field of isothermal hydraulics, conventionally the pressure and the volumetric flow rate are assigned as the effort and the flow variable, respectively. A list of corresponding possible assignments for different energy domains is shown in Table 1.

Table 1: A selection of domains and corresponding conventional variable assignments in the bond graph formalism

Domain	Flow	Effort
hydraulic	volume flow rate	pressure
translational	velocity	force
rotational	angular velocity	torque
electrical	current	voltage
thermal	entropy flow rate	temperature

### 2.1 Bond Graph Elements

The basic set of BG elements consists of an effort source, a flow source, a capacitance, an inductance, a resistance, a transformer, and a gyrator, which are

given with corresponding constitutive equations in Table 2.

Table 2: Basic bond graph elements

Name	Element	Constitutive Equation
effort source	$Se$	$e = e_s$
flow source	$Sf$	$f = f_s$
capacitance	$C$	$e = \frac{1}{c} \int_{t_0}^t f(t^*) dt^* + e(t_0)$
inductance	$I$	$f = \frac{1}{i} \int_{t_0}^t e(t^*) dt^* + f(t_0)$
resistance	$R$	$e = r \cdot f$
transformer	$TF$	$e_1 = r_{if} \cdot e_2, f_1 = \frac{1}{r_{if}} \cdot f_2$
gyrator	$GY$	$e_1 = r_{if} \cdot f_2, f_1 = \frac{1}{r_{if}} \cdot e_2$

A significant extension of the modeling opportunities is offered by modulated elements. These are generalizations of linear elements where the proportionality coefficients are given by an external signal.

Two further multi-port elements referred to as junctions are defined in the bond graph methodology. These may represent conservation or equilibrium laws but also design constraints among the variables of the elements connected. In the graphical representation, the two power variables are carried by one eponymous bond connecting junctions and other BG elements, that is usually drawn as a half arrow. The flows of all elements connected to a 1-Junction are equal, whereas the sum of efforts carried by all incoming bonds equals the sum of efforts carried by all outgoing bonds. Again a 0-Junction is a dual element corresponding to the 1-Junction, hence for this the reversed relations of effort and flow are valid. For example, related to the hydraulic domain, all elements connected to a 1-Junction have the same flow as being connected in series, and all elements connected to a 0-Junction have the same effort as being connected in parallel.

Formally, a 1-Junction is described by the equations

$$\sum_{k=1}^n s_k \cdot e_k = 0, \quad s_k \in \{+1, -1\}, \quad (2)$$

$$f_1 = f_2 = \dots = f_n, \quad (3)$$

where  $n$  equals the number of elements connected to the junction. In the same manner, a 0-Junction is described by

$$\sum_{k=1}^n s_k \cdot f_k = 0, \quad s_k \in \{+1, -1\}, \quad (4)$$

$$e_1 = e_2 = \dots = e_n. \quad (5)$$

By convention,  $s_k = +1$  for all incoming bonds and  $s_k = -1$  for all outgoing bonds. Hence, the contributions to the constitutive equation of a junction are determined by the directions of the bonds in the graphical representation. Nevertheless, as can be seen by (2) and (4), formally, this is rather a property of the junction itself than of the connection. This fact is considered by the proposed implementation of the BG formalism in Modelica.

According to a specific domain, for each standard BG element a physical interpretation can be given. Considering a combination of linear elements, modulated elements, and sensors observing power variables, it is possible to describe a wide range of nonlinear models by case-related definitions of the external signal. Nevertheless, the definition of application-specific, and, where appropriate, nonlinear elements may lead to a convenient modeling process and ensures the clarity of the obtained models.

## 2.2 Causality

Within the BG formalism, bond connections are representations of information exchange between submodels. As two power variables are associated with each bond, two equations are obliged for their calculation and thus each end of the bond is responsible for one of them. Graphically, the flow determining end is marked by a short stroke. For example, energy storage elements are preferred to have integral causality, thus a capacitance preferably computes effort and an inductance preferably computes flow, whereas sources obviously determine their output variables. Several rules exist for causality assignment, e.g. listed in [3].

The graphical assignment of causality is useful if the equations describing the system behavior are directly deduced from the graphical BG representation. In some modeling tools as for example 20-sim (cf. [6]), the causality is fixed during the modeling procedure. However, it is not required to assign the causality during the modeling process using Modelica, as this is a subtask of the model compilation process, which is performed by suitable matching algorithms. For large models and generally for practical modeling, the manually or a priori fixed causality assignment is less reasonable. Therefore, manual causality assignment is not integrated in the presented BG implementation.

## 2.3 Example

An example of a simple physical system and its BG representation are shown in Fig. 1. The considered

system is a hydraulic cylinder driven by enforced pressures at hydraulic ports assigned with  $PT_1$  and  $PT_2$ . On the mechanical side, a load is executed represented by a force at the corresponding port  $PT_3$ . In this simple representation, basic BG elements are utilized exclusively, which may be less suitable for modeling with practical accuracy requirements.

## 3 BondGraph Library

### 3.1 Standard Bond Graph Elements

The set of standard bond graph elements is comprised of basic BG elements, their modulated complements, and junctions. Thus, these are included in the BondGraph library. Therefore, the corresponding constitutive equations and element interfaces are implemented in Modelica. The power variables are made accessible by acausal connectors, whereas for signals, input-output connectors are defined compatible to blocks of the Modelica Standard Library (MSL). For the energy storage elements, initial conditions are defined locally applying start attributes for differentiated variables. The element parameters are implemented according to the BG methodology. Extending this set, sensors are modeled as simple two port elements that do not affect the power variables. Via a

signal output interface, these elements provide power variables or their product i.e. power, corresponding time derivatives, or integrals. Again, the compatibility with blocks of the MSL is assured.

### 3.1.1 Bonds

According to the bond graph methodology, elements are interconnected by bonds. In contrast to the bonds, Modelica connections do not provide attributes for variable sign and for causality assignment, and their graphical representation. Therefore, if the bonds should be implemented closely to the original methodology, they would have to be objects of a class containing required properties. This approach would make the modeling procedure significantly more cumbersome.

The BondGraph library uses standard Modelica connections for the element interconnection introducing the connect equation directly or graphically. The graphical modeling technique is recommended here, as the BG formalism is a graphical modeling approach. Hence, an alternative method is used to determine the signs of power variables at a junction (cf. (2) and (4)). Therefore, junctions are equipped with a positive and a negative multiple port. These are indicated by a blue and a red circle, respectively. All elements connected to the positive port are considered with a positive sign ( $s_k = +1$ ) and all elements connected to the negative port are considered with a negative sign ( $s_k = -1$ ) in the sum of efforts for a 1-Junction, or in the sum of flows for a 0-Junction. In terms of the standard BG formalism, all incoming bonds are connected to the positive port and all outgoing bonds are connected to the negative port. This yields a clear graphical representation in compliance with (2) and (4) as discussed in Section 2.1.

### 3.1.2 Causality Assignment

As it has been discussed in Section 2.2, the causality assignment is not required by using Modelica. Furthermore, restrictions on algorithmic matching procedures may lead to less efficient model equations resolution. Hence, any regulations of this kind are avoided in the BondGraph library. Nevertheless, a graphical indication of the BG formalism specific causality assignment can be implemented in the animation layer extending the models of the released library by appropriate functionality. In this way, the standard BG causality assignment method might be visualized without eventual affecting of the equation resolution procedure.

### 3.1.3 BondGraph Example

The implementation of the example presented in Section 2.3 is shown in Fig. 2, now using the BondGraph library in Dymola. Here, the pressures and force imposed at the hydraulic and mechanical ports, respectively, are implemented utilizing effort sources and look-up tables from the MSL.

Figure 2: Simple bond graph example implemented using BondGraph

## 3.2 Hydraulic Elements and Effects

Hydraulic processes are subprocesses of fluid-mechanical power exchange. For the modeled processes, this is considered transient and spatially one-dimensional along a main flow direction. Models of the following hydraulic effects are included in the BondGraph library: capacitive energy storage (*HC* and *MHC*), inductive energy storage (*HI*), dissipation (*HR*, *HRL*, *HRT*, and *MHRT*), and processes with source characteristics (*HSe acc* and *HSe ind*). In the hydraulic domain, the power variables  $e$  effort and  $f$  flow are pressure and volume flow, respectively.

### 3.2.1 Working Fluid Properties

For the modeling of these hydraulic processes, the properties of the working fluid are of essential interest, since these may vary significantly within the working range. The *hprop* model of the BondGraph library provides a computation of the hydraulic fluid properties density and viscosity depending on the fluid temperature and the absolute pressure. By default, it is parameterized concerning the working fluid HLP ISO VG 32 as specified by the German industry norm DIN 54524, part 2. The introduced model is valid for the temperature range of [288, 363] K and the feasible pressure lies in a wide range of [1, 10<sup>8</sup>] Pa. The properties computed by the *hprop* model play an important role for

other hydraulic effects and therefore it is contained in the models of hydraulic processes.

For each process, a decisive pressure is defined by the arithmetic mean of the pressures before and after the considered process. This definition assures the independence of the flow direction and is of sufficient accuracy in most cases. Different to the standard bond graph convention, hydraulic processes are implemented as two-port elements in the BondGraph library where the mean values of the pressures at the ports, and also the fluid properties as determined by  $hprop$ , are automatically considered.

The dependence of fluid properties upon other conditions besides pressure and temperature is not modeled. The working fluid is assumed to be a homogeneous mixture of hydraulic oil and air, whereby the relative mass parts in the mixture are assumed to be time and state invariant.

**Density.** The density of the hydraulic oil is described by the equation

$$\rho_{oil} = \rho_{oil,ref} \cdot \exp(\kappa_{oil} \cdot (p - p_{ref}) - \gamma_{oil} \cdot (T - T_{ref})), \quad (6)$$

considering the compressibility and thermal expansion of the oil by the parameters  $\kappa_{oil}$  and  $\gamma_{oil}$ , respectively, whereby the density of air is modeled by the ideal gas law

$$\rho_{air} = \rho_{air,ref} \cdot \frac{p}{p_{ref}} \cdot \frac{T_{ref}}{T}. \quad (7)$$

These densities are then used to obtain the the density of the mixture by

$$\rho = \left( \frac{\mu_{oil}}{\rho_{oil}} + \frac{\mu_{air}}{\rho_{air}} \right)^{-1}, \quad (8)$$

which may be parameterized by the relative mass parts of the hydraulic oil and air.

It is also possible to obtain the compensated compressibility modulus of the working fluid from this model (cf. [7]). Thus it was verified with the conversed available data for the compensated compressibility modulus.

**Viscosity.** The viscosity of the hydraulic oil is modeled by the Roelands relation (cf. [8])

$$\eta_{oil} = \eta_{oil,ref} \cdot \exp \left( \ln \left( \frac{\eta_{oil,ref}}{6.315 \cdot 10^{-5} \text{Pa} \cdot \text{s}} \right) \cdot \psi \right), \quad (9)$$

with

$$\psi = -1 + \left( 1 + \frac{p - p_{ref}}{1.96 \cdot 10^8 \text{Pa}} \right)^\zeta \cdot \left( \frac{T - 138\text{K}}{T_{ref} - 138\text{K}} \right)^\xi. \quad (10)$$

The viscosity of air is described by the own approximation

$$\eta_{air} = \eta_{air,ref} \cdot \frac{\theta(p, T)}{\theta(p_{ref}, T_{ref})}, \quad (11)$$

with

$$\theta(p, T) = p^{0.01} \cdot T^{0.75} + 0.132 \cdot p \cdot T^{-2}. \quad (12)$$

Data used for the approximation is available in [9].

For the calculation of the viscosity of the mixture, relative volume parts of the components are obtained by

$$\phi_{oil} = \frac{\frac{\mu_{oil}}{\rho_{oil}}}{\frac{\mu_{oil}}{\rho_{oil}} + \frac{\mu_{air}}{\rho_{air}}} \quad (13)$$

and

$$\phi_{air} = \frac{\frac{\mu_{air}}{\rho_{air}}}{\frac{\mu_{oil}}{\rho_{oil}} + \frac{\mu_{air}}{\rho_{air}}}. \quad (14)$$

With reference to it's physical characteristic, the viscosity of the homogeneous mixture of hydraulic oil and air is then described by

$$\eta = \frac{\eta_{oil} \cdot \phi_{oil}^{2/3} + \eta_{air} \cdot \phi_{air}^{2/3}}{\phi_{oil}^{2/3} + \phi_{air}^{2/3}}. \quad (15)$$

### 3.2.2 Hydraulic Capacitance

The capacitive storage capability has a significant effect on the dynamic behavior of hydraulic systems. This property results from the elasticity of the considered hydraulic component and consequently from the pressure dependent variability of the enclosed fluid volume in the component. At low pressure, the compressibility of the working fluid has a considerable effect on the capacitive storage capability. Both effects are considered by the hydraulic capacitance model  $HC$  and mathematically described by

$$f = \frac{1}{\rho} \cdot \frac{d}{dt}(\rho \cdot v), \quad (16)$$

with

$$v = v_0 \cdot \exp(c_v \cdot (e - e_0)), \quad (17)$$

where  $e$  is the pressure,  $e_0$  is the initial pressure, and  $f$  is the volume flow difference taken by the component from the main volume flow.

Whereas the initial volume  $v_0$  is a parameter in the  $HC$  model, it can be adjusted by an external signal in the  $MHC$  model. This extends the modeling opportunities and e.g. allows the consideration of components with moving parts as for instance cylinders.

### 3.2.3 Hydraulic Inductance

From a power-based point of view, the inductive energy storage is the dual process to the capacitive storage and it mainly results from the inertia of the working fluid. The relation between the power variables in the inductive storage element is obtained from the principle of linear momentum applied on the enclosed working fluid in the component by

$$e = \frac{d}{dt} \left( \frac{l \cdot \rho}{A} \cdot f \right), \quad (18)$$

where  $e$  is the pressure difference across the component.

### 3.2.4 Hydraulic Dissipation

Dissipative hydraulic processes are highly nonlinear and change their characteristic dependent on the transient flow conditions (cf. [10]). As the hydraulic resistance is described using different models according to the particular effect, several elements are provided by the BondGraph library: strait pipe resistance ( $HR$ ), resistance of a pipe fitting with laminar flow ( $HRL$ ), resistance of a pipe fitting with turbulent flow ( $HRT$ ), and switchable hydraulic resistances ( $MHRT$ ) are distinguished.

**Strait pipe resistance.** The dissipative resistance of strait pipes is extensively studied in the literature (cf. e.g. [11], [12], [13]). The model proposed in this contribution (given by the following set of equations (19)-(25)) is based on the Darcy equation (equation (19), cf. [14]). The pipe friction factor for the entire range of the Reynolds number is obtained with an explicit, continuous approximation of the pipe friction factor equation for laminar flow and of the Colebrook-White equation (cf. [15]).

As can be seen by Fig. 3, the resulting pipe friction factor function  $\lambda(Re)$  (cf. equation (22)) is continuous as well as continuously differentiable, it does not diverge, and also does not include distinctions between different cases (if-then constructs), which yields stable computability. Due to the explicit form of equation (24), our approach also avoids the computationally expensive solution of the originally proposed implicit equation for turbulent flows.

$$e = \lambda \cdot \frac{l \cdot \rho}{2 \cdot d_h \cdot A^2} \cdot |f| \cdot f \quad (19)$$

$$Re = \frac{d_h \cdot \rho \cdot |f|}{A \cdot \eta} \quad (20)$$

$$Re_t = \frac{2 \cdot 6.9}{1 - \left(\frac{r_h}{3.7}\right)^{1.11}} \quad (21)$$

$$\lambda = \frac{\lambda_l}{1 + \exp\left(\frac{Re - Re_{crit}}{0.228 \cdot Re_{range}}\right)} + \frac{\lambda_t}{1 + \exp\left(\frac{Re - Re_{crit}}{-0.228 \cdot Re_{range}}\right)} \quad (22)$$

$$\lambda_l = \frac{64}{Re + Re_{min} \cdot \left(1 - \tanh\left(\frac{Re}{Re_{min}}\right)\right)} \quad (23)$$

$$\lambda_t = \left(\frac{-1.8}{\ln(10)} \cdot \ln\left(\left(\frac{r_h}{3.7}\right)^{1.11} + \chi\right)\right)^{-2} \quad (24)$$

$$\chi = \frac{6.9}{Re + Re_t \cdot \left(1 - \tanh\left(\frac{Re}{Re_t}\right)\right)} \quad (25)$$

In this equation set,  $e$  is the pressure difference across the component. To obtain numerical stability using sigmoidal functions, the following parameters are utilized:  $Re_{crit}$  is the Reynolds number value for the laminar-turbulent flow transition,  $Re_{range}$  is the Reynolds number range for the laminar-turbulent flow transition and  $Re_{min}$  is the Reynolds number value for the zero-flow crossing.

Figure 3: Proposed approximation of pipe friction factor  $\lambda$  according to equation (22). The inset shows the laminar-turbulent transition region in detail with typical values for  $Re_{crit}$  and  $Re_{range}$ .

**Resistance of pipe fittings.** The effect of dissipation due to hydraulic fittings is available by the models  $HRL$  and  $HRT$ . These may be used in case of hydraulic apertures, throttles, bendings, cross-section changes, and similar components. Resistances in these components (cf. [7]) can be described by taking their flow characteristic into account. In case of laminar flow, the viscosity of the fluid strongly affects the resistance which is expressed by the equation

$$e = \frac{e_{ref} \cdot \eta}{\eta_{ref} \cdot f_{ref}^\gamma} \cdot |f|^{\gamma-1} \cdot f. \quad (26)$$

Contrariwise, in case of turbulent flow, the density of the fluid has to be considered:

$$e = \frac{e_{ref} \cdot \rho}{\rho_{ref} \cdot f_{ref}^\gamma} \cdot |f|^{\gamma-1} \cdot f. \quad (27)$$

In both cases,  $e$  is the pressure drop across the component. For both laminar and turbulent resistances, often flow and pressure drop are not in linear relation to each other, but their relation may be described by a characteristic flow exponent  $\gamma$ , e.g.  $\gamma = 2$  if the flow is proportional to the square root of the effort. However, it usually depends on the geometry of the fitting and may therefore be adjusted by a parameter of the model.

**Switchable hydraulic resistance.** Hydraulic valves may be interpreted as switchable resistances and thus be modeled by switchable hydraulic elements. The *MHRT* element represents a signal controlled hydraulic resistance with turbulent characteristic where an input signal allows to control the state of the hydraulic resistance. An input value of 1 corresponds to a complete opened valve, whereas a value of 0 corresponds to a completely closed valve. To generate appropriate control inputs, several blocks are also provided by the BondGraph library. In this way the physical multi-domain nature of valves may be taken into account: though valves affect the hydraulic resistance, they are controlled by mechanical systems which are actuated either manually or by further technical units, e.g. a solenoid actuators. Therefore, array types of power-based models can be efficiently used for the modeling of hydraulic valves (cf. [16]).

### 3.2.5 Processes with Source-Characteristic

**Height change.** In the fluid-mechanical power exchange processes, two subprocesses with effort-source-characteristic are often involved. One of them is the pressure change  $e$  due to fluid displacement in the earth gravitation field, therefore

$$e = \rho \cdot g \cdot d, \quad (28)$$

which is considered by the *MSe acc* model.

**Cross section area change.** The second subprocess is covered by the *MSe ind* element and models the pressure change  $e$  due to a cross sectional area change in hydraulic lines, thus

$$e = \frac{\rho}{2} \cdot |f|^2 \cdot \left( \frac{1}{A_1^2} - \frac{1}{A_2^2} \right). \quad (29)$$

### 3.2.6 Consideration of Nonlinearity

**Causalized elements.** As pointed out in Section 2.2, causality does not have to be assigned in general by using Modelica. Nevertheless, when using nonlinear elements e.g. *HR*, *HRT*, *HRL*, or *MHRT*, it is recommended that the designer observes whether the element has effort-out or flow-out causality in the actual model. Accordingly, the activation of an appropriate formulation of the element equations should be controlled by a parameter. In this way, unnecessary numerical inversion of the nonlinear element equations is avoidable. Hence, the solution time of the model can be shortened and the solution accuracy and stability can be increased.

For instance, in (30) and (31), both causalized forms of the turbulent resistance are given (cf. equation (27)).

$$e = \frac{e_{ref} \cdot \rho}{\rho_{ref} \cdot f_{ref}^\gamma} \cdot |f|^{\gamma-1} \cdot f \quad (30)$$

$$f = \left( \frac{e_{ref} \cdot \rho}{\rho_{ref} \cdot f_{ref}^\gamma} \right)^{\frac{-1}{\gamma}} \cdot |e|^{\frac{1}{\gamma}-1} \cdot e \quad (31)$$

In (32), a form corresponding to the linear resistance element is obtained. The state dependent resistance coefficient  $r$  is separated. Different formulations for the resistance coefficient are then used dependent on the  $par_{caus}$  parameter.

$$e = r \cdot f, \quad (32)$$

with

$$r = \begin{cases} \frac{e_{ref} \cdot \rho}{\rho_{ref} \cdot f_{ref}^\gamma} \cdot |f|^{\gamma-1} \cdot f & \text{if } par_{caus} = 1, \\ \left( \frac{e_{ref} \cdot \rho}{\rho_{ref} \cdot f_{ref}^\gamma} \right)^{\frac{1}{\gamma}} \cdot |e|^{1-\frac{1}{\gamma}} \cdot e & \text{if } par_{caus} = 2. \end{cases} \quad (33)$$

**Variation of the proportionality factors.** Corresponding reformulations and separations of the proportionality factors are often possible and convenient for nonlinear elements with other characteristics. As these coefficients in such reformulated relations are in general time and state variant, their absolute values can attain low values or zero. The same has to be considered for the reciprocal of the absolute value. In these cases, structural changes arise in the interconnected model equations and a numerical solution is either not possible or becomes unstable. For instance, this might result in a non-decaying oscillation of the power variables where the amplitude and particularly the frequency of the oscillation depend on the chosen

solver algorithm and solution tolerance. In this case, an effective and simple modification of the model is the limitation of the value of the proportionality coefficient. The mentioned numerically induced oscillations are avoidable completely by this model extension.

### 3.3 Comparison Remark to BondLib

BondLib is a former successful implementation attempt of the bond graph formalism in the Modelica language presented in [17] awarded as the best free Modelica library in the framework of the Modelica Conference 2005. BondGraph is a conceptually different modeling library, intended rather for pragmatic practical modeling using bond graph methodology then for educational purpose. In contrast to BondLib, BondGraph does not include elements closely corresponding to bonds. Instead, Modelica standard connections are utilized for the interconnection of BG elements. Consequently, the assignment of the variable signs is implemented as a property of junctions instead of using the directional property of bonds. In this way, BondGraph utilizes Modelica more efficiently slightly differing from the graphical representation defined in the BG methodology. Since bonds as elements are excluded, in comparison to a model set up with BondLib, an equivalent model set up with BondGraph involves significantly less elements. Furthermore, the graphical clarity for large models can be maintained more straightforward. The junction implementation in BondGraph permits connection of elements of unlimited number, whereas in the BondLib, junctions with different fixed numbers of ports are available. Hence, model modifications and expansions are performed more efficiently utilizing BondGraph, since originally used junctions may be retained. From this point of view, the BondGraph junction implementation is closer to the BG methodology. The BondLib library offers bonds with fixed causality. As described before, BondGraph avoids any regulations of this kind well motivated following more closely the Modelica approach. Concluding this short comparison, we suggest BondGraph for practical modeling, whereas we recognize that BondLib offers several properties very important for bond graph beginners and educational purpose.

## 4 Industrial Hydraulic Plant

The discussed library is utilized for the modeling of an industrial hydraulic plant. The considered plant

is a riveting system with a hydraulic power transmission. The system can be structured into the following principal units: a hydraulic power supply unit containing an inductance motor and a pump, a valve block, a hydraulic-mechanical actuator, hydraulic pipes interconnecting these units, and a sequence control. Hence, the model to be developed should cover a comprehensive hydraulic network. Figure 4 shows the model top layer.

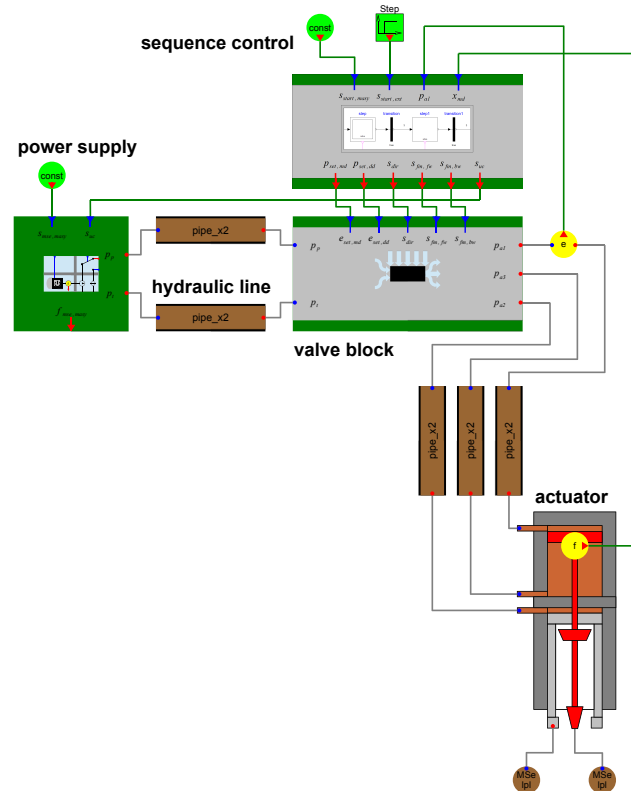

Figure 4: Model of the considered riveting system

The submodels representing principal units are modeled using the BondGraph library and the MSL. A plain example for this model set-up is the model of a hydraulic pipe consisting of hydraulic elements exclusively. A series of hydraulic dissipative and inductive elements separated by hydraulic capacitive elements may be utilized for the description of the pipe behavior. The series starts and ends with turbulent resistances representing resistances of the fittings. The inner part is the repeating of series consisting of a straight pipe resistance and a hydraulic inductance again separated by capacitive elements. This repeating incorporates spatial discretization of the pipe along the main flow direction. Consequently it should be undertaken an appropriate number of times to cover relevant system eigenvalues by the model. An example of pipe

Figure 5: Model of the hydraulic pipe

model with one inductive storage is given in Fig. 5.

The model of the complete plant is a higher index differential-algebraic system consisting of 4923 equations with 106 continuous time states. The operation cycle of the plant of 1.7 s is simulated. Figure 6 shows the normalized displacement  $x$  of the actuator effector, the mechanical energy  $E$  supplied by the inductance motor in the power supply unit, and the pressure  $p$  in the hydraulic circuit.

Figure 6: Simulation results. Plotted are the displacement  $x$  of the actuator, the mechanical energy  $E$  of the inductance motor, and the pressure  $p$  supplied by the pump.

The model parameters are identified by an optimization approach with reference to measurements obtained at a demonstrator plant. Hence, the model is verified against comprehensive experimental data. Furthermore, simulation based optimization of the plant is succeeded with the objective function defined as the consumed energy for an operation cycle (cf. [18]).

## 5 Conclusion

The bond graph methodology is a generalized power-based modeling approach. Hence, it is particularly advantageous for modeling of multidisciplinary systems. Therefore, BondGraph, the Modelica implementation of this approach enables applicants to take advantage of both, the flexible Modelica language and the well structured generalized power-based bond graph formalism. Furthermore, utilizing Modelica as the im-

plementation language, efficient general purpose modeling and simulation environments are made available for the bond graph applicants. Besides the development of BondGraph, a practical application of the library is conducted. Thereby, an industrial hydraulic plant is modeled, simulated, and optimized utilizing the developed modeling library.

chandrasekar@modelon.com   hubertus.tummescheit@modelon.com

## Abstract

This paper focuses on the physical design of hydraulic relief and servo valves and its applications. Specifically, this paper serves to illustrate how the physical design parameters of hydraulic components can be incorporated into system modeling and their effect on the system dynamics and stability characteristics. Detailed physical models of a relief valve and a servo valve developed using the Hydraulics Library<sup>®</sup> are discussed in this paper with particular emphasis on the effect of design parameters on the stability characteristics. A simple design of experiment (DoE) to illustrate robust design methods for hydraulic system design is also shown with the use of the FMI Toolbox (FMIT) for MATLAB<sup>®</sup>. Furthermore with the help of these two valve models, we seek to bring to the attention of the community, a limitation in open loop controls analysis in an acausal modeling environment where the feedback loops are embedded in the physics of the model.

*Keywords: Hydraulic Valves; Hydraulic Component Design; Mechanical feedback; Stability Analysis; Hydraulics Library; FMIT*

## 1 Introduction

Hydraulic control valves use mechanical motion to control or regulate fluid power in a hydraulic circuit. These valves serve as the interface between the mechanics and fluid dynamics in hydraulic systems and their performance characteristics are therefore critical to the safe and optimal operation of the systems in which they are employed [1]. Relief and servo valves are among critical components used in a wide variety of hydraulic systems and are respectively operated to regulate supply pressure to the load and convert fluid power to mechanical actuation.

In this paper, we discuss detailed Modelica models of a pressure relief valve and a servo valve and include the physical design parameters of these valves

and study the effect of these on the stability characteristics.

For the modeling of these valves, the newly developed Elements package of the Hydraulics Library is used. The Hydraulics Library is a commercial Modelica library from Modelon AB that enables modeling of fluid power systems in Modelica. The Elements package is developed to incorporate hydraulic component sizing into the design and modeling process. The library provides a comprehensive set of components typically used in hydraulic system modeling and provides the flexibility to build complex models from the basic building blocks available from the library. The Hydraulics Library with the Elements package is available for use with both Dymola and MapleSim<sup>®</sup>.

Due to its application in multiple engineering domains, the library provides a set of basic building blocks of components from which a more detailed model of a hydraulic system can be constructed. The elements package for example, provides models of a spool and a piston, which are connected through mechanical and hydraulic port connectors in any number of ways to construct detailed models of relief and directional control valves.

In this paper, we present detailed models of a Pressure Relief Valve and an Electro-Hydraulic Servo Valve (EHSV) constructed using components from the Hydraulics Library. Further, a Functional Mock-up Unit (FMU) of these models is imported into MATLAB<sup>®</sup> using the Functional Mock-up Interface Toolbox<sup>1</sup> for MATLAB [5] and linearized to study their stability characteristics and demonstrate robust design techniques. The two examples of the valves, apart from demonstrating the physical design of hydraulic components, also showcase a limitation in an acausal modeling environment where feedback loops embedded within the physics of the model need to be broken for analysis purposes. In controls analysis, such systems can only be linearized by manually

<sup>1</sup>FMIT for MATLAB is a commercial FMI tool from Modelon AB for the integration of physical models in MATLAB/Simulink.

modifying the physical equations. In our opinion, this is not an elegant solution and we illustrate this point through the two examples of the valves.

## 2 Hydraulic Elements Package

The Elements package of the Hydraulics Library provides an easy to use interface to model both the mechanics and hydraulic characteristics of hydraulic systems. Figure 1 illustrates the elements package. The subsequent subsections briefly discuss the various components of the elements package and their features.

Figure 1: The Elements package of the Hydraulic Library

### 2.1 Connecting port interfaces

Three types of connecting ports are used in the components of the Elements package and these are illustrated in Figure 2.

Figure 2: Connecting port interfaces used in the Hydraulics Library

The hydraulic port connectors in Figure 2(a) are the default connectors used throughout the hydraulics library with pressure and mass flow rate as the potential

and flow variables respectively. The connectors in Figure 2(b) are similar to those of Figure 2(a) except for the presence of the auxiliary volume variable. This port is used to connect the variable volume element with components where the volume change arises. The mechanical connectors in Figure 2(c) are the translational mechanical connectors from the Modelica Standard library with displacement and force as the potential and flow variables respectively.

### 2.2 Volumes

The Elements package provides two volume components that differs from the standard lumped volume component in the Volumes package of the library in that the volume is computed outside of the component and determined from the volume variable of the hydraulic port with volume. The first volume component (Figure 3(a)) represents a variable lumped volume where the pressure in the volume is calculated from the following continuity equation:

$$V \frac{dp}{dt} = \frac{\beta}{\rho} \frac{dm}{dt} - \beta \frac{dV}{dt} \tag{1}$$

where  $p$  is the pressure in the volume,  $V$  is the volume computed from the outside of the component and used through the port,  $\rho, \beta$  are the density and bulk modulus of the hydraulic fluid computed at pressure  $p$  and  $m$  is the mass flow through the volume component.

The second volume component (Figure 3(b)) does not include any pressure dynamics and is solely intended for connections between the standard hydraulic port and the port with volume.

Figure 3: Hydraulic volumes used in the Hydraulics Library

## 2.3 Valve Components

The basic building blocks of valve components provided in the Elements package are for leakage, piston, spool and poppet lift and these are illustrated in Figure 4.

- The leakage component (Figure 4(a)) models laminar flow of fluid leakage due to radial clearance, underlap or overlap and the leakage path length is assumed to be a constant. Variable length leakage is expected to be included in a future release of the library.
- The piston (Figure 4(b)) component represents a hydraulic piston with an open chamber ending at both sides. The chamber volume is computed as a function of the displacement due to the net force on the piston head. The pressure and mass flow rate of the fluid into/out of the piston is computed as a function of this change in chamber volume.
- The spool valve (Figure 4(c)) component models the spool and sleeve of a 2-way single land spool valve. The fluid flow through the spool is a function of the spool displacement modeled as a variable area orifice. The flow area of this orifice is computed from the geometry of the valve opening and this option is parameterized with 4 options: linear, quadratic, circular or custom (tabular user input). The spool valve also includes the effect of flow forces computed from the spool displacement and pressure drop across the valve. The valve openings are modeled as orifices and the expressions are regularized for numerical stability in the orifice equations in these components.
- Three variations of a poppet valve (Figure 4(d)-4(f)) are also provided in the library, each differing in the geometry of the poppet lift and seat. Like the spool valve, each of these poppet valves includes the effect of flow forces and regularized expressions for numerical robustness.

## 3 Modeling and Open-Loop Stability Analysis of a Hydraulic Pressure Relief Valve

Hydraulic relief valves act to regulate pressure in a hydraulic system where the pressure to be controlled

Figure 4: Building blocks to model hydraulic valves

is sensed in the valve end area and compared with a spring force setting [1]. In this work, the pressure relief valve described in [1] is modeled as a 3-way 2-land spool valve in Dymola using components from the Modelica Standard Library and the Hydraulics Library and the schematic of the valve is shown in Figure 5.

The spring with spring constant  $K_s$ , is preloaded with a force of  $F_0$ . This preloading sets the pressure  $P_c$ , in the spool valve chamber such that the valve is open with a displacement of  $x$  at steady state. As the supply pressure to the load increases, the spring is compressed to open the spool valve to allow more flow through the valve and into the tank maintained at atmospheric pressure. This relieves the excess pressure in the supply line. The opening of the valve is restricted between the geometric constraints of the spool and the supply

Figure 5: Pressure Relief Valve [1]

pressure determines the level of opening of the valve. The Modelica model of the relief valve is shown in Figure 15.

The geometric parameters of the valve were obtained from data sheets from Eaton Corp. [3] and the procedure for the derivation of valve parameters from data sheets is described in [4]. These parameters and the boundary conditions of the system are tabulated in Table 1. In Figure 15, the pistons are identical with the exception of one having a real input for the purpose of open loop analysis. With the boundary conditions from Table 1, the trajectories of the spool displacement and the pressures in the volumes are shown in Figure 6. Figure 6(a) shows an increase in the flow rate of 1% in the supply line pressure modeled as a step function. This increase in the supply flow increases the net pressure force in the spool valve and opens the valve more (Figure 6(b)) resulting in a larger flow area (Figure 6(c)) and hence more flow through the valve. This relieves the excess pressure in the supply line resulting in an increase in pressure of in the supply line of about 1.6% (Figure 6(d)).

### 3.1 Open Loop Stability Analysis of Pressure Relief Valve

The dynamic model of the pressure relief valve in Figure 15 was perturbed from its steady state (Figure 6) by an increase in the supply pressure. This model was set-up at this steady state operating point and linearized for open loop analysis. The open loop model was set-up such that the pressure in the piston and the force the pressure exerts on the spool are decoupled (or “broken”). This means that the transients in the pressure are de-coupled from the pressure-force equation. This is an example of a feedback loop embedded within the physics of the model. There ap-

(a) Supply flow

(b) Spool displacement (also valve opening)

(c) Flow area of valve compared with maximum flow area of  $4.8919 \times 10^{-4} \text{m}^2$

(d) Supply line pressure

Figure 6: Trajectories of the inlet flow, line pressure and valve opening

appears to be no elegant way to break these loops for open loop controls analysis other than modifying the equations manually. The block diagram representation of the relief valve of Figure 5 is shown in Figure 7 [1]. The inner loop represents the change in the force due to change in the volume of the piston and the outer loop represents the change in the force due to the change in the supply line pressure. In this analysis, only the effect of the line pressure on the force needs to be decoupled and is "broken" by duplicating the section of the model connecting the supply line to the piston using a master-slave approach as labeled in Figure 17. In the master section, the line pressure is held at steady-state by blocking the transients whereas in the slave, the volume of the slave piston is held at steady-state while allowing the transients of the line pressure. The pressure-force in the slave piston is the output of the open loop system representing the breaking of the outer loop of the block diagram of Figure 7. The real input to this piston represents the input force represented as  $F_0$  in Figure 7. The linearized system has 6 states:  $x, \dot{x}, P_C, P_S, P_{val}, P_{CS}$  where the symbols correspond to those introduced in Table 1 with  $x, \dot{x}$  representing the spool displacement and velocity  $P_C, P_{CS}$  are the pressure in the master and slave piston connected to the damping orifice and  $P_{val}$  is the pressure of the fluid in the spool valve.

The state space system of the relief valve is represented as:

$$\begin{bmatrix} \dot{P}_C \\ \dot{P}_S \\ \dot{P}_{val} \\ \dot{x} \\ \dot{\dot{x}} \\ \dot{P}_{CS} \end{bmatrix} = A_{lin} \begin{bmatrix} P_C \\ P_S \\ P_{val} \\ x \\ \dot{x} \\ P_{CS} \end{bmatrix} + B_{lin} F_0$$

$$F_{out} = C_{lin} \begin{bmatrix} P_C \\ P_S \\ P_{val} \\ x \\ \dot{x} \\ P_{CS} \end{bmatrix} + D_{lin} F_0$$

where  $A_{lin} =$

$$\begin{bmatrix} -4.18 \times 10^3 & 0 & 0 & 0 & 7.17 \times 10^9 & 0 \\ 2.13 \times 10^4 & -7.74 \times 10^5 & 6.19 \times 10^5 & 0 & 0 & 0 \\ 0 & 7.74 \times 10^4 & -1.02 \times 10^5 & 1.94 \times 10^{13} & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ -0.068 & 0 & 0.0072 & -4.7857 \times 10^6 & 0 & 0 \\ 0 & 4.18 \times 10^3 & 0 & 0 & 0 & -4.18 \times 10^3 \end{bmatrix}$$

$$\text{and } B_{lin} = \begin{bmatrix} 0 & 0 & 0 & 0 & -199.998 & 0 \end{bmatrix}^T, C_{lin} = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & -3.42 \times 10^{-4} \end{bmatrix}.$$

The Bode plot of the above linearized system is shown in Figure 8.

Component	Parameter	Value
Spring Damper	Pre-load force $F_0$	150N
	Spring Constant $K_s$	10000N/m
Mass	m	0.005kg
Spool Valve	Chamber volume $V_c$	$3 \times 10^{-5} m^3$
	Spool area $A_s$	$3.4212 \times 10^{-4} m^2$
	Radial Clearance r	$1 \times 10^{-5} m$
Piston	Volume $V_d$	$5 \times 10^{-5} m^3$
	Area A	$3.4212 \times 10^{-4} m^2$
Supply flow	$Q_{in}$	$0.002 m^3 s^{-1}$
Load Pressure	$P_L$	5bar
Damping Orifice	Area $A_{do}$	$5 \times 10^{-7} m^2$
	Transition Pressure	0.1bar
Metering Orifice	Area $A_{mo}$	$5 \times 10^{-5} m^2$
Outlet Orifice	Area $A_{out}$	$2.5 \times 10^{-5} m^2$

Table 1: System parameters and boundary conditions

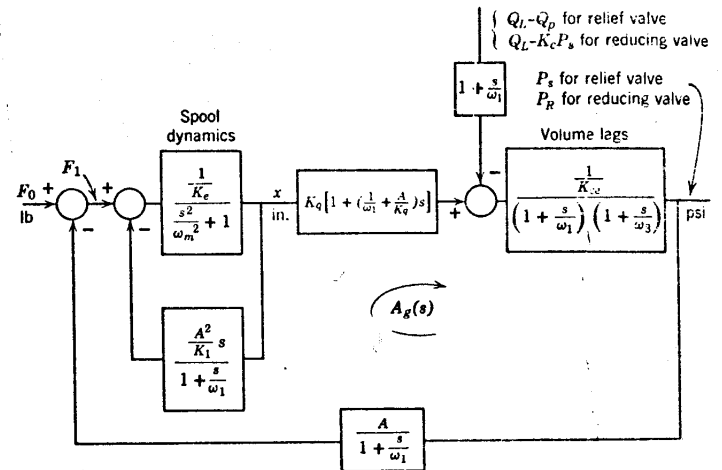

Figure 7: Block diagram representation of the relief valve

The steady state gain of the valve as seen from the magnitude plot of Figure 8 is affected by the flow-pressure coefficient of the spool valve and its volume at steady state. The coefficient is expressed as:

$$K_1 = \frac{q_{val,SS}}{2P_{val,SS}} \quad (2)$$

where  $q_{val,SS}$  and  $P_{val,SS}$  are the steady state flow rate and pressure through the spool valve respectively. This coefficient is directly affected by the geometric parameters of the valve and the type of valve opening (see Section 2.3) which gives the relationship between the spool displacement and the flow area. Similarly, the sizing of the orifices in the relief valve model also affects the corresponding flow-pressure coefficients which then impact the frequency response and

Figure 8: Bode plot of the linearized pressure relief valve system

therefore the stability characteristics. Further design rules for relief valves can be found in [1].

### 3.2 Robust design study of the relief valve model

The effect of design parameters on the gain and the phase margin of the system is discussed next. A Functional Mock-up Unit (FMU) of the model is imported into MATLAB using the FMI Toolbox for MATLAB. FMIT has tools for conducting Design of Experiments [5] and a simple design of experiment is illustrated here to show the effect of the geometric parameters of the valve on the stability characteristics.

The orifice areas of the damping and outlet orifices in the PRV model of Figure 17 are set with respect to a constant factor of the area of the metering orifice. These multiplicative factors are then varied in the DoE and the changes in the frequency response analyzed. First, the damping orifice area is varied through 100 points uniformly distributed between factors of 0.01 to 0.025 in comparison to the metering orifice area which is constant at  $5 \times 10^{-5} \text{m}^2$ .

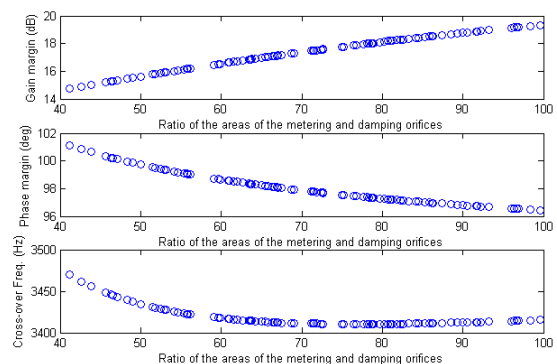

Figure 9 shows the bode plots, step response and the variance in the gain, phase margins and the cross-over frequency for different sizes of the damping orifice. The bode plot of Figure 9(a) shows differences in the open-loop gain at higher frequencies. While the damping orifice area has no influence on the steady-state gain, it can be observed that the response time is clearly affected by the damping orifice. As the damping orifice area increases, the damping ratio of the system also increases. The gain margin and phase

(a) Bode plot

(b) Step response

(c) Gain, phase margins and cross-over frequency

Figure 9: Effect of the damping orifice area on the frequency response

(a) Bode plot

(b) Gain, phase margins and cross-over frequency

Figure 10: Effect of the piston area on the frequency response

margins also do not show significant sensitivities to changes in the damping orifice area as seen by a change of 6dB and 6 deg in these quantities respectively.

The next design parameter of interest is the area of the piston in the valve. It is assumed that the pistons in the spool valve, and both pistons in the PRV model of Figure 15 are assumed to have equal areas and for the sake of simplicity, the rod areas in these pistons are assumed to be negligible. The piston areas are then varied over 100 uniformly distributed points across a range of  $1 \times 10^{-4}$  to  $5 \times 10^{-4} \text{m}^2$  and linearized about the respective steady state points.

The bode plot of Figure 10(a) shows that there is a significant sensitivity in the steady state gain to changes in the piston area. In fact, the steady state gain decreases with increasing piston area with iden-

tical damping characteristics. The gain and the phase margin (Figure 10(b)) also show significant increase with increasing piston areas. A suitable choice of piston area can be made from this plot with a gain of 3dB (or more) and a phase margin between 30 and 60 degrees to result in reasonable trade-offs between bandwidth and stability.

## 4 Modeling and Open Loop Stability Analysis of an Electro-Hydraulic Servo Valve

A single stage Electro-Hydraulic servo valves is modeled in this work with a torque motor directly attached to a 2-land 4-way directional control valve. A representation of this valve used to actuate an aircraft control surface is shown in Figure 11 [2].

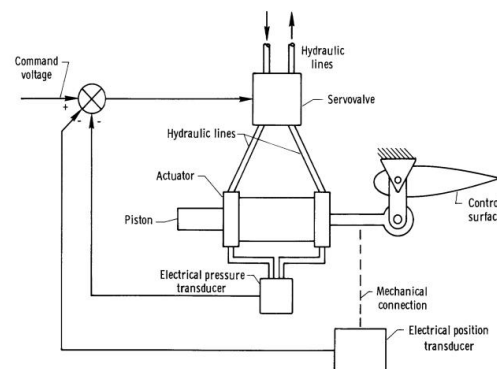

Figure 11: Schematic of a single stage servo valve to actuate an aircraft control surface

The directional control valve used in this hydraulic actuation system was modeled using a combination of volumes, spool valves and pistons from the Elements package and is shown in Figure 12.

Each pair of the spool valve and the piston are identical and the sizing of these are identical to that of the pressure relief valve discussed in Table 1. The complete model of the system is shown in Figure 16.

The function of the torque motor in Figure 16 is to convert the input voltage into the corresponding spool displacement to displace the directional control valve by an appropriate amount in the desired direction to open one of the spool valves that connect port P to port A or port P to port B for flow from port P which correspondingly opens the spool valves that connect port B to port T and port A to port T for flow into port T. Ports A and B are connected to the two hydraulic ports of a

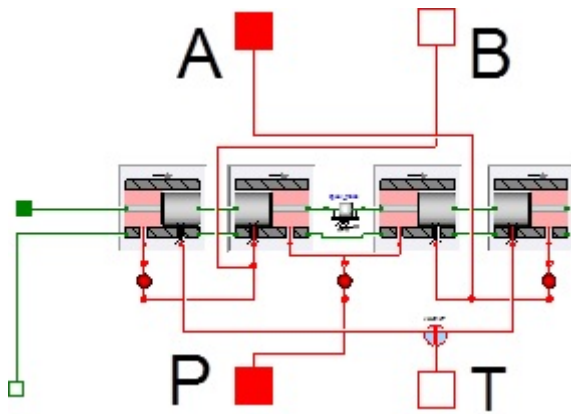

Figure 12: Model of a direction control valve made from components of the Elements package

differential cylinder to convert the fluid power into mechanical displacement to actuate the control surface.

The torque motor dynamics are not modeled in this work for simplicity but are represented as the following transfer function [2]

$$X_s(s) = \frac{0.003}{0.0025s + 1} E(s) \quad (3)$$

where  $X_s(s)$  and  $E(s)$  are the Laplace transform representation of the spool displacement of the directional control valve and the voltage signal to the torque motor respectively.

The pressure differential in the cylinder moves the piston against the preload force of the spring. This displacement of the piston in the cylinder is then sensed and acts as the feedback signal. The error between the input signal and the piston position is then amplified to be the voltage input of the torque motor.

The piston is assumed to be at a steady state at a position of 0.3 m. A pulse signal is sent as the input and the trajectories of the spool displacement of the directional control valve and that of the piston are plotted in Figure 13.

From Figure 13(a), as the piston is commanded to shift in the positive direction, the torque motor causes the directional control valve spool to displace in the positive direction (Figure 13(b)) to open the spool valves connecting ports P to A and ports B to T. The flow from port P through port A enters the piston and increases the pressure in that chamber to cause an increase in the net force on the spring to push the piston in the commanded direction. The pulse command shows the movement of the piston in both directions and the flows into the cylinder from the valve are plotted in Figure 13(c).

(a) Piston position and command

(b) Spool displacement of DCV

(c) Flow rate into cylinder

Figure 13: Trajectories of the piston, spool positions and flow rate into cylinder

The stability characteristics can be studied by breaking the feedback loop and setting the piston position as the output and the commanded position as the input. The model is linearized and the Bode plot of Figure 14 shows the frequency response of the system.

Figure 14: Bode plot of the linearized servo valve actuation system

It might be noted that the loop opening in this example is straightforward since the control law is outside of the physics of the model. In the case of the relief valve, the pressure force equation is part of the physics of the valve and there appears to be no elegant way with any Modelica based tool to break these loops other than to manually modifying the equations to enable the model to be used for controls analysis. For modeling, Modelica provides the great advantage that the modeler does not have to transform the model manually to block diagram form. For open loop control analysis, and a feedback loop that is embedded into the physics, the modeler will have to derive a block diagram form also in Modelica in order to obtain the open loop equations. It is however possible to integrate the open loop variant for certain typical feedback situations in library models. This will be made available in the upcoming version of the Hydraulics Library. In a block diagram based modeling environment like Simulink where there is no clear distinction between the physics of the model and the control system, such loop breakage is straight forward. The Simulink feature to automatically apply the steady-state value as offset at the input at which the loop is broken should also be available in Modelica tools.

It may however be possible to provide improved automated support for open loop stability analysis in Modelica tools, because the symbolic processing in

Modelica compilers for efficient code generation is very similar to the causalization process when deriving a block diagram from model equations. Another issue with open loop analysis of hydraulic components is that SI units, which are typically used in the model equations, are very badly scaled for the open loop analysis. The scaling that Modelica tools apply internally through the use of the nominal attribute does not help, because for the stability analysis the user would like to have properly scaled equations that are consistent between the linearized system and the closed loop model.

## 5 Conclusion

In this paper, we discussed the physical design of hydraulic components using the Hydraulics library and illustrated the application of robust design techniques to improve the physical design of valves with Modelica and FMI based tools. The application of the Elements package demonstrated both the modeling of relief valves and also in constructing more complex components from the basic building blocks already available from the library. We also highlighted a limitation in controls analysis of models where the feedback loops are embedded within the physics. There is a new paradigm developing in emerging physical systems where the feedback loops are embedded tightly within the physics of these systems and it is imperative that these aspects are addressed in Modelica and its associated tools.

# Exploiting Actuator Limits with Feedforward Control based on Inverse Models

Manuel Gräber  
TLK-Thermo GmbH  
Hans-Sommer-Str. 5, 38106 Braunschweig, Germany

## Abstract

Feedforward control based on inverse dynamic plant models (linear or nonlinear) is a suitable method to enhance set-point tracking performance of control systems. In reality actuators always have limits, but limiting functions can not be inverted. A common approach to handle this issue is to invert the unlimited plant model and detune the feedforward filter in order to stay always in between the actuator limits. This approach causes a loss in performance for rapid set-point changes, because the actuator range is not entirely used. In this article a rather simple but powerful method is presented, which overcomes this performance issue for many types of plant models. Actuator limits are fully exploited, and the obtained trajectories are close to optimal ones. Simulation and measurement results demonstrate the usability of the proposed feedforward structure.

*Keywords: set-point tracking; model inversion; actuator saturation; nonlinear control; model-based control; anti-windup*

## 1 Introduction

Assuming the dynamic behaviour of a plant is known, and a control task is to drive the plant output to a given set-point or track a given trajectory. A reasonable idea is to use the known plant behaviour to compute the needed plant input. Mathematically spoken a dynamic plant model is inverted. The original physical model computes the model output as reaction to the plant input. Whereas the inverse model computes the plant input for a given output. Modelica as equation-based modeling language provides a powerful possibility to automatically generate inverse dynamic models. In many cases inverse models can directly be derived from forward models. Details about model inversion with Modelica can be found in [11].

There are different ideas, where to place the inverse

model inside a control loop. In this paper we concentrate on the most obvious variant: using the inverse model in the feedforward path.

Feedforward control based on inverse dynamic plant models (linear or nonlinear) has been proven to be a suitable method to enhance set-point tracking performance of control systems. Successful applications have been reported in [8, 5].

But there is one issue, that often dramatically decreases the performance of feedforward designs: actuator limits. Every real-world control system has limited actuators. That means the control signal  $u(t)$  is constrained by

$$u_{\min} \leq u(t) \leq u_{\max} \quad (1)$$

The problem with Equation (1) is, that it is not invertible. A common approach is, to not include input constraints and invert an unconstrained plant model. But what happens if the unconstrained inverse model in a feedforward path computes plant inputs which violate constraints (1)? A straightforward solution is sketched in Figure 1. A filter  $F$  and the inverse plant model  $\tilde{G}^{-1}$  is used to compute an input signal out of reference signal  $r$ . A limiter finally cuts off the unconstrained input signal  $v$  at its limits and feeds the input signal  $u$  to the plant  $G$ .

Figure 1: Feedforward control with inverse plant model and actuator limitation.

It's easy to imagine, that if we apply a step jump to  $r$  this can lead to very large values of  $v$  at the first time points. Its magnitude of course depends on the inverse model and the filter. Theoretically, for most plant models a step jump of  $r$  with no filter ( $F = 1$ ) would even lead to an infinite impulse of  $v$ . But large values of  $v$  generate *actuator saturation*, that means  $u$  is equal  $u_{\max}$  or  $u_{\min}$ . The resulting difference between

$u$  and  $v$  causes a inconsistency between the states of the inverse plant model and the plant. Which directly means performance decrease of the feedforward control. This effect can be interpreted as *windup*, which is well known for integral controllers. In Figure 4 example simulation results are plotted, where saturation of  $u$  leads to unwanted oscillation of plant output  $y$ .

Well-known anti-windup techniques for feedback controllers, which can be described in state-space form, are conditioning [7] or the more general observer-based approach described in [1]. Although these schemes are developed for feedback controllers they could also be used for feedforward control. In fact the proposed method in this article shows similarities to observer-based approaches, but as described in Section 2 there is one important difference.

Straightforward approaches to avoid windup for inverse models as feedforward are: filter detuning or application dependent trajectory planning (e.g. set-point ramps). Drawbacks of these methods are the lack of generality and a loss of performance – at least if simple approaches are used. In [11] handling actuator limits is briefly discussed, although it is not the main scope of this article. As one possibility it is suggested to provide feasible reference trajectories by online or offline solving of dynamic optimization problems. This approach provides high performance potential. Due to its optimal character actuator limits can be fully exploited. But dynamic optimization is usually a non-trivial task.

In [10] actuator saturation is addressed with feedback from the plant according to *internal model control*. This general approach has the advantage to be not application specific. And with only one remaining tuning parameter its simple to parameterize. As a result the output of the inverse model  $v$  stays within its limits but does not fully exploit them.

Instead of detuning the filter  $F$  or using application dependent trajectory planning, a more general method to avoid windup is presented in this article. The basic concepts and ideas are described in Section 2. No theoretical proof of stability is given, but numerical experiments in Section 4 and real-world experiments in Section 5 demonstrate the usability of the proposed feedforward scheme. Benefits of this approach are:

- applicable to nonlinear (SISO) systems
- easy to set up using Modelica
- only one tuning parameter: filter frequency
- full exploitation of actuator limits, almost time-optimal trajectories

## 2 Feedforward with Actuator Limits

The basic idea of the new control structure is sketched in Figure 2. The original feedforward system in Figure 1 is complemented with an internal feedback loop. Similar to anti-windup schemes for integral controllers [1] the actuator saturation signal  $v - u$  is fed back with a constant gain  $k$  to the input signal.

Figure 2: Proposed feedforward control with internal anti-windup feedback.

If the unconstrained signal  $v$  is beyond its limits the negative feedback will decrease the windup effect and the constraint violation. The actual performance of this compensation strongly depends on the filter  $F$  and the gain factor  $k$ . In the following we will design  $F$  and  $k$  in a way, that there will practically no constraint violation of  $v$ .

The basic idea is to use a very high gain  $k$  to drive constraints violations to zero. See [12] for details on high gain feedback for nonlinear systems. In order to achieve stability of the feedforward loop with high gains, the open loop  $F\tilde{G}^{-1}$  has to fulfill a few requirements:

1.  $F\tilde{G}^{-1}$  must be stable.
2.  $F\tilde{G}^{-1}$  must have stable zero dynamics (minimum phase for linear systems).
3. Relative degree of  $F\tilde{G}^{-1}$  must be equal zero.

Condition 3 actually is stricter than needed. For stability of the high gain feedback loop a relative degree equal one would be sufficient. But numerical experiments show, that the feedforward performance is much better, if we restrict the relative degree to zero. Resulting in a direct algebraic feed through from  $F$ 's input to  $\tilde{G}^{-1}$ 's output and a nonlinear implicit algebraic equation of the overall feedforward system of equations (see Section 3). This is a crucial feature of the proposed implicit method, which distinguishes this method from observer-based explicit anti-windup schemes described in [1].

The open loop requirements can be transformed into requirements for  $F$  and  $\tilde{G}$ . Condition 1 and 2 hold also for the classical feedforward control of Figure 1 and

lead to the requirements that plant model  $G$  must be stable and must have stable zero dynamics. Condition 3 can easily be fulfilled if we choose the order of the filter  $F$  equal to the relative degree of  $\tilde{G}$ .

1.  $\tilde{G}$  must have stable zero dynamics.
2.  $\tilde{G}$  must be stable.
3. Order of Filter  $F$  must be equal to the relative degree of  $\tilde{G}$ .

It is important to note, that these requirements are not (yet) theoretical proven sufficient conditions. They are motivated by the theory of high-gain feedback and successful numerical experiments with various linear and nonlinear plant models.

### 3 Feedforward control using Modelica

Modelica provides a convenient possibility to generate feedforward control laws based on the proposed method. Due to its equation-based design the error-prone plant model inversion is handled by the Modelica compiler. Using the free Modelica Standard Library (MSL) and a given forward plant model, this task can even be done graphically. In Figure 3 the graphical representation of an example feedforward control system is shown. The plant is modelled as linear second order system, but it could be any other SISO Modelica model. This structure corresponds exactly to Figure 2. Plant model inversion is easily defined by exchanging input and output with the MSL block `InverseBlockConstraints`. See [11] for further details on model inversion with Modelica.

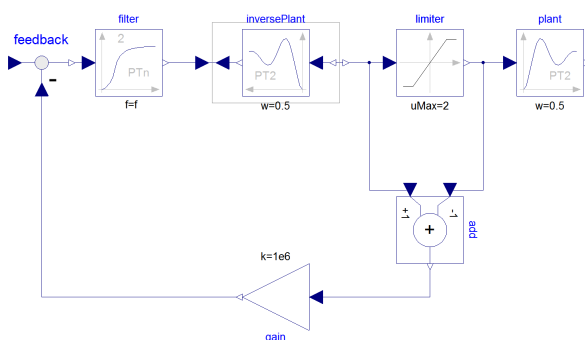

Figure 3: Graphical Modelica implementation of the proposed feedforward structure.

According to the requirements in Section 2 the chosen filter order is two – identical to the plant model's

relative degree. This means there is a direct algebraic relation between the filter input and the output of the inverse plant model. Using the notation of Figure 2 this relation can be expressed as function  $f$  with

$$v = f(r - k(v - u), \mathbf{x}) \quad (2)$$

where  $\mathbf{x}$  is the vector of internal states of  $F\tilde{G}^{-1}$ . Together with Equation (1) we obtain a nonlinear system of equations

$$v = f(r - k(v - u), \mathbf{x}) \quad (3a)$$

$$u = \begin{cases} u_{\max} & v > u_{\max} \\ u_{\min} & v < u_{\min} \\ v & \text{else} \end{cases} \quad (3b)$$

which can be reduced to one unknown  $v$ . To conclude this analysis: the resulting anti-windup feedforward control law is a system of differential and algebraic equations (DAE), with at least one nonlinear algebraic equation.

A straight-forward way to test this control law at a real plant is to use Functional Mock-up Unit (FMU) [3] export capabilities of Modelica tools. The resulting FMU for model-exchange comes with an embedded solver for implicit equations. The drawback is, that one has no control of the internal iterative solution process. But at least for prototyping purposes this approach works very well. In Section 5 a FMU exported from Dymola is used as controller at a real plant. With TLK-Thermo's FMI Suite the FMU is imported into the data acquisition and control environment LabView.

## 4 Simulation Experiments

In this section we look at two different linear example plants, modelled with the Modelica Standard Library. We study the effect of different filter parameters, which is the remaining degree of freedom of the proposed feedforward control. Finally optimal control trajectories are presented and compared to the obtained ones.

### 4.1 Plant Models and Simulation Setup

The chosen example plant models are two stable but differently damped second order systems. Angular frequency is 0.5 and gain is 1.0 in both cases. The resulting transfer functions are of the form

Figure 4: Plant input and output response to reference steps of different height. Conventional feedforward design.

Figure 5: Plant input and output response to a reference step. Conventional feedforward ( $k = 0$ ) with different filter cut-off frequencies  $f$  (Hz) compared to proposed anti-windup design ( $k = 10^6$ ).

$$G(s) = \frac{1}{4s^2 + 4Ds + 1}$$

with

$$D = 0.2 \quad (4a)$$

and

$$D = 1.2 \quad (4b)$$

Plant models and the proposed feedforward control are implemented in Modelica using MSL blocks. The graphical representation of the total simulation model is shown in Figure 3. For both plants actuator limits are  $-2$  and  $2$ . Gain  $k$  of the internal feedback loop is set to a comparable high number of  $10^6$ , which ensures that  $v$  virtually stays in between the actuator limits. According to the requirements in Section 2 the filter order is two.

## 4.2 Filter Tuning

The remaining degree of freedom for designing of the feedforward control is the filter's cut-off frequency  $f$ . In general higher values for  $f$  lead to a more aggressive feedforward control. This behaviour is identical

for the proposed anti-windup scheme as well as for the common scheme of Figure 1. In the latter case one would choose the filter frequency, so that the unconstrained plant input  $v$  would stay inside the actuator limits. There are two drawbacks with this approach. First, by not exploiting actuator limits we lose performance in terms of rise or settling time. Second, given a filter frequency  $f_1$  works well for a reference step of 1, it is by no means guaranteed, that it does also work for higher step jumps. Instead of using a pure linear filter one would need to implement an application dependent algorithm for *Trajectory Planning*.

The proposed additional internal feedback (see Figure 2) solves both issues. Actuator limits are fully exploited using a general not application specific approach. In the following this is illustrated with comparative simulation results for both feedforward schemes with the slightly damped plant model (4a).

In Figure 4 plant input and output responses to reference steps using the conventional feedforward scheme ( $k = 0$ ) are plotted. In both cases the filter frequency is 0.1 Hz. For a reference step of 0.5 (red) the input signal  $u$  stays inside the actuator limits. Whereas a reference step of 1.5 (black) leads temporarily to unconstrained input  $v$  above  $u_{\max}$ . The plant input  $u$  is chopped off at  $u_{\max}$ , which leads to a mismatch be-

Figure 6: Response to reference unit step at  $t = 1$  for different filter cut-off frequencies (in Hz). Slightly damped plant model with  $D = 0.2$ .

tween the states of the inverse plant model and the plant. This wind-up effect can be observed at the plant output  $y$  in form of unwanted oscillations (black).

Using internal high-gain feedback wind-up can be avoided. As a result we can use higher filter frequencies and fully exploit actuator limits. In Figure 5 simulation results for a step height of 0.5 are shown. The red curves are identical to Figure 4. If we increase the filter frequency to 0.4 Hz (black) we observe actuator saturation and oscillations of  $y$ . Things change dramatically if we turn on feedback with  $k = 10^6$  (blue). Now, plant input  $u$  also hits its limit, but plant output  $y$  behaves perfectly smooth. Compared to feedforward without feedback (red) the settling time is decreased by 63%.

A natural question is, what happens if the filter frequency is further increased? An answer is given in Figure 6. Using identical plant and feedforward setup as in the simulations above, the filter frequency is changed. Increasing  $f$  from 0.1 to 0.2 Hz leads to a better feedforward performance. At 0.5 Hz we already see a small overshoot of  $y$ , and at 1.0 Hz there are notable oscillations in  $u$  and  $y$ .

Simulation experiments with the well-damped plant model (4b) give similar results, plotted in Figure 7. Here, we can choose higher filter frequencies. At  $f = 1$  Hz there is still no overshoot of  $y$ . Further increase

Figure 7: Response to reference unit step at  $t = 1$  for different filter cut-off frequencies (in Hz). Well damped plant model with  $D = 1.2$ .

of  $f$  finally also leads to oscillations in  $u$  and  $y$ .

To conclude these observations: Depending on the plant dynamics there seems to be a critical filter frequency  $f_{\text{crit}}$ . Values of  $f$  greater than this critical frequency lead to overshooting or even oscillating plant outputs.

As conclusion from additional simulation experiments, that are not shown in this article:  $f_{\text{crit}}$  strongly depends on the plant dynamics. Whereas dependencies to actuator limits and the reference signal (e.g. step height) seem to be very weak.

As consequence of these observations we formulate a tuning rule for filter frequency  $f$ :

- Simulate a step jump of the reference signal with the given plant model.
- Increase  $f$  until overshooting of the plant output is observed. This is  $f_{\text{crit}}$ .
- Choose  $f$  to be less than  $f_{\text{crit}}$ . Smaller values lead to increased robustness against model uncertainty.

This tuning rule is by no means theoretically founded. It is purely derived from simulation experiments.

Figure 8: Time-optimal trajectories of plant input and output for rapid set-point changes compared to trajectories obtained with anti-windup feedforward. Well-damped plant model.

Figure 9: Time-optimal trajectories of plant input and output for rapid set-point changes compared to trajectories obtained with anti-windup feedforward. Slightly-damped plant model.

### 4.3 Comparison with Optimal Trajectories

In Section 4.2 several control trajectories are obtained with the proposed feedforward algorithm. Now we want to find out, how good they are. More precisely, we compare them with optimal trajectories, defined by the solution of the *Optimal Control Problem*

$$\min_{\mathbf{x}(\cdot), u(\cdot)} t_e \quad (5a)$$

$$\text{s.t.} \quad \frac{d\mathbf{x}}{dt}(t) = \mathbf{f}(\mathbf{x}(t), u(t)) \quad (5b)$$

$$-2 \leq u(t) \leq 2 \quad (5c)$$

$$\mathbf{x}(0) = \mathbf{0} \quad (5d)$$

$$\frac{d\mathbf{x}}{dt}(t_e) = \mathbf{0} \quad (5e)$$

$$y(t_e) = 1 \quad (5f)$$

$\mathbf{x}$  denotes the vector of state variables and  $\mathbf{f}$  is the corresponding ODE function of plant model (4). Optimization task is to drive the plant from  $\mathbf{x}(0) = \mathbf{0}$  as fast as possible to steady state with  $y(t_e) = 1$ .

OCP (5) is solved numerically using *Direct Multiple Shooting* within the software package MUSCOD-II [4, 6, 9]. The obtained optimal trajectories of  $u$  and

$y$  are plotted for both plants in Figure 8 and 9 together with feedforward trajectories. Frequencies of feedforward filter are chosen according to simulation results from Section 4.2. One can see that there are differences of the feedforward control inputs  $u$  to its optimal trajectories. But at the output  $y$  of the well-damped plant Figure 8 there is practically no deviation between optimal and feedforward values. In Figure 9 deviations at the output of the slightly-damped plant can be detected, but they are comparable small. For both plant models the proposed feedforward control provides input trajectories for an almost time-optimal set-point change.

## 5 Real-World Experiments

In this section the proposed feedforward algorithm is tested on a real plant. To eliminate set-point tracking errors from model/plant mismatch feedforward control is enhanced with additional feedback. Measurement results are presented for pure feedforward and combined feedback/feedforward control.

## 5.1 Electric Water Heater

The experimental plant is a water heater as part of an existing test stand, where it is used to provide water flow at a given temperature. As sketched in Figure 10 a water mass flow  $\dot{m}$  with inlet temperature  $T_{in}$  is heated by electrical power  $P_{el}$  and leaves the heater with outlet temperature  $T_{out}$ . The electrical heating power is thyristor controlled with an analog input signal  $u$ . Control task is set-point tracking of plant output  $y = T_{out}$  using input  $u$ .  $\dot{m}$  and  $T_{in}$  can be seen as disturbances.

Figure 10: Schematic view of the controlled plant.

## 5.2 Plant Model

In Modelica a mixed physical/empirical model of the electric water heater is developed. The static behavior is modelled with the energy balance

$$0 = \dot{m}c_p(T_{in} - T_{out}) + P_{el} \quad (6)$$

and a nonlinear empirical relation

$$P_{el} = f(x) \quad (7)$$

where  $x$  is an internal state. Equation (7) describes the nonlinear static behavior of the phase cutting thyristor controller.

The overall plant dynamics are modelled as second order time delay model. The identified transfer function from  $u$  to  $x$  is

$$G_{ux}(s) = \frac{1}{(1 + 5.804s)(1 + 5.809s)} e^{-1.885s} \quad (8)$$

In Figure 11 the measured step response used for identification together with the model step response is shown. Good agreement between fitted model and measured dynamics can be noticed.

## 5.3 Feedforward Measurement Results

Measurement results of the proposed feedforward control applied to the real plant are plotted in Figure 13.

Figure 11: Measured input step response compared to the response of the identified second order time delay model.

The shown experiment spans set-point steps of varying height. Similar to the simulation experiments the feedforward reacts very aggressively to set-point changes and exploits actuator limits (0-10V). Due to model plant mismatch the output does not exactly track the given set-points. The static error is 1-2 K. Compared to the full control range of 27 K this error is relatively small.

If one would still like to drive this static error to zero, the feedforward control can be combined with measurement feedback, as it is done in the next section.

## 5.4 Combined Feedforward and Feedback Control

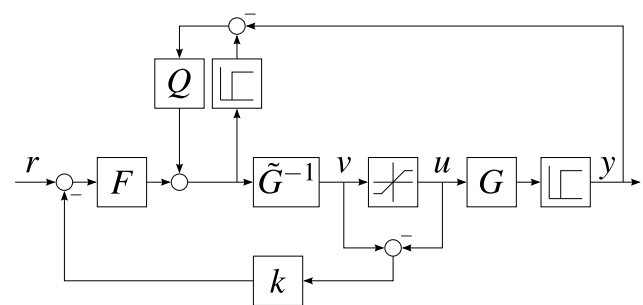

Figure 12: Feedforward and feedback control structure.

There are different possibilities, how to combine feedforward and feedback in one control system. See for example [11] for a brief overview. Following the approach suggested in [2] we add the output of an feedback filter  $Q$  to the input of the inverse plant model. The input of  $Q$  is the difference between measured and desired plant output. The resulting control

Figure 13: Measurement results from feedforward control of a liquid heater.

structure is sketched in Figure 12. For  $Q = 1$  infinity-gain feedback is obtained. Usually  $Q$  is implemented as low pass filter with unity gain. Filter order and frequency are tuning parameters of the feedback loop. Compared to [2] the control structure in Figure 12 has two additional elements. One is the internal feedback loop of the feedforward path as it is discussed in the previous sections. The second addition is a delay block. It is necessary because, plant model (8) includes delay, which is not invertible. This issue can be solved by splitting the model in a continuous block without delay and an additional delay block. Only the continuous block is inverted. The delay block is added afterwards to the desired plant output, before it is compared with the measured real output.

Measurement results obtained with this control structure are shown in Figure 14. As in Figure 13 the closed loop shows fast reaction to set-point changes. Additionally the static control error is eliminated.

## 6 Conclusion

The proposed anti-windup scheme for feedforward control with inverse models leads to near optimal control trajectories for a broad class of plant models: stable nonlinear SISO systems with stable zero dynamics. Because of its equation-based nature Modelica provides an user-friendly possibility to generate ap-

Figure 14: Measurement results from combined feedforward and feedback control of a liquid heater.

propriate feedforward control laws based on (forward) system models of the controlled plant. With one remaining tuning parameter – filter cut-off frequency – the proposed method is easy to configure. Experiments with a real plant show good performance of the anti-windup feedforward control. Control errors due to model plant mismatch are successfully avoided by extending feedforward control with feedback loop.

# An FMI-based Framework for State and Parameter Estimation

Marco Bonvini, Michael Wetter, Michael D. Sohn  
Simulation Research Group, Lawrence Berkeley National Laboratory  
1 Cyclotron Road, 94720, Berkeley, CA

## Abstract

This paper proposes a solution for creating a model-based state and parameter estimator for dynamic systems described using the FMI standard. This work uses a nonlinear state estimation technique called unscented Kalman filter (UKF), together with a smoother that improves the reliability of the estimation. The algorithm can be used to support advanced control techniques (e.g., adaptive control) or for fault detection and diagnostics (FDD). This work extends the capabilities of any modeling framework compliant with the FMI standard version 1.0.

*Keywords: Nonlinear State and Parameter Estimation; Unscented Kalman Filter (UKF); Smoothing; Functional Mockup Interface (FMI); Fault Detection and Diagnosis (FDD)*

## 1 Introduction

In many applications, after the system has been designed, controls and/or fault detection and diagnostics (FDD) algorithms are developed and deployed. These techniques should be able to leverage the models developed during the earlier design stages, thereby increasing the productivity of the overall product development. Advanced control (such as adaptive control or model predictive control) and FDD techniques require an enhanced knowledge of the system state. For example, the flight controller of an airplane should try to estimate the real velocity and position of the aircraft while compensating for measurements errors and sensor noises. When dealing with dynamic system, having an enhanced knowledge about the system state means estimating its state variables with associated error bounds.

This paper proposes a solution for creating a model-based state estimator for dynamic systems described using the FMI standard. This work extends the capabilities of any modeling framework compliant with the FMI standard version 1.0. The FMI is a stan-

dard that allows to embed a simulation model within a unified interface in order to couple simulation models developed using different simulation programs. Although the FMI standard has been created mainly for co-simulation, we leverage this standard for providing an algorithm that is compatible with a large number of simulation and modeling platforms, including Modelica-based ones.

There are several characteristics intrinsic of any model-based state estimation technique. These characteristics are related to the model properties (e.g., the Kalman filter is applicable just to linear models), the assumptions introduced when describing the probability distribution of the state variables (e.g., assuming they are Gaussian) and the computational performance of the underlying algorithm (e.g., the number of simulations or computations to be done in order to provide an estimation).

The state estimation technique used in this work is the unscented Kalman filter (UKF) [1, 2]. The UKF is able to deal with nonlinear systems and it just requires to perform function evaluations of the model in order to compute the evolution of its state variables and the value of its outputs. The UKF has less requirements about the knowledge of the model with respect to other nonlinear state estimation techniques. For example the extended Kalman filter needs to linearize the model [3]. The computational performances of the UKF are modest with respect to other Monte Carlo based techniques (like particle filters [4]), enabling its use for real-time applications.

The proposed work leverages the UKF technique and provides a state and parameter estimation algorithm for a dynamic system (e.g., modeled with Modelica or Matlab) embedded according to the FMI standard as a Functional Mockup Unit (FMU). The model, once exported as FMU can be used to set up a state and parameter estimator to

- calibrate the model during the commissioning phase in order to check if it performs as expected,
- compute a probabilistic estimation of unknown

variables of the system (e.g., observable but not measured) for control or FDD.

The paper is structured as follows. Section 2 starts with a brief introduction about the state estimation and it continues with a description of the unscented Kalman filter and smoothing algorithm, including the modifications required to extend the state estimation procedure to the parameters. Subsection 2.5 gives more information about the implementation details, while subsection 2.6 contains a code snippet that shows how to use the proposed algorithm. Section 3 contains an example that shows how the proposed algorithm can be used to identify faulty operation in a valve in the presence of measurement errors.

## 2 Method

The FMI-based state and parameter estimation algorithm consists of two components: (i) a filter for the state and parameter estimation, (ii) a smoother that improves the quality of the estimation when the measurements are noisy and sometimes erroneous. The proposed algorithm has been written in Python and uses PyFMI [5]. Some of the basic methods and classes provided by PyFMI have been extended to fit our purposes. For example, we modified how FMUs are executed in parallel.

### 2.1 State Estimation

Kalman Filter (KF) [3] are often used to estimate state variables. However, as they are only applicable for linear systems, they are not suited for our applications. For systems that are described by nonlinear differential equations, the state estimation problem can be solved using an Extended Kalman Filter (EKF) [3]. The EKF linearizes around the current state estimate the original nonlinear model. However, in some cases, this linearization introduces large errors in the estimated second order statistics of the estimated state vector probability distribution [6]. Another approach is to simulate sample paths that generate random points in the neighborhood of the old posterior probability, for example by using Monte Carlo sampling, and adopting particle filters for the state estimation [4]. These techniques are robust with respect to model nonlinearities, but they are computationally expensive. The UKF faces the problem representing the state as a Gaussian random variable, the distribution of which is modeled non-parametrically using a set of points known as sigma points [1]. Using the sigma points, i.e., by propagating

a suitable number of state realizations through the state and output equations, the mean and the covariance of the state can be captured. The favorable properties of the UKF makes its computational cost far lower than the Monte Carlo approaches, since a limited and deterministic number of samples are required. Furthermore, the UKF requirements fit perfectly with the infrastructure provided by PyFMI since it provides an interface to the FMU model that allows to set state variables, parameter and running simulations.

### 2.2 The Unscented Kalman Filter

The Unscented Kalman Filter is a model based-techniques that recursively estimates the states (and with some modifications also parameters) of a nonlinear, dynamic, discrete-time system. This system may for example represent a building, an HVAC plant or a chiller. The state and output equations are

$$\mathbf{x}(t_{k+1}) = f(\mathbf{x}(t_k), \mathbf{u}(t_k), \Theta(t), t) + \mathbf{q}(t_k), \quad (1a)$$

$$\mathbf{y}(t_k) = H(\mathbf{x}(t_k), \mathbf{u}(t_k), \Theta(t), t) + \mathbf{r}(t_k), \quad (1b)$$

with initial conditions  $\mathbf{x}(t_0) = \mathbf{x}_0$ , where  $f: \mathfrak{R}^n \times \mathfrak{R}^m \times \mathfrak{R}^p \times \mathfrak{R} \rightarrow \mathfrak{R}^n$  is nonlinear,  $\mathbf{x}(\cdot) \in \mathbb{R}^n$  is the state vector,  $\mathbf{u}(\cdot) \in \mathbb{R}^m$  is the input vector,  $\Theta(\cdot) \in \mathbb{R}^p$  is the parameter vector,  $\mathbf{q}(\cdot) \in \mathbb{R}^n$  represents the process noise (i.e. unmodeled dynamics and other uncertainties),  $\mathbf{y}(\cdot) \in \mathbb{R}^o$  is the output vector,  $H: \mathfrak{R}^n \times \mathfrak{R}^m \times \mathfrak{R}^p \times \mathfrak{R} \rightarrow \mathfrak{R}^o$  is the output measurement function and  $\mathbf{r}(\cdot) \in \mathbb{R}^o$  is the measurement noise.

The UKF is based on the typical prediction-correction style methods:

1. PREDICTION STEP: predict the state and output at time step  $t_{k+1}$  by using the parameters and states at  $t_k$ .
2. CORRECTION STEP: given the measurements at time  $t_{k+1}$ , update the posterior probability, or uncertainty, of the states prediction using Bayes' rule.

The original formulation of the UKF imposes some restrictions on the model because the system needs to be described by a system of initial-value, explicit difference equations (1). A second drawback is that the explicit discrete time system in (1) cannot be used to simulate stiff systems efficiently. The UKF should be translated in a form that is able to deal with continuous time models, possibly including events.

Although physical systems are often described using continuous time models, sensors routinely report

time-sampled values of the measured quantity (e.g. temperatures, pressures, positions, velocities, etc.). These sampled signals represent the available information about the system operation and they are used by the UKF to compute an estimation for the state variables.

A more natural formulation of the problem is represented by the following continuous-discrete time model

$$\frac{d\mathbf{x}(t)}{dt} = F(\mathbf{x}(t), \mathbf{u}(t), \Theta(t), t), \quad (2a)$$

$$\mathbf{x}(t_0) = \mathbf{x}_0, \quad (2b)$$

$$\mathbf{y}(t_k) = H(\mathbf{x}(t_k), \mathbf{u}(t_k), \Theta(t), t_k) + \mathbf{r}(t_k), \quad (2c)$$

where the model is defined in the continuous time domain, but the outputs are considered as discrete time signals sampled at discrete time instants  $t_k$ . The original problem described in equation (1) can be easily derived as

$$\begin{aligned} \mathbf{x}(t_{k+1}) &= f(\mathbf{x}(t_k), \mathbf{u}(t_k), \Theta(t_k), t_k) \\ &= \mathbf{x}(t_k) + \\ &\quad \int_{t_k}^{t_{k+1}} F(\mathbf{x}(t), \mathbf{u}(t), \Theta(t), t) dt \end{aligned} \quad (3)$$

Our implementation uses this continuous-discrete time formulation and the numerical integration is done using PyFMI that works with a model embedded as an FMU. Despite not shown in (2) and (3) the model may contain events that are handled by the numerical solver provided with the PyFMI package.

The UKF is based on the the Unscented Transformation [1] (UT), which uses a fixed (and typically low) number of deterministically chosen sigma-points<sup>1</sup> to express the mean and covariance of the original distribution of the state variables  $\mathbf{x}(\cdot)$ , exactly, under the assumption that the uncertainties and noise are Gaussian [1]. These sigma-points are then propagated simulating the nonlinear model (2) and the mean and covariance of the state variables are estimated from them. This is significantly different from Monte Carlo approaches because the UKF chooses the points in a deterministic way. One of the most important properties of this approach is that if the prior estimation is distributed as a Gaussian random variable, the sigma points are the minimum amount of information needed to compute the exact mean and covariance of the posterior after the propagation through the nonlinear state function [6].

<sup>1</sup>The sigma-points can be seen as the counterpart of the particles used in Monte Carlo methods.

Figure 1 illustrates the filtering process which we will now explain. At time  $t_k$ , a measurement of the outputs  $\mathbf{y}(t_k)$ , the inputs and the previous estimation of the state are available. Simulations are performed starting from the prior knowledge of the state  $\hat{\mathbf{x}}(t_{k-1})$ , using the input  $\mathbf{u}(t_{k-1})$ . Once the results of the simulations  $\hat{x}_{sim}(t_k)$  and  $\hat{y}_{sim}(t_k)$  are available, they are compared against the available measurements in order to correct the state estimation. The corrected value (i.e. filtered) becomes the actual estimation. Because of its speed, the estimation can provide near-real-time updates, since the time spent for simulating the system and correcting the estimation is typically shorter than the sampling time step, in particular for building or HVAC applications, where computations take fractions of second and sampling intervals are seconds or minutes.

The Algorithm 1 summarize the steps performed by the UKF. The interested reader can find more information and details of the actual implementation in [7].

### 2.3 Smoothing to Improve UKF Estimation

In this subsection, we discuss an additional refinement procedure to the UKF. The distribution  $P(\mathbf{x}(t_k) | \mathbf{y}(t_1), \dots, \mathbf{y}(t_k))$  is the probability to observe the state vector  $\mathbf{x}(t_k)$  at time  $t_k$  given all the measurements collected. By using more data  $P(\mathbf{x}(t_k) | \mathbf{y}(t_1), \dots, \mathbf{y}(t_k), \dots, \mathbf{y}(t_{k+N}))$ , the posterior distribution can be improved through recursive smoothing. Hence, the basic idea behind the recursive smoothing process is to incorporate more measurements before providing an estimation of the state. Figure 2 represents the smoothing process. While the filter works forwardly on the data available, and recursively provides a state estimation, a smoothing procedure back-propagates the information obtained during the filtering process, after some amount of data becomes available, in order to improved the estimation previously provided [8].

The smoothing process can be viewed as a delayed, but improved, estimation of the state variables. The longer the acceptable delay, the bigger the improvement since more information can be used. For example if, at a given time, a sensor provides a wrong measurement, the filter may not be aware of this and it may provide an estimation that does not correspond to the real value (although the uncertainty bounds will still be correct). The smoother observes the trend of the estimation will reduce this impact of the erroneous data, thus providing an estimation that is less sensitive to measurement errors.

Figure 1: On-line state estimation filtering procedure.

Procedurally, the smoothing algorithm starts from a user-specified point in the data stream and back updates the previously filtered estimation. Algorithm 2 describes the smoothing procedure.

### 2.4 Parameter Estimation

The importance of the state estimation has been stressed, and we described the UKF and Smoother as solutions to this problem. While state estimation is particularly important for controls, parameter estimation is important for model calibration and fault detection and diagnostics. Consider, for example an heat exchanger. Suppose it is characterized by one heat exchange coefficient that influences the heat transfer rate between the two fluids. During the design of the heat exchanger it is possible to compute an approximation of it. However, it is not possible to know its value exactly. After the heat exchanger is created, identifying the value of it is important to verify if the design requirements have been met. Another example is real-time monitoring in which it is continuously monitored during the operation in order to continuously check if it has been reduced by fouling and the heat exchanger need to be serviced.

Continuous parameter estimation is possible by extending the capabilities of the UKF and Smoother to estimate not just the state variable, but also the parameters of the system. The approach is to include the parameter in an augmented state  $\mathbf{x}^A(\cdot)$ , defined as

$$\mathbf{x}^A(\cdot) = [\mathbf{x}(\cdot) \quad \mathbf{x}^P(\cdot)]^T, \quad (4)$$

where  $\mathbf{x}^P(\cdot) \subseteq \Theta(\cdot)$  is a vector containing a subset of the full parameter vector  $\Theta(\cdot)$  to be estimated. The new components of the state variables need a function that describe their dynamics. Since in the normal operation, these values are constant, the associated dynamic is

$$\frac{d \mathbf{x}^P(t)}{dt} = \mathbf{0}, \quad (5)$$

where  $\mathbf{0}$  is a null vector. These null dynamics have to be added (2). The result is a new continuous-discrete time system

$$\frac{d \mathbf{x}^A(t)}{dt} = F_A(\mathbf{x}^A(t), \mathbf{u}(t), \Theta(t), t) \quad (6a)$$

$$\mathbf{y}(t_k) = H(\mathbf{x}^A(t_k), \mathbf{u}(t_k), \Theta(t_k), t_k) + \mathbf{r}(t_k), \quad (6b)$$

with

$$F_A(\mathbf{x}^A(t), \mathbf{u}(t), \Theta(t), t) = \begin{bmatrix} F(\mathbf{x}(t), \mathbf{u}(t), \Theta(t), t) \\ \mathbf{0} \end{bmatrix} \quad (7)$$

Note that augmenting the state variables leads to a nonlinear state equation even if  $F(\cdot, \cdot, \cdot, \cdot)$  is a linear function. Therefore, for parameter estimation, a nonlinear filtering and smoothing technique is required.

### 2.5 Implementation

The former sections explained on the state and parameter estimation. This section describes the software implementation and describes specific issues that we addressed.

**Algorithm 1: Filtering**

Notation: The superscript  $(i)$  indicates that the quantity is related to the  $i$ -th sigma point,  $w_m^{(i)}$  and  $w_c^{(i)}$  are the weights associated to the  $i$ -th sigma point,  $n$  is the dimension of the state vector  $\mathbf{x}(\cdot)$ , and  $[\cdot]_i$  is an operator that if applied to a matrix  $A$  returns its  $i$ -th column. Vectors are indicated with bold characters.

Given the initial knowledge of the state distribution  $\mathbf{x}(t_0) \sim N(\mu_0, P_0)$ , and given the output measurement covariance matrix  $R_0$

1. Initialize  $k = 0$  and set parameters  $\alpha, \beta, \lambda$  (with  $0 \leq \alpha \leq 1$  – other configuration details in [2])
2. Define  $2n + 1$  sigma-points

$$\begin{aligned} \mathbf{x}(t_k)^{(0)} &= \boldsymbol{\mu}_k, \\ \mathbf{x}(t_k)^{(i)} &= \boldsymbol{\mu}_k + \left[ \sqrt{(n+\lambda)P_k} \right]_i, \quad i = 1 \dots n, \\ \mathbf{x}(t_k)^{(i)} &= \boldsymbol{\mu}_k - \left[ \sqrt{(n+\lambda)P_k} \right]_{i-n}, \quad i = n+1 \dots 2n. \end{aligned}$$

3. Compute the weights associated to each sigma-point

$$\begin{aligned} w_m^{(0)} &= \lambda / (n + \lambda), \\ w_c^{(0)} &= \lambda / (n + \lambda) + (1 - \alpha^2 + \beta), \\ w_m^{(i)} &= 1 / 2(n + \lambda), \quad i = 1 \dots 2n, \\ w_c^{(i)} &= 1 / 2(n + \lambda), \quad i = 1 \dots 2n. \end{aligned}$$

4. Compute the predicted state (i.e. perform a simulation) for each sigma-point, and the predicted weighted mean, and the predicted covariance

$$\begin{aligned} \mathbf{x}(t_{k+1})^{(i)} &= f(\mathbf{x}(t_k)^{(i)}, \mathbf{u}(t_k), \Theta(t_k), t_k), \quad i = 0 \dots 2n+1, \\ \boldsymbol{\mu}_{k+1}^- &= \sum_{i=0}^{2n+1} w_m^{(i)} \mathbf{x}(t_{k+1})^{(i)}, \\ P_{k+1}^- &= P_k + \sum_{i=0}^{2n+1} w_c^{(i)} \left( \mathbf{x}(t_{k+1})^{(i)} - \boldsymbol{\mu}_{k+1}^- \right) \left( \mathbf{x}(t_{k+1})^{(i)} - \boldsymbol{\mu}_{k+1}^- \right)^T. \end{aligned}$$

5. Redefine the new sigma-points  $\mathbf{x}(t_{k+1})^{(i)}$  using the predicted mean  $\boldsymbol{\mu}_{k+1}^-$ , and covariance  $P_{k+1}^-$  as shown in step (1).
6. Compute the measured outputs using the new sigma-points, then compute the mean output  $\hat{\mathbf{y}}_{k+1}$  and its covariance  $S_{k+1}$

$$\begin{aligned} \mathbf{y}(t_{k+1})^{(i)} &= H(\mathbf{x}(t_{k+1})^{(i)}, \mathbf{u}(t_{k+1}), \Theta(t_{k+1}), t_{k+1}), \quad i = 0 \dots 2n+1, \\ \hat{\mathbf{y}}_{k+1} &= \sum_{i=0}^{2n+1} w_m^{(i)} \mathbf{y}(t_{k+1})^{(i)}, \\ S_{k+1} &= R_0 + \sum_{i=0}^{2n+1} w_c^{(i)} \left( \mathbf{y}(t_{k+1})^{(i)} - \hat{\mathbf{y}}_{k+1} \right) \left( \mathbf{y}(t_{k+1})^{(i)} - \hat{\mathbf{y}}_{k+1} \right)^T. \end{aligned}$$

7. Compute the cross covariance between the state and the output

$$C_{k+1} = \sum_{i=0}^{2n+1} w_c^{(i)} \left( \mathbf{x}(t_{k+1})^{(i)} - \boldsymbol{\mu}_{k+1}^- \right) \left( \mathbf{y}(t_{k+1})^{(i)} - \hat{\mathbf{y}}_{k+1} \right)^T.$$

8. Compute the filter gain and update the predicted mean and covariance of the state

$$\begin{aligned} K &= C_{k+1} S_{k+1}^{-1}, \\ \boldsymbol{\mu}_{k+1} &= \boldsymbol{\mu}_{k+1}^- + K [\mathbf{y}_{k+1} - \hat{\mathbf{y}}_{k+1}], \\ P_{k+1} &= P_{k+1}^- - K S_{k+1} K^T. \end{aligned}$$

9. Compute the state estimation as  $\hat{\mathbf{x}}(t_{k+1}) \sim N(\boldsymbol{\mu}_{k+1}, P_{k+1})$ .

10. Increment  $k$ , and go to step (2).

Figure 2: Improving the estimation using the smoothing. Backward propagations of the filtering results can improve the former estimation.

Algorithm 2: Smoothing

1. Initialize  $k \geq 0$  and define the amplitude of the smoothing window  $N > 0$  such as data at time  $t_{k+N}$  are available.
2. Initialize  $j = 1$ .
3. Draw the  $1 + 2n$  sigma-points  $\mathbf{x}(t_{k+N-j})^{(i)}$  using  $\mathbf{x}(t_{k+N-j})$  as mean value, and  $P_{k+N-j}$  as covariance matrix.
4. Propagate the sigma points through the dynamic model (prediction step) and compute the mean, covariance and cross covariance

$$\begin{aligned} \mathbf{x}(t_{k+N-j+1})^{(i)} &= f(\mathbf{x}(t_{k+N-j})^{(i)}, \mathbf{u}(t_{k+N-j}), \Theta(t_{k+N-j}), t_{k+N-j}), i = 0 \dots 2n + 1, \\ \mu_{k+N-j+1}^- &= \sum_{i=0}^{2n+1} w_m^{(i)} \mathbf{x}(t_{k+N-j+1})^{(i)}, \\ P_{k+N-j+1}^- &= P_k + \sum_{i=0}^{2n+1} w_c^{(i)} \left( \mathbf{x}(t_{k+N-j+1})^{(i)} - \mu_{k+N-j+1}^- \right) \left( \mathbf{x}(t_{k+N-j+1})^{(i)} - \mu_{k+N-j+1}^- \right)^T, \\ C_{k+N-j+1} &= \sum_{i=0}^{2n+1} w_c^{(i)} \left( \mathbf{x}(t_{k+N-j+1})^{(i)} - \mu_{k+N-j+1}^- \right) \left( \mathbf{x}(t_{k+N-j})^{(i)} - \mathbf{x}(t_{k+N-j}) \right)^T. \end{aligned}$$

5. Compute the smoother gain, and post-correct the previous estimation providing the smoothed mean and covariance

$$\begin{aligned} K &= C_{k+N-j+1} \left[ P_{k+N-j+1}^- \right]^{-1}, \\ \mu_{k+N-j}^s &= \mu_{k+N-j+1}^- + K \left[ \mathbf{x}(t_{k+N-j+1}) - \mu_{k+N-j+1}^- \right], \\ P_{k+N-j}^s &= P_{k+N-j} + K \left[ P_{k+N-j+1}^s - P_{k+N-j+1}^- \right] K^T. \end{aligned}$$

6. If  $j < N$  then set  $j := j + 1$  and go to step (2), otherwise exit.

N.B. At the end of each time step the state is estimated as  $\hat{\mathbf{x}}^s(t_{k+N-j}) \sim N(\mu_{k+N-j}^s, P_{k+N-j}^s)$ .

The first barrier to overcome was that the state estimation procedure refers to the full vector of state variables  $\mathbf{x}(\cdot)$ . However in many applications, the number of state variables is higher than the ones to be estimated. An example are sensors that sometimes contain a unitary gain first order filter. Including all the state variables in the estimation is not desirable because

- the number of sigma points required by the UKF, and thus the number simulations to be run, grows with the number of state variables.

- for every state variable or parameter estimated the user must provide an initial guess for mean value and the covariance.

Therefore, the user is allowed to select a subset of the state variables and parameters to be estimated by the UKF algorithm.

Similarly, an FMU may have several outputs, but only few of them may be measured and used by the UKF. The outputs for which a measurement is available and used by the UKF are denominated measured

outputs. The measured outputs requires additional information such the covariance (i.e., the uncertainty associated to the measure) and a time serie containing the data.

All the inputs and the measured outputs have to be associated with a time serie. This can be done by associating them with a specific column of a csv file.

Another issue has been encountered regarding the range of validity of states and parameters. For example, the level of water contained in a tank has to be positive but not greater than the height of the tank. We addressed this issue by constraining the sigma points within user specified upper and lower limits. As default, the min and max values specified in the FMU model description file are used.

We also implemented the ability to run the simulations in parallel. The computationally demanding part of the UKF and Smoother is the time integration done using PyFMI. However this section of the algorithm is entirely parallelizable. By default, our implementation uses one less thread as there are processors to run the simulation, while a thread manages the simulation and collects the results. The simulation results generated by PyFMI can optionally be written to files or not.

All these functionalities have been embedded in few classes that use PyFMI. In particular we have defined a new class representing the FMU model in a more general term since the state estimation is a task that involves more than a simple simulation, which is the aim of PyFMI.

## 2.6 Code snippet

This subsection contains a code snippet that illustrates how the FMU-based state and parameter estimation framework works. In this example the FMU model represents a mass-spring-damper system, where the input is the force  $F$  applied to the mass, and the measured output is the mass acceleration  $a$ . The two corresponding data series are stored in a csv file named data.csv. The states to be estimated are the position  $x$  and its velocity  $v$ .

```
# Path of the FMU model
filePath = "./model.fmu"

# Instantiate the model
m = Model(filePath, atol=1e-5, rtol=1e-4)

# Path of the CSV file that contains the data series
csvPath = "./data.csv"

# Associate the columns of the csv file to the input
input = m.GetInputByName("F")
input.GetCsvReader().OpenCsv(csvPath)
input.GetCsvReader().SetSelectedColumn("Force")

# Associate the columns of the csv file to the output
output = m.GetOutputByName("a")
output.GetCsvReader().OpenCsv(csvPath)
output.GetCsvReader().SetSelectedColumn("acceleration")
```

```
# Specify that this output has to be compared against
# measured data contained in the CSV file
output.SetMeasuredOutput()

# Specify output measurement covariance
output.SetCovariance(1.0)

# Specify the subset of the states to be estimated
m.AddVariable(m.GetVariableObject("x"))
m.AddVariable(m.GetVariableObject("v"))

# Get a reference to the states to be estimated
var_x = m.GetVariables()[0]
var_v = m.GetVariables()[1]

# Specify initial value for the position
# and the boundary limits (e.g., position x must be positive)
var_x.SetInitialValue(2.5)
var_x.SetCovariance(0.5)
var_x.SetMinValue(0.0)

# Specify initial value for the velocity
var_y.SetInitialValue(0.0)
var_y.SetCovariance(0.2)

# Initialize simulator
m.InitializeSimulator()

# Instantiate UKF and pass to it the model
UKF = ukfFMU(m)

# Run the filter from 0.0 to 10.0 seconds
time, X, Sx, y, Sy = UKF.filter(start = 0.0, stop = 10.0)

# plotting ...
```

This framework reduces the effort to set up a state or parameter estimation. The model can be created in Modelica and directly imported as an FMU, avoiding the user to rewrite the model in the right format required by the UKF. Other functionalities provide an easy way to specify the state variables or parameter to be estimated, together with the data series to be used as inputs and outputs.

## 3 Application: FDD

This section contains an example that shows how the FMU-based state and parameter estimation algorithm can be used for fault detection and diagnosis.

FDD algorithms based on state estimation techniques are known to be more suitable than other approaches based on neural networks or principal component analysis for detecting multiple faults [9, 10, 11], they can compute the fault probabilities and they provide an indication of what is not working as expected in the system. All these features are possible thank to the probabilistic description of the state variables and parameters the estimation techniques provide.

A drawback of state estimation based strategies is that they require a slightly higher modeling effort, e.g., to include explicit fault descriptions in the model itself. However, various open-source modeling tools (e.g. OpenModelica and JModelica), and modeling libraries for buildings (Modelica Buildings library [12]) are available, and they provide two main advantages: reducing the effort required to set up the model, and

Figure 3: Schematic of the system.

reducing the risk of modeling errors since they are typically validated and tested.

The availability of these tools and libraries together with the FMU-based state and parameter estimation algorithm put in place a framework for creating with a low level of effort a model-based FDD algorithm.

The considered system is a valve that regulates the water flow rate in a water distribution system (see Figure 3). The system is described by the following equations

$$\dot{m}(t) = \phi(x(t))A_v\sqrt{\rho(t)}\sqrt{\Delta p(t)}, \quad (8a)$$

$$x(t) + \tau\dot{x}(t) = u(t), \quad (8b)$$

where  $\dot{m}(\cdot)$  is the mass flow rate passing through the valve,  $\Delta p(\cdot)$  is the pressure difference across it,  $u(\cdot)$  is the valve opening command signal,  $x(\cdot)$  is the valve opening position,  $\tau$  is the actuator time constant,  $\phi(\cdot)$  is the power-law opening characteristic,  $A_v$  is the flow coefficient and  $\rho(\cdot)$  is the fluid density (please note that the square root of the pressure difference is regularized around zero flow in order to prevent singularities in the solution). The system has three sensors (see Figure 3) that respectively measure the pressure difference across the valve, the water temperature  $T(\cdot)$  and the mass flow rate passing through it. All the sensors are affected by measurement noise. In addition, the mass flow rate sensor is also affected by a thermal drift.

$$T^N(t) = T(t) + \eta_T(t) \quad (9a)$$

$$\Delta p^N(t) = \Delta p(t) + \eta_P(t) \quad (9b)$$

$$\dot{m}^{N+D}(t) = (1 + \lambda(T(t) - T_{ref}))\dot{m}(t) + \eta_m(t) \quad (9c)$$

The measurement equations are described in (9), where the superscript  $N$  indicates a measurement affected by noise, the superscript  $N+D$  indicates the presence of both noise and thermal drift,  $T_{ref}$  is the reference temperature at which the sensor has no drift,  $\lambda$  is the thermal drift coefficient and  $\eta_T(\cdot)$ ,  $\eta_P(\cdot)$ , and  $\eta_m(\cdot)$  are three uniform white noises affecting respectively the temperature, pressure and mass flow rate

Figure 4: Input signals of the faulty valve model: water temperature (blue) and pressure difference (green). The lines represent the data generated by simulation, while the dots represent the sampled and noisy version provided to the UKF.

measurements. These signals are sampled every two seconds.

Suppose during the operation, at  $t = 80$  s, the valve becomes faulty. The fault affects the ability of the valve to control its opening position. The valve opening cannot go below 20% (causing a leakage) and over 60% (it gets stuck). At  $t = 250$  s, the valve stuck position moves from 60% to 90%.

The fault identification procedure is asked to identify whether the valve not works as expected, that is its opening position follows the command signal. The fault identification is performed using the UKF that uses as input signals for its model the noisy pressure difference (see Figure 4), the noisy water temperature (see Figure 4) and the command signal (see Figure 6). The command signal is noise free because it is computed by some external controller and not measured. The UKF compares the output of its simulations with the measured mass flow rate (see Figure 5) that is affected by both noise and thermal drift. The effect of the thermal drift is visible in Figure 5 where the green dots represent the measured mass flow rate while the green line is the actual mass flow rate passing through the valve.

The UKF and the smoother estimate the value of the state variable  $x(t)$  representing the valve opening position and the parameter  $\lambda$ , the thermal drift coefficient. The length of the augmented state is  $n = 2$ . Hence for every estimation step, the UKF performs  $1 + 2 \times 2 = 5$  simulations. The UKF has the initial conditions  $x(0) \sim N(0.8, 0.05)$  and  $\lambda \sim N(0, 0.7 \cdot 10^{-3})$ , the output noise

Figure 5: The green line represent the mass flow rate that is passing through the valve. The green dots are the measurements of the mass flow rate (affected by noise and sensor thermal drift) used by the UKF. The red line is the UKF estimation, while the blue line is the smoother estimation.

covariance matrix is  $R = [0.05]$ , and the filter coefficients are  $\alpha = \frac{1}{\sqrt{3}}$ ,  $\beta = 2$  and  $k = 3 - n = 1$ .

As shown in Figure 5, the measured mass flow rate (green dots) are far from the real mass flow rate (green line). Despite the measurement error, the UKF and the smoother provide an estimation with a good accuracy (red and blue lines in Figure 5). The mass flow rates computed by the UKF,  $\hat{m}$ , and the smoother,  $\hat{m}^S$ , are close to the real one,  $\dot{m}$ , because they are able to estimate both the valve opening position and the sensor drift coefficient, as shown in Figures 6 and 7. As expected the smoother is able to provide a better estimation since it uses more data. The time spent by the UKF to perform the simulations and computing the estimations was about 0.05 s, that is lower than the sampling time of 2 s. The speed of this UKF based FDD algorithm allows a real-time implementation for this particular application.

## 4 General Applicability

The UKF and in general state/parameter estimation techniques are well known solutions used in many fields. We presented an approach that reduces the effort needed to set up a state and parameter estimation for models created with simulation programs that are FMI compliant. The example shows how this tool can be used for FDD purposes in the context of HVAC systems. However, this tool can be used in other con-

Figure 6: The green line is the opening valve signal. The blue line is the actual opening value affected by faults. The red and blue lines are the UKF and smoother estimations of the valve opening position (the area surrounding the estimation is the  $\sigma$ -confidence interval).

texts. For example, state and parameter estimation techniques are used to support guidance and control systems in the automotive, robotic and aerospace industries.

## 5 Conclusion

We proposed a model-based state and parameter estimator for dynamic systems described using the FMI standard. The paper explained the nonlinear state estimation and smoothing techniques employed by the algorithm, together with the details necessary to implement it. The last section shows how the FMU-based state and parameter estimator can be used to set up a fault detection algorithm capable of identifying faults in a valve, even in presence of wrong and noisy measurements.

This algorithm extends the functionalities of any simulation program that implements the FMI standard version 1.0. As shown in the example, this algorithm has a direct application in FDD, but it can also be used for model calibration and process control together with adaptive or model predictive control schemes. The main advantage of this algorithm is that it allows to reuse models from the design phase, it extends the capabilities of FMI compliant modeling frameworks and it reduces the time and investments necessary to develop advanced control strategies, calibration and FDD.

Figure 7: The green line is the sensor thermal drift coefficient, while the red and blue lines are the estimations of the thermal drift coefficient computed by the UKF and smoother (the area surrounding the estimation is the  $\sigma$ -confidence interval).

## Abstract

As automatic sensing and Information and Communication Technology (ICT) get cheaper, building monitoring data is easier to obtain. The abundance of data leads to new opportunities in the context of energy efficiency in buildings. This paper describes ongoing developments and first results of data-driven grey-box modelling for buildings. A Python toolbox is developed based on a Modelica library with thermal building and Heating, Ventilation and Air-Conditioning (HVAC) models and the optimisation framework in JModelica.org. The tool chain facilitates and automates the different steps in the system identification procedure, like data handling, model selection, parameter estimation and validation. The results of a system identification and parameter estimation for a single-family dwelling are presented.

*Keywords: buildings, grey-box models, parameter estimation, collocation method*

## 1 Introduction

The continuous progress in ICT has led to the availability of small and low-cost sensors, low power wireless data transfer protocols, cheap and accessible data storage and powerful servers. Applied to the building sector, these technologies can be used to collect massive amounts of building monitoring data at relatively low costs. The abundance of data gives rise to new opportunities and applications in existing buildings like fault detection, energy efficiency analysis and model-based building operation. A first step in many of these applications is the creation of a building energy model.

Building models can be classified in three categories: white-box, grey-box and black-box models [1–3]. White-box modelling bases the model solely on

prior physical knowledge of the building. Most building simulation software falls under this category, like TRNSYS, EnergyPlus and many others [4]. Black-box modelling bases the model solely on response data (monitoring of the building) and a universal model set, including e.g. AR and ARMAX. No physical insight is required for making a black-box model. Grey-box identification methods and tools cater for the situation where prior knowledge of the object is not comprehensive enough for satisfactory white-box modelling and, in addition, purely empirical black-box methods do not suffice because the involved physical processes are too complex.

The difference between white- and grey-box modelling is not in the complexity of the model. A single-state model can be a white-box model if all parameters can be fixed based on physical knowledge only. However, when one or more parameters in a white-box model are estimated based on a fitting of the model to measurement data, the model becomes grey, no matter its complexity. Therefore, the distinction between white and grey cannot be made by only looking at the model structure; one has to know how the model parameters have been identified.

All three model types can be either deterministic or stochastic. A deterministic model cannot explain the differences between the model output and the true variations of the states (observations). Madsen and Holst [2] therefore introduced a Wiener process in the system equations to cope with the simplifications of the model and uncertainties in inputs and monitoring. The obtained model is a stochastic state-space model.

For existing buildings with available monitoring data, the grey-box approach is considered to combine the best of two worlds: physical insight and model structure from the white-box paradigm and parameter estimation and statistical framework from the black-box paradigm. This paper describes an approach to

grey-box modelling for buildings and the development of a toolbox combining Modelica and Python. The resulting framework will be referred to as *the toolbox* in the remainder of this paper.

The aim of the toolbox is to identify low-order models from (limited) building monitoring datasets. When the dataset is generated by a detailed building simulation model instead of an existing building, we speak of model order reduction. The obtained models can be used in order to set up Model Predictive Control (MPC) or to scale up simulations from single buildings to neighbourhoods and districts.

This paper describes the methodology of the toolbox and presents some results of the application to a model order reduction of a single-family dwelling.

## 2 Methodology

### 2.1 Overview

A high-level overview of the toolbox is shown in Figure 1. The toolbox is composed of four major components:

1. Modelica library *FastBuildings* with thermal zone models, HVAC components and building models;
2. different *.mop files* specifying the model components and which parameters to estimate;
3. *JModelica.org* as a middle layer for compilation of the *.mop files* as well as formulation and solution of the optimisation problem;
4. Python module *greybox.py* delivering the user interface and top-level functionality.

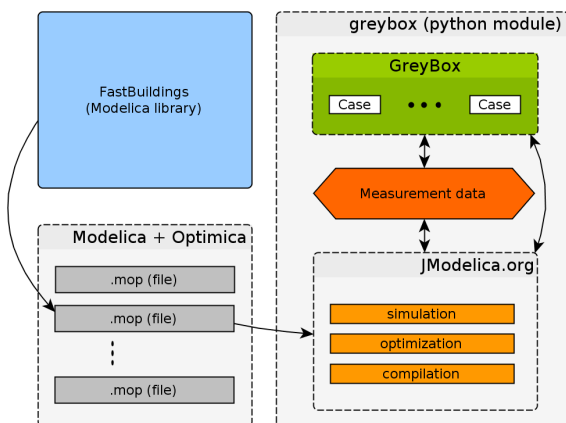

Figure 1: Overview of the grey-box buildings toolbox

### 2.2 Modelica

Modelica is gaining importance in the building simulation community [5, 6]. The choice of Modelica for the construction of the models is based on two major arguments. First, Modelica allows for linear, non-linear and hybrid model formulations and therefore it does not limit the model structure as such. Second, Modelica is equation-based, thus allowing efficient Newton-type solvers to be used as an alternative to for example genetic algorithms. Moreover, as shown in Section 3, the interfaces of the low-order models are identical to the detailed building model used in the *IDEAS* library [7], enabling easy model exchange.

### 2.3 Models

Every model structure for which the parameters have to be estimated is characterized by a different *.mop* file, of which the format is very similar to an ordinary Modelica (*.mo*) file. The *.mop* file extension is specified by JModelica.org, which is described in Section 2.4. Each *.mop* file has the same structure and has to define two models: one model for simulation, called *Sim*, and one for parameter estimation, called *ParEst*. By default, the models are based on the *FastBuildings* Modelica library, which has been developed in conjunction with this toolbox. However, this is not required for the toolbox to work, as long as some naming conventions are followed. The *FastBuildings* library is introduced in Section 3. Any parameter present in the model can be estimated, including initial values of the states.

### 2.4 The JModelica.org platform

The toolbox relies heavily on the JModelica.org [8] platform, which is an open-source tool for modelling, simulation and optimisation of dynamic systems described by Modelica code. For simulation purposes, JModelica.org relies on the Functional Mockup Interface [9]. For optimisation purposes, JModelica.org offers various algorithms and also supports the Modelica language extension *Optimica*. *Optimica* allows for high-level formulation of dynamic optimisation problems of the type presented in Section 2.5. The file format *.mop* is used for *Optimica* code.

The optimization algorithm used by the toolbox to estimate the parameters is collocation-based and is presented in Section 2.6 and described in more detail in [10], where in particular optimal control is also treated. IPOPT [11], built with the MA27 solver of HSL [12], is used to solve the non-linear program (NLP) that arises from the collocation method.

Since IPOPT uses a gradient-based method, first- and second-order derivatives of all the expressions in the NLP with respect to all of the decision variables are needed. To this end, CasADi [13] is used to construct the NLP and then to compute the needed derivatives by algorithmic differentiation.

## 2.5 Problem formulation

Identification of the unknown model parameters is formulated as a dynamic optimization problem of the general form

$$\text{minimize} \quad \int_{t_0}^{t_f} e(t)^T \cdot Q \cdot e(t) dt, \quad (1a)$$

$$\text{with respect to} \quad \dot{x}, x, w, u, p,$$

$$\text{subject to} \quad F(t, \dot{x}(t), x(t), w(t), u(t), p) = 0, \quad (1b)$$

$$x(t_0) = x_0, \quad (1c)$$

$$\forall t \in [t_0, t_f].$$

The system dynamics are modelled by a single, possibly implicit, non-linear and time-variant, differential-algebraic equation (DAE) system of at most index one. That is, an equation system of the form (1b), where  $t$  is the time,  $x$  is the state,  $w$  is the vector-valued algebraic variable,  $u$  is the vector-valued system input, which includes both control variables and known disturbances, and  $p$  is the vector of parameters to be estimated. Since a gradient-based method will be applied to solve the dynamic optimization problem,  $F$  needs to be twice continuously differentiable with respect to all of its arguments except the first one (time). This disables the use of hybrid models. Initial conditions are given by specifying the initial state, that is, on the form of (1c), where  $t_0$  is the start time. The initial state is usually unknown, in which case some, or all, elements of  $x_0$  can also be introduced as elements of the vector  $p$ .

The objective (1a) of the optimisation is to minimise the integrated quadratic deviation  $e$  of the model output from the corresponding measurement data. The model output  $y$  is typically some of the states, but could also be some of the algebraic variables (and also inputs, as discussed below). The matrix  $Q$ , which typically is diagonal, is used to weight the different outputs. The measurement data is assumed to be a function of time, denoted by  $y_m$ . Since measurements are typically discrete in time, they are simply interpolated linearly to form  $y_m$ . The output deviation  $e$  is then given by

$$e(t) := y(t) - y_m(t). \quad (2)$$

The inputs can be treated in two different ways. The first is to assume that the inputs are known exactly by their measurement data and eliminate them from the problem. The second way is to have an error-in-variables approach where the inputs are kept as decision variables and treat them as model output, that is, include them in the vector  $y$  and penalize their deviation from the corresponding measurement data. The second way is useful for coping with uncertainties in the measurement data.

## 2.6 Solution algorithm

The approach taken to solve (1) is based on low-order direct collocation, see [14]. The idea is to divide the time horizon into a number of elements,  $n_e$ , and approximate the time-variant system variables  $\dot{x}, x, w$  and  $u$  by a polynomial of time within each element, called a collocation polynomial. These polynomials are determined by enforcing the dynamic constraints at a certain number of points,  $n_c$ , within each element. These points are called collocation points and  $t_{i,k}$  is used to denote collocation point number  $k \in [1..n_c]$ , where  $[1..n_c]$  denotes the integer interval between 1 and  $n_c$ , in element number  $i \in [1..n_e]$ . The system variables' values at these points, denoted by

$$(\dot{x}_{i,k}, x_{i,k}, w_{i,k}, u_{i,k}, e_{i,k}) :=$$

$$(\dot{x}(t_{i,k}), x(t_{i,k}), w(t_{i,k}), u(t_{i,k}), e(t_{i,k})),$$

are then interpolated based on Lagrange interpolation polynomials to form the collocation polynomials. There are different schemes for choosing the placement of collocation points with different numerical properties. In this paper we only consider Radau collocation. All collocation methods correspond to special cases of implicit Runge-Kutta methods and thus inherit desirable stability properties making them suitable for stiff systems.

This approximation reduces the Problem (1), which is of infinite dimension, into a finite-dimensional non-

linear program of the form

$$\min. \sum_{i=1}^{n_e} \left( h_i \cdot \sum_{k=1}^{n_c} \omega_k \cdot e_{i,k}^T \cdot Q \cdot e_{i,k} \right), \quad (3a)$$

$$\text{w.r.t. } \dot{x}_{i,k}, x_{i,l}, w_{i,k}, u_{i,k}, p,$$

$$\text{s.t. } F(t_{i,k}, \dot{x}_{i,k}, x_{i,k}, w_{i,k}, u_{i,k}, p) = 0, \quad (3b)$$

$$x_{1,0} = x_0, \quad (3c)$$

$$x_{n,n_c} = x_{n+1,0}, \quad \forall n \in [1..n_e - 1], \quad (3d)$$

$$\dot{x}_{i,k} = \frac{1}{h_i} \sum_{l=0}^{n_c} \alpha_{l,k} \cdot x_{i,l}, \quad (3e)$$

$$\forall (i, k, l) \in ([1..n_e] \times [1..n_c] \times [0..n_c]).$$

The NLP objective (3a) is an approximation of the original objective (1a) based on a Gaussian-like quadrature formula, where the measurement error  $e_{i,k}$  in each collocation point is summed and weighted by the corresponding element length  $h_i$ , which is fixed a priori, and the quadrature weight  $\omega_k$ , which depends on the choice of collocation points. Notice that the decision variables are not only the unknown parameters  $p$ , but also the discretized system variables  $\dot{x}_{i,k}, x_{i,l}, w_{i,k}$  and  $u_{i,k}$ .

Since the states need to be continuous (but not differentiable) with respect to time, the new continuity constraint (3d) needs to be introduced. Because we use Radau collocation, where no collocation point exists at the start of each element, this also requires the introduction of the new variables  $x_{i,0}$ , which represent the value of the state at the start of element  $i$ . With the introduction of  $x_{1,0}$ , the initial condition (1c) is straightforward to transcribe into (3c). The dynamic constraint (1b) is also straightforward to transcribe into (3b), by only enforcing it at the collocation points instead of during the entire time horizon.

Finally, we introduce the constraints (3e) to capture the dependency between  $x$  and  $\dot{x}$ . The state derivative  $\dot{x}_{i,k}$  in a collocation point is approximated by a finite difference of the collocation point values of the state in that element. The finite difference weights  $\alpha_{l,k}$  are related to the butcher tableau of the Runge-Kutta method that corresponds to the collocation method.

All that remains is to solve the NLP (3) in order to obtain an approximate solution to the original Problem (1). This can be done using dedicated NLP software; in our case IPOPT.

## 2.7 Toolbox functionality and workflow

The user interacts with the toolbox through the *greybox.py* Python module. This module defines two classes *GreyBox* and *Case*, as shown in Figure 1.

The idea is to instantiate the *GreyBox* class once for the system identification of a given building. The *GreyBox* object will contain many different instances of the *Case* class. Every *Case* is an attempt (successful or not) to obtain a model for the given building. The *Case* therefore keeps track of the model structure, identification data, initial guess, solver settings and results of a single attempt. The functionality of the toolbox is packed in methods of the *GreyBox* class and can be grouped into different domains, according to the foreseen workflow. This is shown in Figure 2. This workflow is discussed in the following paragraphs.

Figure 2: Workflow and high-level functionality in *greybox.py*

The methods under **data handling** are used to load the data files, resample the data if desired, create data slices of given lengths (for example one week, but can be any period) and show a plot of any data slice. Typically, one data slice is the training set, and the other slices can be used for cross-validation.

When the data has been pre-processed, a model structure has to be specified in the **model selection** step. This is accomplished by specifying the path to a *.mop* file. There are two models in the *.mop* file: a Modelica model for simulation, called *Sim*, and a Modelica + Optimica model for parameter estimation, called *ParEst*. The main difference is that in the model *ParEst*, the value of the Optimica attribute `free` is set to `true` for each parameter to be estimated. The compilation of both models happens automatically by invoking the corresponding *JModelica.org* functionality. This includes extracting information from the model (state vector, parameter vector and required inputs) and getting solver options.

Before the parameter estimation can be started, an **initial guess** has to be specified for each element in the parameter vector. These can be obtained by default, by inheritance, by Latin hypercube sampling or manually.

When the default initial guesses are used, an appropriate value is chosen for each parameter, based on its

name. For example, the naming convention in *FastBuildings* forces all parameter names for thermal resistances to start with 'r' (like `rWa1`), for thermal capacities with 'c' (like `cZon`), for fractions with 'fra' (like `fraRad`), etc. Based on the first letter(s) of a parameter to be estimated, a default initial value can be set.

An alternative for obtaining the initial guess is to start from the optimized parameter vector from a previous case. This is especially useful when a new *.mop* file is selected that has similarities with a previously processed *.mop* file. Due to the naming conventions in *FastBuildings*, the corresponding parameters will have the same name. Therefore, the best initial guess for the parameters in the new model will be the optimal value from the previous estimation. For new parameters, the default initial guess method described above is used.

The last automated option to obtain initial guesses is based on Latin hypercube sampling. Due to the non-convexity of the problem, there can potentially exist many local minima. To investigate the parameter search space more systematically and increase the chances of finding a global minimum, a Latin hypercube sampling method has been implemented. This method will take a single initial guess as well as lower and upper bounds for each parameter and derive a univariate beta distribution from these three values. The distribution can be symmetric or asymmetric, as shown in Figure 3.

Figure 3: Symmetric and asymmetric beta distributions

The Latin hypercube sampling will then derive  $n$  stratified samples from each distribution and combine them randomly to obtain  $n$  different initial guesses. Each of these guesses will be copied to a new case to keep track of the results.

When a case has an initial guess for the parame-

ter vector, the **parameter estimation** can be started. However, the NLP described in Equation (3) requires good initial guesses for each of the decision variables in the collocation problem (including all collocated states and algebraic variables). This is handled by doing a simulation first with the `Sim` model and the initial guess of the parameter vector. The resulting simulation trajectories are used as initial guesses for the decision variables in Problem (3). Numerical scaling factors for each system variable are also computed as the infinity norm of the corresponding trajectory.

The solution time and the number of iterations can vary a lot depending on the initial guess and the ability of the model to represent the measurement data. IPOPT allows the specification of a maximum solution time and/or a maximum number of iterations after which it will interrupt the optimisation. Both can be set in the toolbox, but in practice, specifying a maximum solution time is more intuitive. It is also more effective when the iterations become very slow. Moreover, experience shows that long execution times often lead to solutions far away from the global optimum or even divergence.

The estimation will add the optimized parameter vector to the case, as well as the IPOPT solver statistics.

The **validation** of the results is always based on a post-simulation with the `Sim` model and the optimized values of the parameter vector. There are both visual and quantitative validation methods. The visual methods contain for example time series plots of the resulting trajectories and corresponding residuals, scatter plots of the residuals with monitoring data and a plot of the autocorrelation function of the residuals. This also implies a check on the weights of the matrix  $Q$  from (1a) in case the error-in-variables method is used. When a full Latin hypercube sample has been estimated, a visual check of the different local optima is implemented. This can whether the sample was large enough to suppose the global optimum to be found. The quantitative methods are based on a computation of the root-mean-square error (RMSE) for each trajectory in the vector  $e$  from Equation (2). This can be done on the training data (auto-validation) or on any other dataset (cross-validation). As the RMSE is computed based on the post-simulation, possible discretisation errors in the collocation method are disregarded in the model validation process.

A computation of the confidence interval for each of the estimated parameters is implemented. This will give an indication of the accuracy of the estimation and

the parameter's influence on the model's input-output behaviour. The standard deviation of the estimated parameters  $\hat{p}$  is computed according to Englezos and Kalogerakis [15]. The standard deviation for parameter  $i$  is the square root of the diagonal element on  $(i, i)$  in the covariance matrix  $\text{cov}(\hat{p})$  of the estimated parameters, which is given by

$$\text{cov}(p^*) = \hat{\sigma}^2 (J^T J)^{-1},$$

where  $J$  is the Jacobian of the trajectories with respect to the estimated parameters and  $\hat{\sigma}^2$  is the estimated variance of the output deviation  $e$ .

The final step in the system identification is **model selection**. Model selection should be carried out on two levels: for a single model, and between different models. For a single model, generally a Latin hypercube sampling is executed and the resulting global optimum is taken if it is a valid solution. Valid means that:

- the parameters do not lie on the specified minimum or maximum bounds,
- the parameter values are physically reasonable,
- the confidence intervals are within reasonable bounds.

The normal procedure for an inter-model selection procedure starts by a parameter estimation on a very simple (first-order) model. The obtained parameter values are often a good indication of the order of magnitude of the parameters for the more detailed models later on. Then, different models of higher order and complexity are estimated, and only those for which the single model validation is satisfactory are retained. Among all the retained models, the best model is the one that leads to the lowest RMSE value for cross-validation. This approach avoids overfitting of the model, as will be demonstrated in Section 4. A more focused forward selection procedure as described by Bacher and Madsen [16] can also be applied.

### 3 FastBuildings library

The *FastBuildings* library targets low-order building modelling. The library has sub-packages for thermal zone models (including windows), HVAC, user behaviour, inputs, buildings and examples. Single and multi-zone building models can be created easily by instantiating one of the predefined templates in the *Building* sub-package and redeclaring the desired

submodels, like the thermal zone, HVAC or window model. The following design principles are applied throughout the library.

- The thermal connectors are `HeatPorts` from the `Modelica.Thermal` package.
- Thermal resistors and capacitances are not used from the *Modelica Standard Library* (MSL). Simplified versions with less auxiliary variables are implemented. They have exactly the same interface and connectors for compatibility with the MSL.
- A strict naming convention is used for consistency and to enable the *greybox.py* toolbox to automate certain tasks.
- The library heavily relies on the `extends` construct in order to avoid code duplication. This is specifically useful for the thermal zone models that have increasing complexity as a function of their order.
- An inner/outer component `simFasBui` passes all inputs like weather data, occupancy etc. from the top most level to all sublevels.
- The models for thermal zones, HVAC and user behaviour have exactly the same interface as their equivalents in the *IDEAS* library [7]. Therefore, it is very easy to replace one or more detailed models from an *IDEAS*-based model by a low-order equivalent from the *FastBuildings* library.

Currently, the thermal zone models available in the library are based on a resistor-capacitance (RC) network analogy which is often used for the modelling of thermal processes. This is however not required; any model that specifies a relationship between the heat flows and temperatures at the interface of a thermal zone can be implemented. An example of one of the third-order models in the library is given in Figure 4.

The library is distributed with the *Modelica license 2* and can be found in the *open-IDEAS* source code repository on Github [17].

### 4 Results

The toolbox is applied on a case study for model order reduction on a single family dwelling. A low-order model is derived from the simulated trajectories that are obtained with a detailed model. Prior knowledge about the dwelling is not taken into account in the

Figure 4: Example of a third-order thermal zone model in the FastBuildings library

model selection or parameter estimation, but is given here. The dwelling has two construction layers with a total heated floor surface of  $196 \text{ m}^2$ . The dwelling is designed according to a low-energy standard and has massive walls and floor heating. A total of  $33 \text{ m}^2$  of windows with a  $g$ -value of 0.6 is integrated as follows:  $9.5 \text{ m}^2$  on east,  $10.4 \text{ m}^2$  on south and  $11.6 \text{ m}^2$  on west.

Figure 5 shows the training and validation datasets. Both sets consist of one week of hourly data. Although the 'measurement' data comes from a (detailed) simulation, only a few variables that could easily be measured in a real dwelling are used for this case study. These include: the ambient temperature  $T_{Amb}$ , global solar radiation on a horizontal surface  $IGloHor$ , electricity consumption  $powEle$ , thermal power of the heating system  $qHeaCoo$ , and zone temperature  $TZon$ . Hereafter the detailed simulation data is called measurement data. All of the inputs are eliminated from the problem, as discussed in Section 2.5, except for  $TZon$  which is the fitting variable.

Nine models with different order, equations, and parameters have been identified using Latin hypercube sampling. After validation on single-model level, three models have been eliminated because some of their parameters were positioned on a specified minimum or maximum boundary. The RMSE values for auto

and cross-validation of the six remaining models are shown in Figure 6. This figure shows that a lower RMSE on auto-validation does not necessarily imply a lower RMSE on cross-validation. The best model is the one with the lowest RMSE on cross-validation. For this case it is the model with 11 parameters, we'll call it  $model_{11}$ . This is the model for which the structure is shown in Figure 4. The models with 12 and 13 parameters are overfitted.

We will now analyse the results for  $model_{11}$  in more detail. The sample size was 38 and a maximum CPU time of 5.5 seconds was set. The default solver settings were not changed. This implies that the number of collocation elements corresponds to the number of data points ( $n_e = 168$ ), and each collocation element has two collocation points ( $n_c = 2$ ). From the 38 cases, 10 converged to a solution within the limit of 5.5 seconds. Figure 7 shows the RMSE (auto-validation) compared to the IPOPT objective function for each of these 10 solutions. This plot reveals that 4 local optima have been found; the (supposed) global optimum has been found 3 times. The results also show that the discretisation in the collocation method did not lead to significant errors: there is a strong consistency between the optima found according to Equation (3) and the RMSE of the post-simulation.

Figure 5: Measurement data for two weeks (first week as training data, second week as validation data)

Figure 6: RMSE values for auto and cross-validation for the different models as a function of the number of estimated parameters

Figure 7: Relation between the IPOPT objective value and RMSE for auto-validation (obtained by post-simulation)

A time series plot of the cross-validation is shown in Figure 8. It is important to note that this plot shows an open-loop simulation over one week. The prediction power of the model is very good, with absolute deviations of the zone temperature always below 0.5 K.

Figure 8: Comparison of the model output with the measurement data for an open loop simulation on the validation dataset

The normalized confidence intervals are shown in Figure 9. All parameters seem to have well defined confidence intervals. The most unconfident parameter values are found for the thermal resistance of the infiltration (resInf in Figure 4) and for the thermal capacity of the zone air (capZon in Figure 4).

Figure 9: Normalized confidence interval for the parameters in the selected model

## 5 Conclusion

Inverse modelling is gaining attention in the building simulation community. More specifically grey-box modelling is considered as a strong framework for the creation of low-order models for analysis and control of monitored buildings. This paper presents an approach to obtain useful grey-box models in a largely automated way.

The first step is the creation of a building library with many potential model candidates. The Modelica package *FastBuildings* contains low-order models for thermal zones, HVAC, users, single and multi-zone buildings.

Next, a toolbox is presented that largely automates the parameter estimation of the *FastBuildings* models. It is implemented as a Python module that wraps the functionality of *JModelica.org* and presents the user a high-level interface for all common operations. The use of a gradient-based method allows an efficient numerical solution of the estimation problems. Specific attention is paid to robustness and ease-of-use. A Latin hypercube sampling of the parameter search space overcomes issues related to the non-convexity of the optimization problem.

The toolbox is applied to a model order reduction case study for a single-family dwelling. Only variables that can easily be measured in a real building are used. The selected model has 11 parameters and is able to predict the indoor temperature in an open-loop simulation (with a priori knowledge about weather and electricity consumption) with an RMSE of 0.16 K.

The real value of the toolbox can only be assessed by using the obtained models for model predictive control or for large-scale district simulations. Both applications are foreseen in future work.

## Acknowledgement

Roel De Coninck wishes to acknowledge the EU ITEA2 project *Enerficiency* for supporting his work on behalf of 3E and the EU FP7 project *PerformancePlus* (contract nb. 308991) for supporting his work on behalf of KU Leuven. Fredrik Magnusson and Johan Åkesson gratefully acknowledge support from the Lund Center for Control of Complex Engineering Systems (LCCC) and the ELLIIT Excellence Center at Lund University.

## Abstract

So far, when modelling processes that demand for multi-phase and multi-component fluid property data, the user has to implement the required media models in the Modelica language as these types of fluids are not supported by Modelica.Media. This paper presents a first approach on how to implement fluid property data in process models of an existing library from external sources and highlights which problems have to be overcome. Furthermore, it provides recommendations for the design of an efficient and user-friendly interface to external media packages.

*Keywords: thermal separation; two-phase; multi-component mixture; external fluid property data; transient simulation*

## 1 Introduction and motivation

Using existing model libraries for the modelling of complex chemical processes is especially challenging because it can be hard to comprehend the structure of the models. Nevertheless, when using these models one might want to implement different media models from what is already available. One convenient way is accessing external property packages instead of developing and implementing required fluid property models in the Modelica language. In this context it might be necessary to provide, next to the primary thermodynamic property data, also property derivatives.

The main objective is to develop an interface between existing Modelica libraries such as the `ThermalSeparation` library and fluid property packages, which successfully deal with situations where

the total time derivative of fluid properties is required. This can be the case for several reasons:

- The formulation of the model equations results in a higher index problem.
- The system states do not equal the variables in the derivative operator.
- There are more variables in the derivative operator than there are differential equations.

The simulation tool handles all three situations the same way which is by applying Pantelides' algorithm and deriving the necessary equations in this process [1]. In contrast to the first bullet point, the last bullet points do not necessarily result in a high index problem. But in both cases additional equations have to be derived by time (which can include fluid property relations) to solve the whole set of equations. In the following this technique is referred to as automated index reduction, regardless of the origin of the problem.

In comparison to developing models from scratch where it is possible to maintain an index-1 form of the system, reducing the index of existing models is in general not feasible. Further information on the differential index and index reduction is provided by Fritzson [2].

An earlier attempt to couple the `ThermalSeparation` library to an external property package still lacked a proper interface [3]. Later on a coupling to external fluid properties was successful although the balance equations had to be modified for this purpose because no derivatives were available and the automated index reduction failed [4].

Some general advantages and reasons for the need to interface external thermodynamic property data

<sup>\*</sup>kai.wellner@tuhh.de, schmitz@tuhh.de

with Modelica models are summarized in the following:

- The Modelica language is increasingly used for process modelling in the field of chemical engineering which entails the modelling of multi-phase, multi-component media. Currently, this type of fluids are not supported by Modelica.Media. In case the user needs such media models, an implementation from scratch is required. This also involves coding of flash calculations in order to determine the equilibrium composition for example for a given  $p$ ,  $T$ ,  $x_{total}$ . Depending on the complexity of the fluid mixture and the used equation of state (EoS), the implementation can be quite cumbersome, time-consuming and error-prone.
- Using existing property packages provides a higher flexibility in terms of available components and EoS. For a Modelica model library developed for a wide range of different applications it is typically not practical or even possible to implement a large number of media models covering any application case. Therefore, providing a user-friendly interface to external property packages is an important feature.
- Calculating property data in an external environment can significantly increase the simulation speed [5]. However this is not a general feature because in some cases it can have the exact opposite effect and decrease the simulation speed.

## 2 The ThermalSeparation library

In process engineering the purification of a product plays an important role. Usually the intermediate products are not of the desired purity and have to be treated in a downstream process. Such processes often involve thermal separation like absorption in gas-liquid separation columns. As the operation of post-treatments like separation can be highly dynamic, computer simulations are indispensable for a better understanding of the process and its optimization targeting for example energy consumption or control strategy design.

The ThermalSeparation library has been developed for the simulation of absorption and rectification processes. The challenge when interfacing external fluid property data is that in the current implementation the balance equations are written in an way that

forces the simulation tool to apply automated symbolic index reduction. If that happens, implementing fluid property data from external sources demands special requirements. Further information on how the formulation of balance equations can affect the use of external fluid property packages and how these problems can be overcome is given in section 3.

### 2.1 Library Structure

Compared to earlier versions of the ThermalSeparation library [4] a new feature that has been implemented in the framework of this paper is the replaceability of the balance equations which easily allows to switch between different formulations of balance equations.

For this work a modified set of balance equations that does not require automated symbolic index reduction is added to illustrate the differences to the original equations in terms of computational performance. A UML class diagram of the library structure is shown in figure 1.

Vapour and liquid medium models that invoke external fluid property calls are added to the respective classes. Moreover, a film model for the external call of the flash calculations is implemented. The classes that are adapted to use external media data are indicated with a bold frame in the UML diagram.

Figure 1: UML diagram of the column model structure.

## 2.2 Interfacing the property package

The use of external sources for the computation of thermodynamic properties is in this paper exemplary demonstrated with the FluidProp package, which is interfaced via the ModelicaFluidProp library [6, 7]. For calculating the actual properties the "PC-SAFT" (perturbed chain statistical associating fluid theory) EoS is employed due to its success in predicting vapour/gas-liquid equilibria of complex fluids and mixtures for a broad range of conditions and due to fact that it also provides the partial derivatives of specific molar enthalpy and specific molar volume with respect to pressure, temperature and composition. These derivatives are necessary to compute the total time derivative (cf. section 3.2). The derivatives are obtained by separate function calls. To enable the use of the total time derivatives in the models of the ThermalSeparation library, the implemented Modelica property functions are modified such that these derivatives are specified by using the derivative annotation. This way the simulation environment can perform automated symbolic index reduction using the specified total time derivatives of the fluid property functions which enables the modeller to perform simulations with variable system states or of higher order index, which would otherwise fail when using external property packages. An example on how the FluidProp calls are implemented in the ThermalSeparation library media models is illustrated in listing 1. The medium definition is programmed in a separate class and mainly consists of string operators that define the fluid constituents and the medium model (EoS) used for the property calculations.

The implemented property functions require as input a string with the thermodynamic state definition (e.g. "PT" for pressure and temperature), the actual values for these states and the overall molar composition. Partial derivatives are currently available with respect to temperature, pressure and composition.

```

model BaseProperties

      Conc);
end BaseProperties;

```

Listing 2: Flash calculation call.

## 3 Modelling approach

There are two different approaches when using external fluid property data concerning the modelling structure of the Modelica process models.

In the first approach an automated index reduction is avoided by writing (or rewriting in case of existing models) the balance equations in an explicit manner with respect to the state variables. The external property data can easily be integrated in general without the necessity to provide any partial derivatives.

In the second approach, the balance equations are written in the most "natural" way which might foster numerical robustness and simulation speed or ease of initialization in case of new models. In case of existing models the balance equations are maintained as coded.

Typically this leads to an implicit formulation of the balance equations.

Both approaches are explained in the following:

### 3.1 Explicit modelling of balancing equations

For a separation column with rate-based modelling approach the balance equations for one stage can be written as:

$$\frac{dN_{i,j}^L}{dt} = \dot{N}_{in,j+1}^L \cdot x_{in,i,j+1}^L - \dot{N}_{out,j}^L \cdot x_{out,i,j}^L + \dot{N}_{PB,j}^L \quad (1)$$

$$\frac{dN_{i,j}^V}{dt} = \dot{N}_{in,j-1}^V \cdot x_{in,i,j-1}^V - \dot{N}_{out,j}^V \cdot x_{out,i,j}^V + \dot{N}_{PB,j}^V \quad (2)$$

$$\frac{dU_j^L}{dt} = \dot{N}_{in,j+1}^L \cdot h_{in,j+1}^L - \dot{N}_{out,j}^L \cdot h_{out,j}^L + \dot{Q}_{PB,j}^L \quad (3)$$

$$\frac{dU_j^V}{dt} = \dot{N}_{in,j-1}^V \cdot h_{in,j-1}^V - \dot{N}_{out,j}^V \cdot h_{out,j}^V + \dot{Q}_{PB,j}^V \quad (4)$$

Where  $N_{i,j}$  refers to the molar content of component  $i$  on stage  $j$  for the liquid and vapour phase respectively.  $\dot{N}_{in}$  and  $\dot{N}_{out}$  are the molar flow rates into and out of the stage. Furthermore,  $x$  is the molar fraction,  $h$  is the specific molar enthalpy,  $\dot{N}_{PB}$  and  $\dot{Q}_{PB}$  are the mole and energy flow rates across the phase boundary and are calculated using constitutive equations. Figure 2 shows a schematic diagram of such column stage.

Figure 2: Schematic diagram of a column stage.

In order to avoid the differentiation of additional equations and therefore the necessity to provide total time derivatives of the fluid properties, the system states have to be the same as the differentiated variables, in this case  $N_i^L$ ,  $N_i^V$ ,  $U^L$  and  $U^V$ . To further increase simulation speed, the system states should equal the thermodynamic states, which are the inputs to the property calls. In this way, the fluid properties

can be directly computed from the state variables and therefore no iterations are required. For this purpose the left hand sides of the differential equations have to be rewritten as a function of the thermodynamic state variables. A recommendation how this can be implemented is given in section 5.

Now the model is designed work without fluid property derivatives. However, as soon as the user chooses a different state variable as the ones named above, additional derivatives are required again. Hence, these types of models are not flexible because variable states can be an advantage in model flexibility as they provide additional robustness.

### 3.2 Implicit modelling of balance equations

Using existing model libraries with external fluid properties can be somewhat more complicated because the balance equations may not always be modelled in an explicit manner as explained in equations (1)-(4). For example in the ThermalSeparation library the balance equations are formulated like this:

$$\frac{d(V_j^L \cdot c_{i,j}^L)}{dt} = \dot{N}_{in,j+1}^L \cdot x_{in,i,j+1}^L - \dot{N}_{out,j}^L \cdot x_{out,i,j}^L + \dot{N}_{PB,j}^L \quad (5)$$

$$\frac{d(V_j^V \cdot c_{i,j}^V)}{dt} = \dot{N}_{in,j-1}^V \cdot x_{in,i,j-1}^V - \dot{N}_{out,j}^V \cdot x_{out,i,j}^V + \dot{N}_{PB,j}^V \quad (6)$$

$$\frac{d[V_j^L \cdot \sum_{i=1}^n (u_j^L \cdot c_{i,j}^L)]}{dt} = \dot{N}_{in,j+1}^L \cdot h_{in,j+1}^L - \dot{N}_{out,j}^L \cdot h_{out,j}^L + \dot{Q}_{PB,j}^L \quad (7)$$

$$\frac{d[V_j^V \cdot \sum_{i=1}^n (u_j^V \cdot c_{i,j}^V)]}{dt} = \dot{N}_{in,j-1}^V \cdot h_{in,j-1}^V - \dot{N}_{out,j}^V \cdot h_{out,j}^V + \dot{Q}_{PB,j}^V \quad (8)$$

Where  $V$  is the volume,  $c$  is the concentration and  $u$  is the specific internal energy.

Experience has shown that this way of modelling balance equations in the ThermalSeparation library provides the best performance in terms of numerical robustness and robust initialization. Moreover, to provide the full flexibility it is necessary to be able to choose the system states freely. Further information on this is given in Dietl [4].

It is obvious that the number of differentiated variables ( $V_j^L$ ,  $V_j^V$ ,  $c_{i,j}^L$ ,  $c_{i,j}^V$ ,  $u_{i,j}^L$  and  $u_{i,j}^V$ ) is higher than the number of differential equations (5)-(8). This results in a system that can only be solved if the missing

derivatives are provided by deriving additional equations. In the present case this also includes the differentiation of fluid properties, which subsequently causes the compilation to fail as the external property functions cannot be differentiated by the simulation environment. One way to circumvent the compilation failure without changing the governing equations is to provide the total time derivatives for the property data according to equations (9) and (10). Therefore, the partial derivatives of the properties with respect to the system states are required. Equations (9) and (10) are contained in the function that is invoked by the derivative annotation in listing 1. In the column model the specific molar volume  $v$  is used to convert the molar fraction  $x$  to the concentration  $c$ .

$$\frac{dh}{dt} = \left(\frac{dh}{dp}\right)_{T,x_i} \cdot \left(\frac{dp}{dt}\right) + \left(\frac{dh}{dT}\right)_{p,x_i} \cdot \left(\frac{dT}{dt}\right) \quad (9)$$

$$+ \left(\frac{dh}{dx_i}\right)_{p,T} \cdot \left(\frac{dx_i}{dt}\right)$$

$$\frac{dv}{dt} = \left(\frac{dv}{dp}\right)_{T,x_i} \cdot \left(\frac{dp}{dt}\right) + \left(\frac{dv}{dT}\right)_{p,x_i} \cdot \left(\frac{dT}{dt}\right) \quad (10)$$

$$+ \left(\frac{dv}{dx_i}\right)_{p,T} \cdot \left(\frac{dx_i}{dt}\right)$$

In contrast to this a higher index problem in chemical process models can arise for example because of the volume constraint when assuming incompressibility of the fluid or when chemical reactions are modelled in an equilibrium fashion [8].

## 4 Example of use

In the following the implementation of both approaches (use of explicit balance equations and use of implicit balance equations) is demonstrated and compared for the simulation of a rate-based column model employing a fluid mixture of n-propane and n-pentane using external property data. Both approaches of modelling balance equations are successfully implemented, which has been proven by the fact that with both models the same solution has been obtained.

Inside the medium models the specific volume, the specific enthalpy and the specific heat capacity are used from FluidProp for both vapour and liquid phase. The specific internal energy can be directly calculated from the specific enthalpy. Additionally, the equilibrium composition is used in the film model. The property calls are invoked using pressure and temperature

Figure 3: Diagram of the Modelica column model.

as thermodynamic states. The system states of the column model are pressure, temperature and molar composition of liquid and vapour phase.

Figure 4 depicts the comparison in simulation time of both models, implicit and explicit balance equations, for a step change in the feed flow rate at 500 seconds when the system has reached a steady-state after initialization.

Figure 4: Comparison of simulation times.

When comparing both models it can be observed that the simulation time for the implicit model is much higher. This is explained by the fact that the calculation of partial derivatives is computationally very expensive which can be seen in sections with high gradients like initialization or change of boundary conditions. There the simulation of the implicitly modelled system slows down significantly in comparison to the model that does not use external derivatives. Thus it can be concluded that from a performance point of view it is advantageous to model the system in an explicit manner in order to avoid the necessity to com-

pute partial derivatives.

While the calculation of the external fluid properties requires the biggest part of the computational effort (especially when partial derivatives are needed), it also possesses a large room for improvement and thus for the decrease of the overall simulation time.

Aside from the external calculation of the partial derivatives there are other possible sources for the slowdown of the simulation in this specific case. First of all this modelling approach combined with the use of external property data introduces numerical jacobians that have to be calculated in order to obtain the solution of the system. These jacobians can both destabilize and slow down the simulation. Furthermore, implicit modelling of the balancing equations in combination with the use of external derivatives can lead to larger blocks of non-linear system of equations that have to be solved iteratively as tearing cannot be applied in an efficient way. Table 1 shows a comparison for the sizes of non-linear system of equations between explicit and implicit modelling approaches for the example of use.

	Implicit model	Explicit model
(1)	{58, 52, 68, 1, 1, 1, 1}	{58, 50, 54, 1, 1}
(2)	{6, 2, 56, 0, 0, 0, 0}	{8, 2, 6, 0, 0}

Table 1: Sizes of non-linear system of equations before (1) and after manipulation (2).

The presented simulations are using rate-based column models from the `ThermalSeparation` library, which means that in terms of external property computations one call is required for each phase and one additional call for the film model in order to determine the thermodynamic equilibrium. If the partial derivatives are needed they are invoked via the derivative annotation additionally for each property call. Having three property calls per column stage is obviously computationally expensive, especially when derivatives are calculated, in comparison to e.g. an equilibrium stage model where only one property call per column stage would be sufficient.

## 5 Recommendations for improvement of the interface and balance equation modelling

The current interface does not provide the possibility to choose between function calls with or without the

output of the total time derivatives via the derivative annotation. If they are needed, they have to be calculated from partial derivatives which have to be invoked with a separate function call. For a future interface it should be possible to opt between functions that provide derivatives and such that do not. In principle it would be sufficient to have one function and the derivatives in the annotation are only calculated when needed. In practice however this does not work because for complex models (like in the example of use) the derivatives are also computed when they are not needed. So on the one hand calculating the derivatives all the time consumes too much CPU time if it is not required but on the other hand sometimes the derivatives are absolutely necessary.

Furthermore it would be convenient if the user can specify the needed derivatives to be able to adapt them to the system states of the model that the derivatives are used in (e.g. the column model). Listing 3 shows a suggestion how such an interface can look like for both options, with and without output of derivatives. The design is inspired by the current implementation and expanded with a `NumericalState` record in case the derivatives are required. The derivatives in the `prop_der.dh[:]` array are arranged in the same order as the numerical states inside the `NumericalState` record. Although these recommendations are related to the current interface of the `ModelicaFluidProp` library they can be taken as general recommendations for the design of future interfaces.

```
(prop) = Medium.AllProps(
    ThermodynamicState,
    Value1,
    Value2,
    Conc);
h=prop.h;

(prop_der) = Medium.AllPropsDer(
    ThermodynamicState,
    Value1,
    Value2,
    Conc,
    NumericalState);
h=prop_der.h;
dhdp=prop_der.dh[1];
dhdT=prop_der.dh[2];
dhdx[1]=prop_der.dh[3];
dhdx[2]=prop_der.dh[4];
```

Listing 3: Design recommendation for fluid property interface

In addition, the general way of modelling balance equations for processes involving multi-phase and multi-component fluids should be reconsidered. The

modelling of balance equations with mass, internal energy and mass fractions originates from the modelling of energy systems. This approach might not be optimal for problems in the field of chemical engineering. For chemical processes the balance equations should rather be set up with volume related properties like for example density or the molar specific volume as explained in Pantelides [8]. For an equilibrium stage model the left hand side of the mole balance can be rewritten according to equation (11).

$$\frac{dN_i}{dt} = V \cdot \frac{d(v \cdot x_i)}{dt} \quad (11)$$

The advantage of this structure is that fluid property calls can directly be invoked with the system states "u, $\rho$ " or "u,v" (depending on whether the model is on mass or molar basis) and still an automated index reduction due to the need of additional derivatives is avoided.

## 6 Summary and conclusions

This paper demonstrates and compares two approaches on the use of external property packages for the computation of fluid data interfaced to Modelica process models. With the exemplary column model using an explicit formulation of the balance equations the use of partial derivatives is avoided. This model is in terms of computational speed favourable in comparison to the model with an implicit formulation of the balance equations. However, especially when utilizing existing model libraries rewriting balance equations is not convenient or feasible. The paper shows that in this case the external property package has to provide partial derivatives of the fluid properties with respect to the system states. This enables the simulation environment to perform automated symbolic index reduction and maintains the flexibility of choosing the state variables freely.

## Abstract

In this article a real-time model for dynamic simulation of a fuel processor is presented. The model is intended for HIL testing of the PLC for a truck Auxiliary Power Unit (APU) system.

The APU comprises a PEM fuel cell and fuel processor to enable direct utilization of on-board diesel. The system is under development in FCGEN, an EU project under the FP7 program FCH JU [1]. One critical challenge is to design the control system (PLC) to ensure failsafe and environmental friendly startup and operation. The startup phase of the fuel processor is the most critical part, since it is a highly dynamic process involving several complex reactors. It is advantageous to verify the control system before the fuel processor is assembled to avoid possible breakage of components. Such verification can be done with a real-time model representing the physical system. In this study such a model is created using Modelica and Dymola. It is shown that it is possible to load and execute a real-time Modelica model capable of realistically mimicking the system response on a HIL platform. The model runs in real time using a first order explicit (Euler) solver with a time step size of 25 ms.

## 1 Introduction

Fuel cell systems are an attractive technology for Auxiliary Power Units for e.g. trucks, because of the high efficiency and low emissions. However, PEM fuel cells operate most efficiently with hydrogen, while at gas stations usually only liquid fuels like diesel and gasoline are available. To circumvent this problem a fuel processor may be used to convert the high order hydrocarbons to a hydrogen rich gas mixture. The aim of the FCGEN [1] program is to design and demonstrate such an APU.

The fuel processor is a complicated system of reactors, heat exchangers and BoP components. System startup needs to be carefully designed to avoid poisoning of reactors and system failure and ensure as short startup time as possible. The control system must be designed to give a smooth and secure startup. Verification and adjustment of the control system is normally performed against the real system. However since the system is complex, such testing may become very expensive and time consuming. Hence it is advantageous to test the system against a model in a HIL (Hardware-In-the-Loop) setup before assembling the full system. In this work such a model is developed and tested.

An example of a previous related work is a physical model made in Modelica of a food processor line tested in a HIL set up in 2008 [2].

## 2 Fuel processor

The fuel processor module (FPM) is based on an Auto-Thermal Reformer (ATR) which converts diesel to syngas through steam reformation. Required heat for the endothermic reformation reaction is supplied by oxidation with a limited amount of air.

A desulphurizer (DS) is added downstream of the ATR to remove sulphur to protect downstream catalysts and the fuel cell.

The PEM fuel cell tolerates only very low CO concentrations (ppm levels). To remove CO from the syngas to the fuel cell, a water-gas shift (WGS) reactor and a preferential oxidizer (PrOx) are added downstream of the DS. To avoid poisoning of the fuel cell during the startup phase, a bypass route is used. A catalytic afterburner (CAB) is used to clean the exhaust gases before release to the atmosphere. In the early start phase a start system is in operation burning diesel in a catalytic start burner (CSB) to pre-heat the FPM. The system scheme is shown in Fig. 1 below.

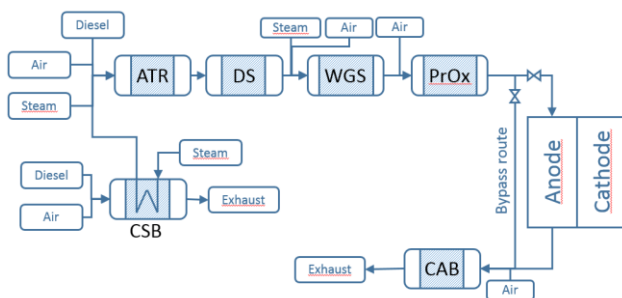

Figure 1: Fuel processor system scheme

The fuel processing module (FPM) is developed by the following partners of FCGEN:

- Volvo Group Trucks Technology, Sweden – coordinator
- PowerCell Sweden AB - plant components, system specification, integration and testing
- Forschungszentrum Jülich GmbH, Germany - ATR and CAB reactors
- Institut für Mikrotechnik Mainz GmbH, Germany - DS, WGS and PrOx reactors
- Johnson Matthey PLC, UK – catalysts for reactors
- Jozef Stefan Institute, Slovenia - control system
- Modelon AB, Sweden – dynamic system model

### 2.1 Startup strategy

The main steps of the startup strategy are;

1. Use the start burner to heat the ATR and downstream reactors to sufficient temperature.
2. Use the start burner to produce steam for the ATR.
3. Ignite the ATR, keep start burner in operation to ensure sufficient fuel and emission conversion.
4. Shut down start burner, start normal operation.
5. Stop by-pass of fuel cell.

## 3 Requirements on HIL model

The aim of this work is to create a model that can be used to test the PLC logic. The simplifications needed to meet the real-time requirement sets a limit on model accuracy. Hence the model will not be suitable nor be used for calibration of PLC logic parameters. The requirements of the HIL simulation model are defined as:

1. The model should be robust and never crash.
2. The PLC requires real-time communication with the plant model. Consequently, no solver step may require a CPU time longer than real time (so called overrun).
3. The model should respond realistically to changes in input signals. For example ATR temperature should respond in the right direction when changing air-fuel ratio or steam mass flow.
4. Trends need to be captured for temperatures and mass flows. Exact numbers are not necessary.
5. Response times are allowed to deviate slightly from reality. In general model response times are longer than real response times, because of the constraint on minimum time constants.

To meet requirement no 2 the model must be fairly simple, and an explicit solver such as the first order Euler method need to be applied. Fast dynamic time scales need to be removed by changing dynamic equations to static. Events need to be eliminated to avoid solver reinitialisation and subsequent overruns. At the same time the model needs to respond realistically to signal changes, as defined in requirement no 3. However, because of the simplicity of the model it cannot be expected to correctly predict absolute temperatures

or times of the system. This accuracy is not needed for the PLC tests.

## 4 Model description

The Modelica model is based on the Fuel Cell Library from Modelon [3]. This newly released product contains a number of component models and examples aimed at PEMFC and other fuel cell applications including fuel processing reactors. The library depends on Modelon Base Library for base classes common to several Modelon libraries. Early work and cornerstone of FCL was carried out by Andersson and Åberg [4]. Dymola features such as drag and drop functionality, graphical user interface, equations in text layer and numerical solvers facilitate development of a dynamic fuel cell model.

The full system includes more than 25 components, including compressors, heat exchangers, valves, reactors and pumps. All relevant components of the fuel processor have been included in the model. The real-time model comprises 217 continuous time states and is of index 1.

Two-phase water medium has been used where necessary. For model robustness pure steam medium was applied wherever possible. Multi-component gas phase media was used for reformat gas and air.

To enable HIL simulations and meet real-time requirement, all extended component models (submodels) need to be simple.

The Dymola model is initially developed for the DASSL implicit ODE solver. To avoid overruns in the HIL simulations an explicit fixed-step solver must be used. The first order Euler solver is applied in this work. To match the real time requirement a sufficiently large time step size need to be used in the Euler solver.

In the following sections the main submodels, real-time adaptations and HIL setup are described.

### 4.1 Chemical reactors

Chemistry is very complex and the final composition is highly dependent on the initial state and local phenomena. Simplified chemistry models are usually valid in a narrow state space. The purpose of this study is to validate and test the FPM control system during normal system startup. It is enough to predict reasonable heat release in each reactor. Detailed species concentrations are not required. Hence simple chemistry models designed for the normal startup and operation range are suitable.

In the ATR fuel is reformed by steam under presence of a limited amount of oxygen. Fuel lean combustion does not need to be covered by the model, and complete conversion is a valid assumption.

The reactors are implemented as homogeneous (lumped) reactor models, utilizing different reaction objects to simulate reaction time characteristics typical for each reactor. The reaction objects used are equilibrium chemistry, complete conversion and reaction kinetics using Arrhenius equation. Heat exchangers, flow losses and heat losses are included where applicable. See Fig. 2 for Dymola model schematics of the WGS reactor. The following chemical reactions are applied in the system:

Combustion (ATR):

Partial oxidation (ATR):

Hydrocarbon steam reformation (ATR):

Water-gas shift (ATR, WGS):

H<sub>2</sub> oxidation (PrOx, CAB):

CO oxidation (PrOx, CAB):

Figure 2: WGS model in Dymola

### 4.2 Start system

The catalytic start burner from Zemission is simply modeled by tabulated temperatures and mass flows as

function of power load. The table based start burner is connected to heat exchangers transferring the heat to the rest of the fuel processor (see Fig. 3). The startup logics involves electrical pre-heating, ignition, certain delays, ramping to operating point etc.

Figure 3: Start system in Dymola

### 4.3 Achieving real-time

A number of model simplifications and changes were introduced to enable real-time simulations:

- Non-linear equations: The submodels were simplified to avoid non-linear equation systems.
- Model simplifications: The model complexity was decreased. The discretized heat exchangers were replaced by lumped models. The discretized ATR, WGS, PROX and CAB reactors were described by lumped reaction volumes connected to lumped heat exchangers.
- Event elimination: The Modelica operator noEvent() was added for applicable functions. Functions not supporting noEvent were exchanged by functions supporting or including noEvent(). In particular IF constructs were removed.
- Minimum flow values: In the real system zero flow or back flow may occur. This can lead to division by zero or very fast dynamics. To avoid this, a negligibly small mass flow is initiated where the real system has zero flow.
- Chemical time scale: The time scale of chemical reactions is generally several orders of magnitude smaller than the required model time step size. Hence the complex dynamic

reaction system is replaced by static equations for most reactors. For reactors with dynamic time scales close to the model time step size the chemical reaction rates are damped sufficiently.

- Time scale for flow: Pressure waves travel fast and yield short time scales. To increase the time scales flow losses and volumes were lumped and increased.
- Simplified media: The higher order original NASA Glenn correlations [5] for thermodynamic properties were replaced by linear correlations for the full temperature range. Hence the possible discontinuity by the break temperature is removed.

To enable offline testing of the fuel processor a simple control system was implemented in Dymola and connected to the bus signals in the fuel processor model. An overview of the control system is shown in Fig. 4. Ramps and tables were used for opening and closing of valves and changing set points for mass flow regulators. Simple integrator controllers were used. The purpose of the model control system is only to test the robustness of the model and the model response; hence it is kept simple.

Figure 4: Model control system

### 4.4 HIL setup

The HIL set-up comprises 5 units. The HIL core form the Host computer, where the model is put together and compiled and the Real-time computer, which actually runs the model simulation in real time. The Real-time computer is connected to the PLC running the FCGEN APU control system via CAN buses. For

operation monitoring and adjustment of control system parameters another computer is used running the SCADA-HMI. This computer can be accessed remotely from J. Stefan Institute, allowing frequent checks and test execution without additional costs. The scheme of the HIL set-up is presented in Fig. 5.

The Real-time computer is a Speedgoat performance real-time target machine running xPC Target. The Dymola Simulink interface is used to import and build the Modelica model in Simulink.

The communication to the PLC includes more than 100 sensor and actuator signals. All signals are added to the model and connected in Simulink. An overview of the model setup in Simulink is seen in Fig. 6.

The time step of the model is 25 ms, which is a trade-off between model accuracy and the real time requirement. The sample time is 500 ms to mimic the real system response times. The communication interval to the PLC is 1 ms to ensure sufficient signal transfer rate.

Figure 5: HIL testing assembly scheme

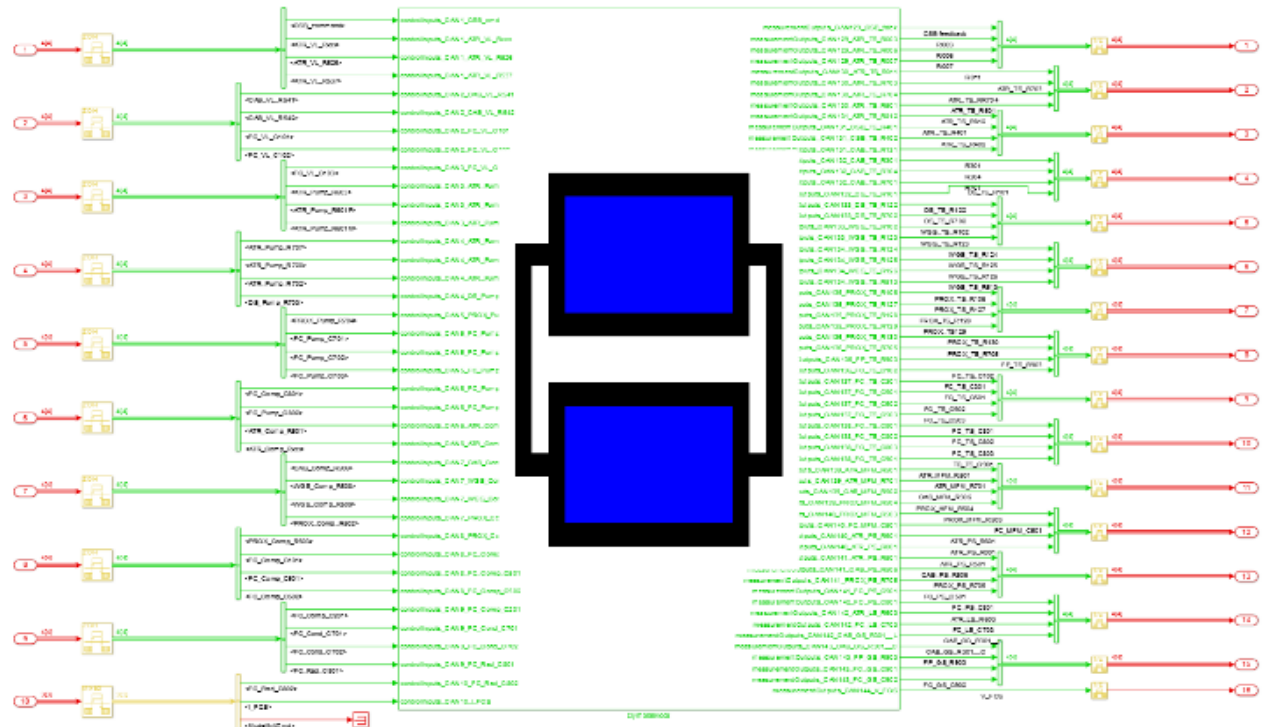

Figure 6: Simulink implementation using the Dymola Simulink interface

### 5 Results and Discussion

The model is tested offline for phase 1 to 4 in the startup strategy (see section 2.1). Air-fuel ratio and steam mass flow is changed to verify the model response. Following the discussion in section 3, the model cannot be expected to deliver correct absolute values or times. Hence temperatures and times are normalized, and absolute values are not presented.

Temperatures through the system are shown in Fig. 7 and 8. Fig. 7 shows the inlet temperatures to the ATR, Fig. 8 shows the reactor exhaust temperatures through the system. The startup events are indicated on the x axis.

The overall dynamics of the model is reasonable; inlet air and steam are heated by the startburner, and the temperature drops when the startburner is turned off. The ATR temperature is increased by startburner heating. By ignition, the temperature is increased, and when CSB is turned off the temperature drops to a stable value.

The transient overshoots seen in the figures arise from the use of simple integrator controllers.

Figure 7: ATR inlet temperatures. The numbers below the x axis indicate start of phase 1-4 defined in section 2.1.

Figure 8: Reactor exhaust temperature. The numbers below the x axis indicate start of phase 1-4 defined in section 2.1.

To test the model response the air-fuel ratio was decreased by lowering the inlet air flow. Since the ATR is run under fuel rich conditions this should lead to decreased ATR outlet temperature. This is confirmed by Fig. 9, where ATR exhaust temperatures for different conditions are plotted.

From this figure it is also confirmed that the ATR temperature is decreased when increasing steam mass flow, as expected.

Figure 9: ATR exhaust temperature for different conditions

To meet the real time requirement reactor volumes and flow losses were increased. To evaluate the effect of these necessary changes comparisons of results with and without these changes are shown in Fig. 10 and 11 below. Both simulations were run with the

Dassl solver. The deviation between original and real time model is considered acceptable.

Figure 10: Temperatures before (\*\_orig) and after (\*\_realtime) modifications of volumes and flow losses to eliminate time constants below 25 ms.

Figure 11: Mass flows before (\*\_orig) and after (\*\_realtime) modifications of volumes and flow losses to eliminate time constants below 25 ms.

Using DASSL on a laptop with an Intel Core™ i7-3740QM CPU @ 2.70 GHz, the model is 68 times faster than real-time. With the Euler solver each time step takes about 4.5 ms without overruns; the model is 5.6 times faster than realtime when using a time step size of 25 ms. The results are confirmed to be consistent using DASSL and Euler, see Fig. 12. At the Speedgoat machine each time step requires slightly more than 20 ms. For this reason a 25 ms step size is chosen for the HIL simulations.

Figure 12: Simulations with DASSL and Euler Solver

The major difficulty in achieving real-time capability was to ensure large enough time constants under all conditions. Lumping volumes in reactors and heat exchangers was not enough. The smallest time constants of the lumped system were  $< 0.05$  ms. To increase the time constants the volumes were increased until the results started to deviate from the original results. Since the time constants were still too small, it was decided to also increase flow losses through the system. This increased the time constants sufficiently while still keeping sufficient accuracy in temperature and mass flows (see Fig. 10 and 11).

The second major difficulty was to ensure stable operation under all circumstances. This was handled by extensive testing of the model, eliminating issues one by one. The major difficulties were connected to back flow and negative mass fractions. Backflow is difficult to consistently handle under all circumstances without event generation and without obtaining non-linear equation systems. Hence a large enough minimum flow from the compressors, pumps and valves was imposed. Negative mass fractions occur when the solver takes a too large step size for a dynamic reaction where one of the reactants is completely consumed. Hence reactions were limited and max limiters were applied on species mass fractions.

The model is currently tested on the SpeedGoat machine using xPC Target. It is confirmed to successfully load and start. Full HIL tests with a PLC will be the subject of future work. Additional model revisions may be required during the course of the PLC tests.

## 6 Conclusions

A real-time model for dynamic simulation of a fuel processor is developed. The following main conclusions are made:

- It is possible to create a real-time capable model using Modelica and Dymola for such a fuel processor system.
- A system of 217 dynamical states needs Euler time steps of about 25 ms to enable HIL simulation on the current hardware configuration.
- Several simplifications were needed to increase the time constants to 25 ms.

## Abstract

This paper presents the results of an on-going project to develop ThermoCycle, an open Modelica library for the simulation of low-capacity thermodynamic cycles and thermal systems. Special attention is paid to robustness and simulation speed since dynamic simulations are often limited by numerical constraints and failures, either during initialization or during integration. Furthermore, the use of complex equations of state (EOS) to compute thermodynamic properties significantly decreases the simulation speed. In this paper, the approach adopted in the library to overcome these challenges is presented and discussed.

*Keywords:* Thermodynamic systems, numerical methods, simulation speed, robustness

## 1 Introduction

Dynamic simulation of thermodynamic systems is required to evaluate and optimize their response time, or to define, implement and test control strategies. [13, 6, 22]. The Modelica language is well adapted to the formulation of thermo-flow problems, mainly because it is an a-causal language that allows interconnecting the models in a "physical" way [5]. In recent years, several libraries have been developed to model thermodynamic and thermal systems in the Modelica language [6, 27]. A number of libraries are now available to model steam and gas cycles (e.g. ThermoSysPro, Power Plants, Thermal Power, ThermoPower, etc.) or refrigeration systems (TIL, AirConditioning, etc.).

However, not all of them are open-access, and few are able to handle non-conventional working fluids such as refrigerants or fluids used in Organic Rankine Cycle (ORC) systems. Thermophysical substance

properties of (moist) air and water are indeed well known and implemented in most simulation tools while those of organic fluids require complex equations of state available only in external libraries such as FluidProp [10], Refprop [16] or CoolProp [1]. Two common solutions when modelling thermodynamic systems requiring external computation of working fluid properties include TIL and ThermoPower:

- TIL is a commercial library for steady-state and transient simulation of thermodynamic systems [26]. The thermodynamic properties are obtained through TILMedia, a library for the calculation of thermophysical substance properties, for example using custom high performance EOS, fast table based bicubic spline interpolation or via an interface for Refprop. It should be noted that TILMedia is not designed according to the Modelica Media standard but provides an interface with the Modelica.Media library. The TIL library includes a variety of models for thermodynamic components (e.g. heat exchangers, expanders, pumps, etc.).
- The ThermoPower library has proven to be well suited for the modelling of power plants, including ORC systems [8]. It can be coupled to the ExternalMedia library [9], an interface between Modelica and, among others, FluidProp. ThermoPower and ExternalMedia are open-source, FluidProp is freely available but not open-source. The models are mainly designed for large-scale power plants with tube heat exchangers. Smaller systems using e.g. plate heat exchangers are less adapted to the ThermoPower library.

The ThermoCycle Modelica library has been developed for the simulation of thermal plants (heat pumps, steam and gas cycles, etc.) with a focus on smaller-capacity systems. It aims at addressing three typical

challenges inherent to the modelling of thermo-flow systems:

1. Computing the thermophysical substance properties of working fluids
2. Computational efficiency
3. Robustness during initialization and integration

Several numerical methods have been developed and implemented in order to enhance the robustness and the simulation speed of the models during initialization and integration. Furthermore, the computation of the working fluid thermophysical properties is achieved by a strong coupling with the open-source thermodynamic properties database Coolprop [1]. The interface between CoolProp and Modelica is based on the Coolprop2Modelica library, a modified version of the ExternalMedia library [9].

## 2 The ThermoCycle Modelica library

The ThermoCycle library aims at providing a robust framework to model small-capacity thermodynamic cycles. The goal is to provide an integrated and fully open-source solution ranging from the thermophysical substance properties, using CoolProp, to the simulation of complex systems with their control strategy. In comparison with alternative libraries dedicated to power plants (ThermoPower, ThermoSysPro, Thermal Power), the ThermoCycle library includes various models dedicated to the modelling of smaller-scale thermal systems, such as volumetric compressors models used for the simulation of heat pump or refrigeration cycles. The key features of the Library are the following:

- Designed for system level simulations
- Full compatibility (connector-wise) with libraries such as MST or ThermoPower, use of stream connectors
- Ability to handle reverse flows and flow reversals
- Various numerical robustness strategies implemented in the components and accessible through Boolean parameters
- High readability of the models (limited levels of hierarchical modelling)

The components provided in the library are designed to be as generic as possible. For example, no detailed

geometry records should be provided by the user to compute the heat exchanger heat transfer and pressure drop. Instead, the user is expected to build a separate detailed model of the component and extract simplified laws to be used in the Modelica component: for a given fluid and operation conditions range, detailed heat transfer correlations can usually be replaced by simplified equations depending on the flow rate only:

$$h = h_{nom} \cdot \left( \frac{\dot{M}}{\dot{M}_{nom}} \right)^n \quad (1)$$

where the  $n$  exponent depends on the flow regime (typically 0.6 for laminar and 0.8 for turbulent). This approach aims at increasing the computational efficiency, and also allows using the same model for different types of components. As an example, the same model can readily be used for shell & tubes or plate heat exchangers only by modifying the  $h_{nom}$  and  $n$  parameters of the simplified heat transfer law.

The same applies for the pressure drops, which can usually be lumped in a single pressure drop on the vapor lines and expressed as a quadratic function of the flow rate. This approach increases the computational efficiency and avoids specific models suitable for one particular component type or geometry only. It is illustrated in Figure 1 for the case of a heat pump: the pressure drops in each line are lumped into two pressure drop components that were calibrated in a separate and more detailed steady-state model. It should be noted that this assumption is valid only if the pressure drops remain limited in both heat exchangers: their influence on the temperature profile should be small compared to the temperature differences and the pinch points of the process.

### 2.1 Modelling of fluid flows

The finite volume approach is selected as general method to simulate fluid flows. Homogeneous one- and two-phase flow are taken into account, while non-homogeneous, multi-phase flows are not considered, yet. The basic fluid flow component is a cell in which the energy and mass conservation equations are applied (Figure 2). Two types of variables can be distinguished: cell variables and node variables. Node variables are distinguished by the "su" (supply) and "ex" (exhaust) subscripts, and correspond to the inlet and outlet nodes of each cell (Fig. 2). The relation between the cell and node values depends on the discretization scheme. Two schemes are implemented in the cell component, the central difference scheme ( $h = (h_{su} + h_{ex})/2$ ) and the upwind scheme ( $h = h_{su}$ ).

Figure 1: Model of an R407c heat pump

Since the model accounts for flow reversal, a conditional statement is added depending on the flow rates at the inlet and outlet nodes. For the central difference scheme,  $h_{su}$  is expressed by Equation 2 (an equivalent equation applies to  $h_{ex}$ ):

$$h_{su} = \begin{cases} h_{ex}^* & \text{if } \dot{M}_{su} \geq 0 \\ 2 \cdot h - h_{ex} & \text{if } \dot{M}_{su} < 0 \text{ and } \dot{M}_{ex} < 0 \\ h & \text{if } \dot{M}_{su} < 0 \text{ and } \dot{M}_{ex} \geq 0 \end{cases} \quad (2)$$

where the flow rates are defined as positive when the fluid flows in the nominal direction (from "su" to "ex"), and where  $h_{ex}^*$  indicates the exhaust node enthalpy of the previous cell.

For the upwind scheme:

$$h_{su} = \begin{cases} h & \text{if } \dot{M}_{su} < 0 \\ h_{ex}^* & \text{if } \dot{M}_{su} \geq 0 \end{cases} \quad (3)$$

Figure 2: Discretized flow model with cells and node variables

The energy balance for one cell is expressed by [21]:

$$V\rho \frac{dh}{dt} = \dot{M}_{su}(h_{su} - h) - \dot{M}_{ex}(h_{ex} - h) + \dot{Q} + V \frac{dp}{dt} \quad (4)$$

and the mass balance is written as a function of the two differentiated state variable  $p$  and  $h$

$$\dot{M}_{ex} - \dot{M}_{su} = V \cdot \frac{dp}{dt} = V \cdot \left( \frac{\partial \rho}{\partial h} \cdot \frac{dh}{dt} + \frac{\partial \rho}{\partial p} \cdot \frac{dp}{dt} \right) \quad (5)$$

where  $\frac{\partial \rho}{\partial h}$  and  $\frac{\partial \rho}{\partial p}$  are considered as thermodynamic properties of the working fluid and are computed in CoolProp. Pressure is considered constant in the cell component.

The cell model has been developed for compressible, incompressible, and constant heat capacity fluid. The overall flow model can be obtained by connecting several cells in series. The final discretization scheme corresponds to a staggered grid, i.e. the thermodynamics states and the state variables (the enthalpies) are calculated inside the cells and the node values ("su" and "ex") are deduced using equations 2 and 3.

## 2.2 Library structure

The library is organized into different sub packages, including:

1. *Components*, is the central part of the library. It is divided in three sub packages: FluidFlow, Heat-Flow and Units. It contains all the models available in the library from the simple cell model for fluid flow to complete models of heat exchangers, expanders and control units. A more detailed description of this package is presented in subsection 2.3.
2. *Examples*, contains simulation models where the components of the library are tested. It includes several ORC plant models and it also provides a step by step package where the procedure to build an ORC power unit and an heat pump system is described in detail.
3. *Functions*, includes the empirical correlations used to characterize some of the library models as well as general purpose mathematical functions.
4. *Interfaces*, contains the connectors used for the library components.
5. *Media*, predefines a list of the fluids available in the library.

Figure 3 shows an overview of the library structure.

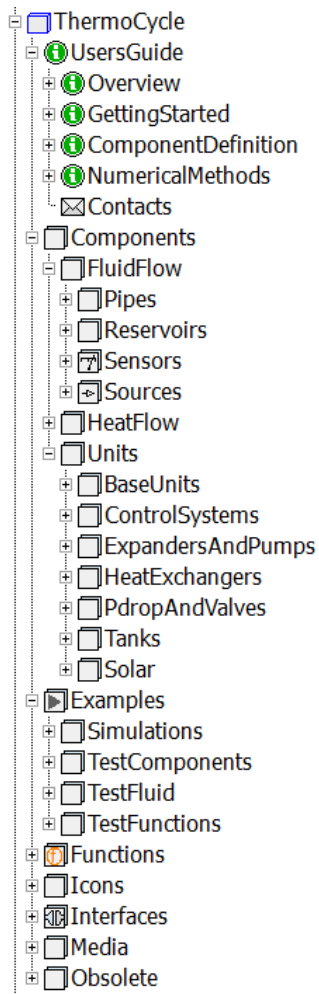

Figure 3: An overview of the library structure from the Dymola graphical user interface

## 2.3 Physical components

The Components package of the library provides a set of models from the basic cell model to higher-level components commonly used in thermal systems. The most common ones are described hereunder.

### 2.3.1 Expansion and compression machines

Since the time constants characterizing expansion and compression processes are small compared to that of the heat exchangers [14], the basic pump expander and compressor models are described by empirically derived algebraic correlations. In particular, pumps are modelled by two empirical equations expressing the isentropic and volumetric efficiencies as a function of the operating conditions, e.g. rotational speed and pressure ratio.

Low capacity systems generally use volumetric expansion machines instead of turbomachinery. Therefore,

special attention has been paid to their modelling in ThermoCycle. Advanced empirical expressions of the efficiency and filling factor are used and implemented, such as the one proposed by Declaye et al. in the case of an open-drive scroll expander [11].

In the case of volumetric compressors, the efficiencies (isentropic, volumetric) can either be user-defined or based on the standard EN12900, which is a well known standard to express the compressor performance as a polynomial function of the evaporation and condensation temperatures.

In addition to these empirical models, more detailed physical models are also available, such as the one proposed by Lemort et al. [17] for scroll machines which takes into account thermal losses, friction losses, internal leakage, internal pressure drop or under and over-expansion (Figure 4). Finally, detailed models of the expansion machine have been included, in which the thermodynamic state of the fluid in the expansion chambers is computed throughout one whole revolution [28]. This type of model is well adapted to the optimization and to the simulation of the component alone, but can hardly be integrated into a more general model because of its significant computational time.

Figure 4: Semi-empirical compressor model

### 2.3.2 Heat exchangers

The base component for all heat exchangers is the cell model, see Figure 2. Two types of cells are distinguished: one for compressible (and two-phase) flows, and one for incompressible flows. Heat exchanger models are built by interconnecting these cells in the appropriate manner together with a wall model [27]. Parallel, counter flow and cross flow models for compressible and incompressible fluids are available. More complex structure can also easily be developed by modifying the interconnections between the different fluid flow models.

In addition to the above models based on the finite volumes method, a moving boundaries heat exchanger model for evaporators has also been included. This type of model is known to be more computationally efficient than discretized models and is less likely to be subject to chattering.

### 2.3.3 Pressure drop and valves

Pressure drops are modelled by lumped parameters used to compute the pressure difference as a function of the flow rate. This function includes a constant term (to model static pressure differences), a linear term (e.g. to model laminar pressure losses) and a quadratic term (to model turbulent pressure losses):

$$\Delta p = \rho \cdot g \cdot h + K \cdot \dot{V} + \frac{1}{A^2} \cdot \frac{\dot{M}^2}{2 \cdot \rho} \quad (6)$$

where  $\rho$  is the fluid density,  $g$  is the gravitational constant,  $\dot{V}$  is the volume flow rate,  $\dot{M}$  is the mass flow rate. The three parameters are  $h$  (the static head),  $K$  (the linear pressure drop coefficient) and  $A$  (the equivalent turbulent orifice area).

Infinite derivative at zero flow in the case of the quadratic term is avoided by using the Modelica *regSquare* function. The fluid is assumed to be incompressible and ambient losses are neglected.

Valves are modelled as a pressure drop whose orifice cross-sectional area can be adjusted by an external signal.

### 2.3.4 Tanks and liquid receivers

Different tank (fully mixed) and liquid receiver models are available. They are modelled using the energy and mass conservation principles, and assuming thermodynamic equilibrium at all times inside the control volume.

### 2.3.5 Solar field

In recent years, several studies have underlined the potential of small-capacity thermal solar organic power systems [19, 18, 20]. Different models of parabolic trough solar collector have therefore been added to the library. The large ratio between diameter and length allows a one dimensional discretization of the absorber tube.

The model is composed by two subcomponents, as shown in figure 5: the Flow1Dim component which models the heat transfer fluid flow in the heat collector element (HCE) and the SolAbs component

Figure 5: Object diagram of the solar field model. a and b indicate respectively the fluid inlet and outlet ports of the flow model (Flow1Dim). c and d indicate the thermal ports.

which solves the dynamic one dimensional energy balance around the HCE. The solAbs component implements the relations between the environmental parameters, direct normal radiation (DNI), incidence angle ( $\Theta_{\text{incid}}$ ), ambient temperature ( $T_{\text{amb}}$ ), wind velocity ( $v_{\text{wind}}$ ) and the axial temperature distribution along the absorber, either based on the Forristal model [12] or based on an empirical correlation derived from the Schott test analysis [3]. The user can choose between different collector geometries based on commercial products. The solar field model is available for compressible and incompressible fluids.

## 3 The CoolProp2Modelica library

The ThermoCycle library aims at modelling different kinds of thermodynamic cycles, including those with unconventional working fluids. The efficient computation of their thermophysical properties is therefore a key aspect of the proposed models. As previously mentioned, the currently available Modelica solutions for computing organic fluid properties are limited to non-open-source databases. In order to propose a fully open-source tool, ThermoCycle has been coupled to CoolProp, an open-source library developed at the University of Liège [1]. The main features of the CoolProp library are the following:

- Fully open-source
- High accuracy Helmholtz energy-based equations of state.
- More than 110 different working fluids
- Properties over 40 incompressible fluids (e.g. thermal oils) and brines (only accessible with p,T or p,h as input variables).

- Low computational time

The interface between Modelica and CoolProp is implemented in the CoolProp2Modelica library, a modified version of the ExternalMedia library [9].

In thermo-flow systems, the computation of the thermophysical properties amounts for a significant share of the total computational time. In order to enhance fluid property calculation speed, two interpolation methods, the tabular Taylor series expansion (TTSE) and the bicubic interpolation method, have been developed and integrated into the CoolProp main source code [1]. The interpolation tables (the working fluid properties computed on a 200x200 grid over the whole range of states) are built at the beginning of the simulation (at the first property call) and stored in memory for further use. This process requires between 2 s and 10 s. All subsequent property calls are performed using the selected interpolation method. It should be noted that, contrary to the bicubic method, the TTSE method generates discontinuities in the computation of the fluid properties. This discontinuity is however very small and does not constitute an issue during simulation.

In order to assess the effectiveness of the developed methods, a benchmark test was carried out comparing the different available fluid properties database with respect to the elapsed time per property call from Modelica. The properties were called a large amount of times and in different areas of the thermodynamic diagram (liquid, two-phase and vapor). The results are presented in figure 8 and show that Coolprop is significantly faster than Fluidprop and slightly slower than the commercial library TILMedia/RefProp. However, when the TTSE method is activated, the computational time is one order of magnitude lower than TILMedia, demonstrating the efficiency of the proposed interpolation method.

Figure 6: Elapsed time per property call from Modelica in the case of propane (in ms)

In addition to the interpolation methods, smoothing methods to deal with the discontinuity of the density derivatives in the two-phase zone, described in section 4, have also been implemented. The open-source characteristics of CoolProp is a non-negligible advantage since it allows the process to be fully transparent for the end-user, who only needs to activate a flag in the Modelica property call, as shown in figure 7. In this example, the fluid name is modified to instruct CoolProp not to compute the transport properties, the debug level is set to unity, the density is smoothed out in the vapor quality interval from 0 to 0.15, and the TTSE interpolation method is activated.

```

package R245faCoolSmooth
extends CoolProp2Modelica.
Interfaces.ExternalTwoPhaseMedium(
  mediumName = "R245fa",
  libraryName = "CoolProp",
  substanceNames = {"R245fa|calc_transport=0|debug=1|
rho_smoothing_xend=0.15|enable_TTSE=1"});
end R245faCoolSmooth;

```

## 4 Numerical aspects

Dynamic modelling of thermodynamic cycles can be a challenging task, among others because of the numerous numerical issues arising both during initialization and during integration. In order to enhance the performance and the robustness of the ThermoCycle library, different numerical methods have been implemented and tested. They are presented and discussed in this section.

### 4.1 Initialization

The convergence of the Newton Solver during initialization is a key challenge when modelling complex system. Several strategies have been developed, such as the *homotopy* method [25]. In addition to this method, a slightly different approach is proposed in ThermoCycle: the system is initialized on a simplified system of equations, and the more complex non-linear equations, such as the computation of the heat transfer coefficients as a function of mass flow, are activated one by one during integration using an *initialization* component developed for that purpose.

## 4.2 Chattering and flow reversals

The phenomenon of chattering may occur when discontinuities in the model variables are present [15]. This phenomenon can lead to extremely slow simulation, or to simulation failures because the computed variables exceed acceptable boundaries. In discretized two-phase flow models, the main discontinuity often occurs in the density derivative on the liquid saturation curve. Simulation failures or stiff systems can occur if the cell-generated (and purely numerical) flow rate causes a flow reversal in one of the nodes due to this discontinuity. The computation of  $h_{su}$  and  $h_{ex}$  switches from one value to the other in equations 2 and 3.

In addition to chattering, flow reversals can also result in a singular and non-solvable set of equations, as shown in [24]. A solvability criterion can be expressed as

$$h_{su} > h + \frac{\rho}{\frac{\partial \rho}{\partial h}}, \quad (7)$$

where  $\partial \rho / \partial h$  is a negative term.

This inequality states that in cases of flow reversal, an unsolvable system of equations appears, if the enthalpy of the entering fluid is below a certain limit. A formal demonstration of this effect can be found in [24].

Therefore, to ensure the robustness of the simulation and to avoid chattering or unsolvable systems, two strategies can be employed:

1. Avoid flow reversals caused by the density derivative discontinuity, see Eq. 5.
2. If flow reversal occurs (it is physically possible), make sure that the backward flow enthalpy is higher than the limit described in Eq. 7.

The first strategy can be expressed by an inequality stating that purely numerical, cell-generated flow rates must be lower than the flow rate circulating through the cycle, which can be written (for a single cell):

$$\dot{M}_{ext} \gg \frac{V}{N} \cdot \frac{d\rho}{dt} = \frac{V}{N} \cdot \left( \frac{\partial \rho}{\partial h} \cdot \frac{dh}{dt} + \frac{\partial \rho}{\partial p} \cdot \frac{dp}{dt} \right) \quad (8)$$

According to Eq. 8, flow reversals and thus chattering or simulation failures are likely to occur if:

- The number of cells ( $N$ ) is low
- The working fluid flow rate ( $\dot{M}_{ext}$ ) is low
- The internal volume ( $V$ ) is high
- The working conditions are highly transient (i.e.  $dp/dt$  and  $dh/dt$  are high)

Different methods are implemented in ThermoCycle to avoid the simulation issues described above. Some are implemented at the Modelica level while others require a modification of the thermodynamic properties of the working fluid and are therefore implemented into CoolProp. It should also be noted that some of these methods have already been proposed in the literature, while some others are new. They are briefly described hereunder. A more comprehensive description is available in [23].

- *Filtering method*: In this strategy, a first order filter is applied to the fast variations of the density with respect to time. This filter therefore acts as "mass damper" and avoids transmitting abrupt variations of the flow rate due the density derivative discontinuity.
- *Truncation method*: This strategy acts on the terms  $\partial \rho / \partial p$  and  $\partial \rho / \partial h$  of Eq. 8. The peak in the density derivative occurring after the transition from liquid to two-phase is truncated, reducing the numerical flow rate generated by the density derivative discontinuity.
- *Smoothing of the density derivative*: The idea behind this method is to smooth out the density derivative discontinuity using a spline function. Modifications of the thermophysical properties are implemented at the level of the equation of state, i.e. inside the CoolProp database. The main drawback of this method is that the density function is still calculated with the original equation of state: the smoothed density derivative is not consistent with the density function provided by the EOS. This might cause a mass defect during the simulation.
- *Smoothing of the density function*: In order to avoid the mismatch between the density function and its derivative, one possible solution is to smooth the density for a range of vapour qualities (i.e. making it C1-continuous) and recalculating its partial derivatives in the smoothed area. In this situation, the density derivatives are continuous but not smooth, which should still be manageable for the solver.
- *Mean densities method*: The mean densities method was originally proposed by Casella [4] and successfully tested by Bonilla et al. [2]. It is also the method implemented in the ThermoPower Modelica library [7]. A mean density and its partial derivatives are computed in each cell as a function of the node densities, which

eliminates the discontinuity in the partial derivatives.

- *The enthalpy limiter method*: Contrary to the previous methods, the enthalpy limiter method does not aim at avoiding flow reversals. Instead, it ensures that the system of equations remains solvable even in case of flow reversal. As indicated in Eq. 7, the enthalpy of the fluid entering a cell should have a minimum value, ensuring that the system of equations can be solved. The enthalpy limiter method is the practical implementation of this constraint in the cell model. It was originally proposed by Schulze et al. [24] and implemented in the TIL Modelica library.
- *Smooth Reversal Enthalpy*: In case of flow reversal a discontinuity appears in the computed node enthalpy. In this method, this is solved using a smooth transition function for the computation of the enthalpy as a function of the flow rate close to zero. The main drawback is the generation of a highly nonlinear algebraic system that has to be solved by the simulator.

A comparison of these different methods, based on the simulation of a flow model with a high number of cells, in terms of simulation speed, simulation accuracy and mass and energy imbalance shows that adopting the proposed methods can dramatically improve the simulation performance and even allow to simulate flow reversals where traditional models generate simulation failures. The main concern is the error they introduce in the simulation results and the possible mass and energy unbalances they generate. In [23], the methods have been tested on a test system submitted to highly transient conditions. Results have shown that although numerical artifacts are generated, the error remains of the same order of magnitude as the error linked to the standard finite volume model with a  $10^{-4}$  tolerance. This is an important statement showing that the proposed models can ensure failure-free simulation even in highly transient conditions. It should also be noted that those transient conditions are likely to generate chattering or stiff systems are usually concentrated in specific times of the simulation (e.g. start-up and shut-down), in which robustness is more important than accuracy.

## 5 ThermoCycle Viewer

When debugging or interpreting simulation results, it is generally useful to post-process the raw time-data

before displaying it. To that end, an analysis tool has been developed, which scans the simulation results and automatically detects all thermodynamic states to display them on a thermodynamic diagram (e.g. T-s or p-h). The heat exchanger temperature profiles are also detected, displayed, and animated as a function of time.

Figure 8: Graphical interface to display thermodynamic states and temperature profiles

## 6 Conclusion

The development of the ThermoCycle library is an on-going process aiming at providing a completely open-source tool for the dynamic modelling of thermodynamic cycles. The library comprises a number of components which can be used to simulate a wide range of physical systems. Special attention has been paid to the implementation of new and existing numerical methods to enhance the robustness and the simulation speed of the models during initialization and integration. The ThermoCycle and CoolProp2Modelica libraries are being released together with ThermoCycle Viewer through the library website (URL: [www.thermocycle.net](http://www.thermocycle.net)). Current work now focuses on the integration of new components (moving boundaries models, thermocline and stratified storage, evaporator with frosting, etc.) and on the experimental validation of the proposed models. At the present time, the library and the thermophysical properties database are both open-source, but are running exclusively under Dymola. Porting the library to the OpenModelica platform is another ongoing work, which should lead to a fully integrated open-source solution for the modelling of thermal systems.

## Abstract

We discuss the challenges of building a simulation framework for hybrid systems, in particular the well-known Zeno effect and correct composition of models idealised by abstracting irrelevant behavioural details (e.g. the bounce dynamics of a bouncing ball or the process of fuse melting in an electrical circuit). We argue that the cornerstone of addressing these challenges is the definition of a semantic framework with an appropriate underlying model of time.

Using two simple examples, we illustrate the properties of such a model and explain why existing models are not sufficient. Finally, we propose a new Zeno-free semantic model that allows mixing discrete and continuous behaviour in a rigorous way and provides for the compositional behavioural abstraction.

Although it is based on non-standard analysis, we explain how our semantic model can be used to develop hybrid system simulators.

*Keywords:* Hybrid Modeling Languages; Non-Standard Analysis; Models of Signals; Behavioral Abstraction; Operational Semantics

## 1 Introduction

A large number of modelling, verification and simulation frameworks for hybrid systems have been designed in the past years. Although, a complete overview is beyond the scope of our paper, we observe that they broadly fall in two categories: those that put special emphasis on a rigorous model definition, such as, for instance, the Ptolemy project [6] (based on [14]), the Zélus synchronous language [3] (based on the semantics in [1]) and SpaceX [7]; and those that have chosen a more pragmatic, informal approach, such as the Modelica language [8] and the as-

sociated tools, and the Scicos block-diagram modeller and simulator [4].

All the associated tools share the same basic model of execution alternating between continuous phases and sequences of ‘run-to-completion’ discrete actions [3] as formalised by the notion of hybrid automata [11]. None of these approaches attempts to include the operational semantics of differential equations in their core semantic model: execution of the continuous phases is delegated to numerical solvers, which are used to advance physical time and compute the values of physical signals.

Except for Zélus, none of the above semantic models are Zeno-free, which means that, as explained in the next sections, they do not reflect the fact that time diverges and rely on analysing the solver output to detect and advance past the Zeno points [13] (cf. Section 2). This poses a fundamental problem, since the solver behaviour at this point is usually unspecified.

Furthermore, none of the above proposals allows *compositional behavioural abstraction*: idealised models do not account for the physical nature of phenomena, in particular the fact that original, *high-fidelity* signals are *continuous*. However, this property is assumed by most users and validated by most real-life systems. Hence, it must be a fundamental property of signals and should be reflected in their idealisations.

In our view, to achieve maximum robustness of a simulation framework, it is crucial to define the semantic model before designing either the language or the simulator. Thus, the design of a hybrid simulation framework should involve the following steps.

First of all, one must define a semantic model that properly accounts for the expected elementary properties of systems to be simulated. This includes dynamic behaviour properties, but also “higher level” ones, such as modularity.

The second step consists in designing a simulator

capable of computing acceptable approximations of the dynamics of models conforming to the semantic model above. Successful completion of this step validates the semantic model by showing that all conforming models can be simulated.

The third step involves the design of a language powerful enough to express a useful subset of models that provably conform to the semantic model. In order to avoid errors at simulation time or, worse, spurious simulation results, the semantic validity of a model must be provable statically, e.g. by type-checking.

Finally, once both the semantic model and the language have been defined, one has to design a compiler for this language, which would perform the necessary static checks and reject the invalid models.

In this paper, we focus on the first step above, i.e. defining the appropriate semantic model. Indeed, in our opinion, current semantic models still lack some of the properties required by real-life systems.

In particular, modularity is an extremely important property for both correctness and practical usability of hybrid simulation frameworks. One of us has already discussed some modularity issues in Modelica [9]. In the present paper, we focus on another—probably the most important—aspect contributing to modularity, which is *compositional behavioural abstraction*.

Realistic hybrid models almost always require part of the physical behaviour to be abstracted by means of “ideal equations”—such as conditional and reset equations—that typically yield discontinuities in physical signals. Below, we will use the term *behavioural abstraction* more generally to designate any mechanism that enables concrete physical behaviour to be “hidden” by considering *idealised* models. Intuitively, from the point of view of an external observer, behavioural abstraction makes the model “jump” over instants corresponding to activations of abstraction mechanisms. Thus, idealisation consists in explicitly providing a constraint to be met *after* these instants.

It is well known from physical system modelling experts that, although extremely useful in practice, behavioural abstraction often leads to inconsistencies and even to singularities in simulation code, especially when abstractions are *composed*. Informally, we say that behavioural abstraction is *compositional* if substituting an ideal sub-model—instead of a high-fidelity one—within a larger model does not introduce new behaviours that were not present in the original model (a counter-example is given in Section 3.1).

The cornerstone of a semantic framework that would address the above issues is the underlying

model of time.

Traditional definition of the simulation time-line either relies on a fixed basic step, provided as a simulation parameter, or a variable step adjusted based on events detected during the simulation. The former has the advantage of being Zeno-free by construction, since at each simulation step the time advances by a constant value, but produces wrong simulation results whenever the signal activity is higher than the fixed sampling frequency. Variable step simulation, on the other hand, improves the simulation precision by sacrificing Zeno-freeness. However, in both cases, the semantics of a model is only defined at simulation time depending on the choice of time steps. Hence, model validity cannot be statically proven.

In Section 3.1, we argue that, to ensure compositionality of behavioural abstraction and reflect the intrinsic continuity of physical phenomena, the time model must be *densely ordered*.<sup>1</sup> Indeed, as a result of behavioural abstraction, several causally dependent events happen at the same instant. Traditional time models above do not provide any possibility to preserve the causality information in the semantic model, leading to spurious behaviours.

The *super-dense* time approach [14] addresses this problem by defining time as a subset of the cartesian product  $\mathbb{R} \times \mathbb{N}_0$ . However, solutions of differential equations are obtained by means of standard operational semantics. Thus, although causality between instantaneous events can be preserved, the problems related to the Zeno effect persist.

Recent use of Non-Standard Analysis [12] in the design of operational semantics for hybrid systems [1, 2, 16] has led to the definition of a *linear* time that is 1) *discrete*, i.e. instants can be considered in isolation; 2) *well-ordered*, i.e. for each time instant, there is a uniquely defined *next instant* respecting the usual temporal order; and 3) it can be treated as a *continuum*. These properties make it suitable to express both discrete and continuous dynamics in a *unified* fashion and avoid the Zeno effects. However, as a consequence, such time model cannot be densely ordered. Indeed, it features *consecutive instants*, which, by definition, do not have any instants between them.

In this paper, we propose a new, Zeno-free semantic model also based on a non-standard model of time, which allows mixing discrete and continuous behaviour in a rigorous way. In addition, this new model also allows compositional behavioural abstrac-

<sup>1</sup>A partially ordered set is said to be densely ordered if for all elements  $x$  and  $y$  for which  $x < y$  there exists a  $z$  such that  $x < z < y$ .

tion: density of time is reestablished so that physical signals remain continuous even when idealised, which avoids the emergence of “impossible behaviours”.

The key idea behind our proposal is to discretise the *value* of signals instead of time. Discretisation is necessary in order to associate *dates* with events [1, 2, 16]. However, discretising signal values allows us to choose these dates among all non-standard reals, rather than fixing a regular time-line in advance. Thus, we consider discrete signal *activity* in the frame of a densely-ordered time-line compatible with the requirements of compositional behavioural abstraction. This approach has something in common with [10], where well-ordered time scales are constructed as subsets of a common densely-ordered time reference.

The paper is structured as follows. In Section 2, we explain the need for an operational semantics that can cope with the Zeno paradox, and how non-standard analysis can be used to define such a semantics. In Section 3, we show why previous proposals based on non-standard analysis do not ensure compositional behavioural abstraction, by taking an example involving the *composition* of several abstractions. Finally, in Section 4, we present our proposal, also based on non-standard analysis, but where discretisation is no longer applied to the time-line but to signal values, leading to a more intuitive definition of time that, moreover, allows compositional behavioural abstraction.

## 2 Why non-standard semantics?

### 2.1 Behavioural abstraction example

The famous bouncing ball model, whereof a Modelica implementation is given in Listing 1, is probably one of the simplest models involving behavioural abstraction. In this model, the physics of the bounce have been abstracted away: we consider that, at bounce time, the velocity, which was negative just before the ball hits the ground, *instantaneously* becomes positive, with a magnitude decreased by 20%. Figure 1 shows the simulation results for  $x$  in the  $[0, 1.1]$  time interval.

Despite its apparent simplicity, this model poses severe challenges to language theorists as we shall see.

### 2.2 The Zeno effect

We suppose here that physical time is based on standard reals (i.e.  $\mathbb{R}$ ). How does our model behave with such a time model?

Let’s introduce the following notations:

Listing 1: A bouncing ball model, in Modelica.

```

model BouncingBall
  Real v, x;
  constant Real g = 10;
  initial equation
    v = 1.0;
    x = 0.0;
  equation
    der(v) = -g;
    der(x) = v;
    when x < 0 then
      reinit(v, -0.8 * pre(v));
      reinit(x, 0.0);
    end when;
end BouncingBall;

```

Figure 1: Simulation results for the bouncing ball model with the DASKR solver (altitude of the ball with respect to time)

- $t_i$ , for  $i \in \mathbb{N}_0$ , denotes the initial instant of the  $i^{\text{th}}$  flight of the ball;
- $v_i$ , for  $i \in \mathbb{N}_0$ , denotes the (positive) velocity of the ball at  $t_i$ .

According to the model, the trajectory of the ball in-flight has to verify:

$$\dot{v} = -g \quad (1a)$$

$$\dot{x} = v \quad (1b)$$

Equations (1a) and (1b) can be solved analytically for  $v$  and  $x$ , for  $t \in [t_i, t_{i+1})$ , giving:

$$v(t) = -g \cdot (t - t_i) + v_i \quad (2a)$$

$$x(t) = -\frac{1}{2}g \cdot (t - t_i)^2 + v_i \cdot (t - t_i) \quad (2b)$$

Since at  $t_{i+1}$  the ball hits the ground (that is,  $x = 0$ ), we must have:

$$0 = -\frac{1}{2}g \cdot (t_{i+1} - t_i)^2 + v_i \cdot (t_{i+1} - t_i) \quad (3)$$

From (3) we deduce the duration of the  $i^{\text{th}}$  flight (notice that it only depends on the velocity of the ball at  $t_i$ ):

$$t_{i+1} - t_i = \frac{2}{g}v_i \quad (4)$$

Also, from (2a) and (4), we deduce that:

$$\lim_{\substack{t \rightarrow t_{i+1} \\ t < t_{i+1}}} v(t) = -v_i \tag{5}$$

It follows that:

$$v_{i+1} = 0.8v_i \tag{6}$$

From (4), (5) and (6), we deduce the total duration of all flights until the  $n^{\text{th}}$  bounce, for any  $n \geq 0$ :

$$\begin{aligned} t_n - t_0 &= \sum_{i=0}^{n-1} t_{i+1} - t_i = \frac{2}{g} \sum_{i=0}^{n-1} v_i = \frac{2v_0}{g} \sum_{i=0}^{n-1} 0.8^i \\ &= \frac{2v_0}{g} \cdot \frac{1 - 0.8^n}{1 - 0.8} \end{aligned} \tag{7}$$

Finally, we conclude from (7) that:

$$\lim_{n \rightarrow \infty} t_n - t_0 = \frac{10v_0}{g} = 1 \tag{8}$$

In other terms time *converges*, meaning that the lifespan of the model is finite! This unexpected result is a manifestation of the *Zeno effect* which prevents the model from moving forward in time past the convergence limit, called the *Zeno point*. As a consequence, simulating a physical model past its Zeno point—which solvers kindly accept to do, as illustrated on Figure 1—means that we are no longer executing the alleged semantics of our favourite modelling language: we are observing a *free and necessarily wrong interpretation* of our program by the simulation tool. This is extremely embarrassing since Zeno effects cannot be spotted during simulation and since many practical models contain *abstraction mechanisms* such as Modelica’s *reinit* operator, conditional equations, etc., whose composition is known to yield such issues: how to prove that we are not actually running a model out of its actual time domain?

### 2.3 Discussion of the example

Physical system theorists may argue that the issue with our bouncing ball model comes from the usage of inappropriate abstraction mechanisms. Indeed, application of a classical energetic approach (such as the standard Bond Graph for instance) instead of the more direct equation-based approach would have naturally lead to a time-diverging model: from this point of view, a bouncing ball model is no more than a damped *oscillator*, whose solution exhibits an exponential decay as time diverges.

However, in practice, the price to pay to benefit from the virtues of energetic modelling is often too

high in terms of model complexity. Applied to our example for instance, such an approach would force us to express contact with the ground in a more detailed fashion (typically, by means of modulated C and R elements in Bond Graph, which poses the additional problem of finding an adequate modulation constraint). Quite often, we do not *know enough* of the phenomena to be able to write meaningful high-fidelity equations.

Furthermore, simulation performance may suffer dramatically from excess modelling details. For instance, if we simulate our original bouncing ball model with a solver based on the Trapezoidal rule (which is an order 2 method) we see that it performs very well (this is not very surprising since the flight trajectory is a parabola). On the other hand, performance dramatically collapses when the same solver is given a detailed version of the bouncing ball model. Interestingly, a closer look at the performance profile reveals that most of the CPU time is spent in solving the contribution of additional details of the high-fidelity model, which correspond precisely to the phenomenon we wanted to abstract away! Experimenting with real-world models brings us to similar conclusions: abstraction mechanisms help focusing on important parts of models, making the result often simpler and more efficient (but error-prone).

So it seems that we have to live with “dirty” abstractions: does it mean that we also have to accept unsound semantics for the sake of performance and simplicity? Fortunately no, as shown in the next sections: remember that our conclusions follow the initial premise assuming a time model based on  $\mathbb{R}$ .

### 2.4 Non-standard approach

A closer look at (7), which actually represents the *work* performed by our bouncing ball model in the course of the simulation, reveals the profound cause of our problem: we are assuming that *any* countable family of joined, nonempty sub-intervals (our  $[t_i, t_{i+1})$ ) eventually partitions any simulation interval. Of course, this property does not hold: it would be equivalent to assuming that the sum of the terms of *any* sequence of positive reals would certainly diverge.

How could it be possible to define an operational semantics that would ensure time divergence even in presence of behavioural abstractions? Let us make the following experiment: We successively apply the fixed-step forward Euler method (see Listing 2) to our bouncing ball model with decreasing step sizes, as shown in Figure 2. We observe progressively better

approximations of the solution, since the problem is stable and since we can find a step size that ensures stability of the method itself. Notice that since we have chosen a fixed-step scheme, the process of simulation simply cannot exhibit Zeno effects: it terminates after at most  $\lceil \frac{t_{end}-t_0}{h} \rceil$  steps, where  $h$  is the step size.

So why not define step-by-step calculation of the *ideal* trajectories generated by models—which is what operational semantics of hybrid systems is all about—in terms of the standard forward Euler method? The reason is that whatever the step size we choose this method only gives *approximations* of the trajectories of interest. Furthermore, as small as a candidate step size would be, it would always be possible to forge models that would require a smaller one, for instance, linear models having eigenvalues large enough to make the solution unstable and divergent (the first slope on Figure 2 shows the behaviour of the method in such a situation).

Notice also that this reasoning applies to *any* numerical integration method, not only forward Euler. The point is: numerical methods have to perform steps and there is no smallest possible step that would fit *all* models.

In order to define our reference calculation steps, we would have to choose a step that would be smaller than any positive real number. Furthermore, this reference step would have to be *positive* to ensure time divergence. This is precisely the definition of a *positive infinitesimal*, as these have been used in 17th and 18th centuries by mathematicians and physicists such as Leibniz and Newton.

The common idea of real numbers was different from the modern one. For instance, to compute the derivative of a given function  $f(x)$ , one would consider the *increment* of this function given an infinitesimal increment  $dx$  to  $x$ . Thus the derivative  $f'(x)$  was defined by setting

$$f'(x) = \frac{f(x+dx) - f(x)}{dx}.$$

For example, applying this reasoning to  $f(x) = x^2$ , one obtains the following computation

$$f'(x) = \frac{(x+dx)^2 - x^2}{dx} = \frac{2x dx + dx^2}{dx} = 2x + dx \approx 2x,$$

where the last relation signifies that  $dx$ , being infinitesimal, *vanishes* in the final expression.

The notion of infinitesimal was formalised in 1960s by Robinson (see [15]), by defining a set  ${}^*\mathbb{R}$  of *non-standard reals*, which is an ordered field extension of

Figure 2: Simulation results for the bouncing ball model using forward Euler on  $[0, 1.1]$  with step sizes 0.1, 0.01,  $10^{-3}$  and  $10^{-6}$  respectively (altitude of the ball).

$\mathbb{R}$  that contains all usual real numbers, but also the *infinitesimal* reals and their inverses, which are the *infinitely great* reals, i.e. those with an absolute value strictly greater than any usual real number  $r \in \mathbb{R}$ . One also speaks of *finite* (or *limited*) reals  $x$ , such that  $|x| < y$  for *some* positive  $y \in \mathbb{R}$ ;

In particular, two non-standard real numbers  $x$  and  $y$  are said to be *infinitely close* (denoted by  $x \approx y$ ) if and only if  $x - y$  is infinitesimal.

Among all non-standard real numbers, one can, of course, consider the set  ${}^*\mathbb{Z}$  of *non-standard integers* that, on top of standard integers, contains infinitely great ones, having absolute value greater than any  $n \in \mathbb{N}$ . Similarly, it is possible to define the set of non-standard natural numbers  ${}^*\mathbb{N}_0$  (including zero).

The field  ${}^*\mathbb{R}$  of non-standard reals has been used by several authors to define operational semantics of continuous and hybrid systems [1, 2, 12, 16]. The key idea is to *change the definition of time*, by replacing standard reals with a subset of *non-standard* ones.

The proposal in [2, 16] consists in defining time as:

$$\mathbb{T} \stackrel{def}{=} \{ \varepsilon \cdot n \mid n \in {}^*\mathbb{N}_0 \} \quad (9)$$

for *some* reference positive infinitesimal  $\varepsilon$  (notice that *any* positive infinitesimal fits our constraints). It should be noted that  $\mathbb{T}$  contains arbitrary large numbers: in particular, it is possible, given any positive real  $t$ , to find  $n \in {}^*\mathbb{N}_0$  such that  $\varepsilon \cdot n$  is greater than  $t$ . This property is due to  ${}^*\mathbb{R}$  being Archimedean in the non-standard sense<sup>2</sup>, as shown in [2]. Also, it should be noted that although  $\mathbb{T}$  may contain absolutely no standard real (for some “unfortunate” choice of  $\varepsilon$ ), it is possible to *approximate* any standard real  $x$  by a non-standard real of the form  $\varepsilon \cdot n$  such that:

$$|x - \varepsilon \cdot n| < \varepsilon$$

which means that the error committed in the approximation is *negligible* in comparison to any positive element of  $\mathbb{R}$  (recall that  $\varepsilon$  is a positive *infinitesimal*).

We are now ready to define the meaning of a differential equation:

$$\dot{x} = f(x, t) \stackrel{def}{=} x_{next} = x + \varepsilon \cdot f(x, t) \quad (10)$$

where:

- $\varepsilon$  is the reference time step introduced in (9);
- $x_{next}$  is the “next” value of  $x$ , that is  $x(t + \varepsilon)$ .

<sup>2</sup>It can be shown, however, that  ${}^*\mathbb{R}$  is *not* Archimedean in the standard sense, because of the existence of infinite elements.

Listing 2: A Haskell program implementing the forward Euler method to the bouncing ball model.

```
euler t0 tEnd (v0, x0) h = step 0 (v0, x0)
  where
    step i (vNow, xNow)
      | tNow > tEnd = []
      | otherwise =
          (tNow, xNow) : step (i + 1) (vNext, xNext)
    where
      tNow          = t0 + h * fromInteger i
      (vNext, xNext) = advance tNow (vNow, xNow)
    advance _ (vNow, xNow)
      | xNow < 0.0 = (-0.8 * vNow, 0.0)
      | otherwise = (vNow - h * 10.0, xNow + h * vNow)
```

Why would an operational semantics based on (9) and (10) prevent Zeno effects? For exactly the same reason why standard forward Euler method prevents them: because time is forced to advance by fixed—although infinitesimal—steps and because the non-standard Archimedean property of  ${}^*\mathbb{R}$  allows arbitrarily large times to be overstepped.

However, we are not completely done yet. Indeed, due to the multiplication by  $\varepsilon$  in (10), our operational semantics maps time instants as well as values of real signals to *non-standard* reals, although we would like our models to eventually yield standard real values. Fortunately, any limited non-standard real can be *uniquely* represented as the sum of their standard and infinitesimal parts [2, 12, 16]. All we need to do is to eventually discard infinitesimal parts of non-standard reals in order to construct our final standard signals.

Operational semantics based on this idea lead to *uniform* treatment of discrete and continuous dynamics: differential equations, reset equations (e.g. Modelica’s *reinit* operator) and difference equations are actually all treated as non-standard difference equations.<sup>3</sup> As an illustration of this, the program of Listing 2 implements the operational semantics of our bouncing ball model, provided

- $v0$  and  $x0$  are standard reals and  $h$  is an arbitrary infinitesimal;
- integers (used as step indexes) are non-standard;
- infinitesimal parts of the output are discarded.

Notice that, past  $t = 1$ , as experiments with standard Euler method suggest, the ball sticks to the ground—more exactly, standardisation of the model’s variables

<sup>3</sup>It is interesting to contrast this uniformity with Modelica’s informal semantics as given in the current language specification.

Figure 3: Velocity of the ball on  $[0, 1.1]$  resulting from interpretation of the bouncing ball model with non-standard semantics.

yields two standard functions of time which map every  $t \geq 1$  with zero. Indeed, from (6) we know that the standard part of  $v$  converges to zero as  $t$  converges to 1. It follows that for every  $t \geq 1$ , dynamic equations of the model, as a consequence of (10), only produce infinitesimal values since the product of  $\varepsilon$  by any limited real yields an infinitesimal number.

### 3 Behavioural abstraction issues

As shown in [1, 2], operational semantics built on time model (15) successfully explain the behaviour of programs like the bouncing ball model of Listing 1—even beyond  $t = 1$ . In particular, abstraction of the bounce phenomenon meets our expectations: velocity and altitude *instantaneously* take an explicitly specified value at bounce time and then *continuously* evolve from this new starting point until the next bounce.

It should be noted that, in this model, while altitude keeps its continuous character around bounce instants, velocity *loses* it, as illustrated in Figure 3. Nevertheless, interpretation of the bouncing ball model remains satisfactory with respect to the requirements which only demand a high-fidelity behaviour between bounces and a correct (and instantaneous) repositioning of velocity and altitude at bounce time for the next flight to start.

However, as shown below, loss of continuity due to abstraction may cause practical models of systems to fail unexpectedly.

#### 3.1 A problematic example

We consider in Listing 3 a simple fuse sub-model, which behaves like an electrical switch that is closed by default but that can eventually become open if the branch current exceeds a limit.

Listing 3: A fuse sub-model, in Modelica.

```
import Modelica.Electrical.Analog.*;

model Fuse
  extends Interfaces.OnePort;
  parameter Real iMax;
  parameter Real Ron;
  parameter Real Roff;
  protected Real R;
  protected Boolean on;
  initial equation
    on = true;
  equation
    when i > iMax then
      on = false;
    end when;
    R = if on then Ron else Roff;
    v = R * i;
end Fuse;
```

Figure 4: An electrical circuit using two instances of the fuse sub-model defined in Listing 3.

Listing 4: A ramp voltage source sub-model, in Mod-  
 elica.

```

import Modelica.Electrical.Analog.*;

model RampVoltageSource
  extends Interfaces.OnePort;
  parameter Real startTime;
  parameter Real k;
  parameter Real vMax;
  equation
    v =
      if time >= startTime then
        min(k * (time - startTime), vMax)
      else 0.0;
  end RampVoltageSource;
    
```

Using this sub-model, we build a model of the system shown in Figure 4, which is composed of a ramp voltage source (defined in Listing 4), two fuses and a simple linear resistor, in series. We suppose in this model that the fuses have *distinct* rated currents. Notice that, according to the definition of the fuse sub-model, the time required by a fuse to break the circuit is negligible with respect to the time required by the ramp voltage source to reach its maximum value<sup>4</sup>.

Suppose we are given these parameter bindings:

$$\text{src.startTime} = 0.1 \quad (11a)$$

$$\text{src.k} = 2 \quad (11b)$$

$$\text{src.vMax} = 1 \quad (11c)$$

$$\text{f1.iMax} = 0.005 \quad (11d)$$

$$\text{f1.Ron} = 10^{-6} \quad (11e)$$

$$\text{f1.Roff} = 10^6 \quad (11f)$$

$$\text{f2.iMax} = 0.006 \quad (11g)$$

$$\text{f2.Ron} = 10^{-6} \quad (11h)$$

$$\text{f2.Roff} = 10^6 \quad (11i)$$

$$\text{r.R} = 100 \quad (11j)$$

and this initial state:

$$\text{time} = 0 \quad (12a)$$

$$\text{f1.on} = \text{T} \quad (12b)$$

$$\text{f2.on} = \text{T} \quad (12c)$$

According to our non-standard semantics, we have to solve the following dynamic equations to determine

<sup>4</sup>This property is enforced by the use of a *when* clause in the definition of the fuse sub-model in Listing 3.

the dynamic behaviour of our model:

$$\text{src.v} = \begin{cases} \min(2(\text{time} - 0.1), 1) & \text{if } \text{time} \geq 0.1 \\ 0 & \text{otherwise} \end{cases} \quad (13a)$$

$$\text{src.i} = i \quad (13b)$$

$$\text{f1.R} = \begin{cases} 10^{-6} & \text{if } \text{f1.on} \\ 10^6 & \text{otherwise} \end{cases} \quad (13c)$$

$$\text{f1.v} = \text{f1.R} \cdot i \quad (13d)$$

$$\text{f1.i} = i \quad (13e)$$

$$\text{f2.R} = \begin{cases} 10^{-6} & \text{if } \text{f2.on} \\ 10^6 & \text{otherwise} \end{cases} \quad (13f)$$

$$\text{f2.v} = \text{f2.R} \cdot i \quad (13g)$$

$$\text{f2.i} = i \quad (13h)$$

$$\text{r.v} = 100i \quad (13i)$$

$$\text{r.i} = i \quad (13j)$$

$$\text{time}_{\text{next}} = \text{time} + \varepsilon \quad (13k)$$

$$\text{f1.on}_{\text{next}} = \text{f1.on} \wedge \neg(i > 0.005) \quad (13l)$$

$$\text{f2.on}_{\text{next}} = \text{f2.on} \wedge \neg(i > 0.006) \quad (13m)$$

where

$$i = \frac{\text{src.v}}{100 + \text{f1.R} + \text{f2.R}} \quad (13n)$$

Notice that this model has *three* state variables, namely *time*, *f1.on* and *f2.on*, hence the three non-standard difference equations (13k), (13l) and (13m).

Figure 5 shows the corresponding results. Notice that, as expected, only the first fuse melts (see second slope in Figure 5) since its rated current is lower than that of the first fuse (see (11d) and (11g)).

In this first experiment, only the behaviour of fuses has been abstracted away by considering their melt duration to be negligible with respect to the raise duration of the ramp source. But what happens if we also abstract the behaviour of the ramp source, considering its raise duration negligible with respect to the entire operating duration of the system?

Abstracting the ramp source in this context means replacing it with a *step* source, leading to a new system of dynamic equations, where (13a) is replaced with:

$$\text{src.v} = \begin{cases} 1 & \text{if } \text{time} > 0.1 \\ 0 & \text{otherwise} \end{cases} \quad (14)$$

Figure 5: Solution of (13) with parameter bindings (11) and initial state (12).

Figure 6: Solution of the system of dynamic equations resulting from the abstraction of the ramp voltage source.

Figure 6 shows the corresponding results. We can see that *both* fuses melt as a consequence of the raise of the voltage source signal. This fact contradicts our initial assumption of a model where only one fuse may melt, if ever. This last experiment has shown that an operational semantics based on a global, fixed infinitesimal step does not preserve *strict ordering* of events when behavioural abstractions are composed.

### 3.2 Conclusions from the experiments

The reason why we observe an accidental synchronisation of events after abstracting the behaviour of the ramp voltage source is that the time-line is “running out of available free slots” where to insert possible intermediate events. In our example, events corresponding to melts, whenever they eventually occur, must necessarily do so *strictly before* the ramp signal of the voltage source reaches its maximum value.<sup>5</sup> However, in a fixed-step non-standard operational semantics, when a standard difference equation is activated

<sup>5</sup>Because it is the voltage raise itself, after its “conversion” to current through the load  $r$ , that triggers an eventual melt.

to reset the value of a state variable, or when a conditional equation switches (as in our example), new values are scheduled for the *next* instant, leaving no room for possible intermediate events to occur during this transition. So it seems that we should *densify* time in the neighbourhood of “urgent” actions.

## 4 Proposed semantic model

In this section, we introduce some basic notions that will be used to construct our model of a signal as well as defining the meaning of a differential equation.

We suppose given a positive infinitesimal real  $\varepsilon$  that we call the *real activity threshold*. Notice that, contrary to traditional fixed-step simulation, the semantics of the system is independent from the specific choice of  $\varepsilon$ .

For  $r \in {}^*\mathbb{R}$ , we denote  $r + \varepsilon \cdot {}^*\mathbb{Z} \stackrel{def}{=} \{r + \varepsilon \cdot k \mid k \in {}^*\mathbb{Z}\}$ , where  ${}^*\mathbb{Z}$  is the set of non-standard integers. We define the base time-line  ${}^*\mathbb{T}$  as the non-negative values of  ${}^*\mathbb{R}$ :

$${}^*\mathbb{T} \stackrel{def}{=} {}^*\mathbb{R}_0^+ \quad (15)$$

Thus,  ${}^*\mathbb{T}$  is a *linear continuum* (under the standard temporal order  $<$ ), which contains all non-negative standard real numbers. An *instant* is an element of  ${}^*\mathbb{T}$ . In particular, we have non-standard instants.

Notice that, contrary to [1, 2, 16], we propose here a base time-line that is neither discrete, nor well-ordered. However, since  ${}^*\mathbb{T}$  is *densely ordered*, intermediate instants exist between any two given distinct instants.

The question that arises now is: how to recover discreteness (as required to express the notion of *next* instant) as well as time divergence? The key idea lies in a *generalisation* of the usual concept of *clock* as encountered in synchronous languages.

### 4.1 Time, signals and dates

#### 4.1.1 Time

A *time signal*  $t$  with the initial value  $t_0 \in {}^*\mathbb{R}$  is defined as the following right-continuous step map:

$$\begin{aligned} t : {}^*\mathbb{T} &\rightarrow t_0 + \varepsilon \cdot {}^*\mathbb{Z} \\ \tau &\mapsto t_0 + \varepsilon \cdot n_\tau \end{aligned} \quad (16)$$

with

$$n_\tau = \left\lfloor \frac{\tau}{\varepsilon} \right\rfloor \in {}^*\mathbb{N}_0$$

where  $\lfloor \cdot \rfloor$  denotes the non-standard floor function.

In particular, for any  $\tau \in \mathbb{R}_0^+$  we have:

$$st(t(\tau) - t_0) = \tau$$

meaning that the standardisation of  $t$  coincides with a standard time signal that would start from  $st(t_0)$ .

By definition, a *date* is an element of the co-domain of a time signal.

Notice the fundamental change of perspective with respect to [1, 2, 16]: instead of discretising the *domain* of the time signal, we discretise its *co-domain*. Thus, we can associate a discrete and well-ordered set of dates with a time signal, despite its densely ordered domain. Notice also that dates and instants are different concepts: while instants are densely ordered, dates are not. In the next sections, we show how to extend this idea to *any* signal.

### 4.1.2 Signals

We call a (*non-standard*) signal  $x$  a map from a subset of  ${}^*\mathbb{T}$ —the *domain* of the signal, denoted  $\text{Dom}x$ —to a *discrete* set—its *co-domain*, denoted  $\text{Codom}x$ . A signal maps instants to *values*.

We distinguish two families of signals:

**discrete-time signals** have their domain (called their *clock*) in a discrete subset of  ${}^*\mathbb{T}$ ;

**dense-time signals** are right-continuous step signals, whereof the domain is  ${}^*\mathbb{T}$ .

A few remarks can be made regarding this taxonomy:

- We do not require zero (i.e. the least element of  ${}^*\mathbb{T}$ ) to belong to the domain of a discrete-time signal: zero is only guaranteed to be a lower bound of the domain. In other terms, the birth instant of a discrete-time signal does not necessarily coincide with the birth instant of the model.
- Physical signals introduced in [1, 2] belong to the *discrete-time* family of signals.
- In some sense, compared with [2], we loose some uniformity by introducing two kinds of signal domains, with distinct topologies. However, practical implementations of modelling languages have to make a semantic distinction between signals at some point (to avoid ill-posed problems). In [1], for instance, the type system classifies signals in “discrete” and “continuous” ones (although they share the same representation).

Notice that, according to the definition of a signal, the co-domain of any signal is discrete. This raises the question of the representation of *real* signals in general, and *continuous* (or *physical*) signals in particular. We impose the following restrictions:

**real signals** have co-domains of the form  $r + \varepsilon \cdot {}^*\mathbb{Z}$ , where  $\varepsilon$  is the real activity threshold and  $r$  the start value of the signal;

**continuous (or physical) signals** are dense-time real signals that can only change their value by  $\pm\varepsilon$ .

### 4.1.3 Signal activity

The *activity* of a signal  $x$ , denoted  $\text{Act}x$ , is the discrete (possibly finite, but often non enumerable) subset of  $\text{Dom}x$  defined as:

$$\text{Act}x = \{\tau \mid x(\tau^-) \neq x(\tau)\} \quad (17)$$

where

$$x(\tau^-) = \lim_{\substack{\tau' \rightarrow \tau \\ \tau' < \tau}} x(\tau')$$

Intuitively, the activity of a signal can be seen as the set of instants corresponding to its “perceptible changes” from the point of view of an external observer. Notice that we have required the co-domain of signals to be discrete: this implies that the activity of a signal  $x$  contains *all* the instants at which “something happened” to  $x$  from an external observer point of view, whatever the accuracy of the measure.

## 4.2 Differential equations

If one assumes the existence of a *maximal* clock such as

$$\{\varepsilon \cdot n \mid n \in {}^*\mathbb{N}_0\}$$

then the sole concept of non-standard *difference equation* suffices to express dynamic behaviour of models. Indeed, as explained in previous sections, the solution yielded by the (non-standard) forward Euler scheme coincides with the actual, standard solution of the corresponding differential equation, after standardisation. But we have also seen that this uniform approach reaches its limits when composition of abstract models comes into play.

Density of possibly detectable events should be ideally correlated to the behaviour of signals instead of being imposed by a rigid, fixed-step scheme: indeed, more *activity* potentially implies more events.

Also, if one would be able to *predict* the occurrence of an event from the behaviour of the implied

signal(s) instead of waiting for the *next* time instant and then realise that *several* pending events need to be (wrongly) treated simultaneously, one would avoid the issues mentioned in previous sections.

The key idea is to define differential equations in such a way that activity of signals can be predicted, and then to use the concept of activity instead of the concept of clock to represent (mutually desynchronised) event sources. This idea is not new: B. P. Zeigler [17] already introduced most of the necessary concepts in his theory of systems. QSS solvers [5] are practical applications of this theory.

Recall that in [1, 2], the semantics of a differential equation was defined by means of a non-standard version of the forward Euler method, which is the simplest order-one method based on the classical time slicing approach. In the following, we will define the meaning of a differential equation by means of a non-standard order-one QSS-like method and show how this new approach solves behavioural abstraction issues.

Assume that the following are given:

- a non-empty interval  $[\tau_a, \tau_b) \subseteq {}^*\mathbb{T}$ ,
- a non-standard real number  $x_0 \in {}^*\mathbb{R}$ ,
- a non-standard real signal  $y : [\tau_a, \tau_b) \rightarrow y_0 + \varepsilon \cdot {}^*\mathbb{Z}$ .

Then the differential equation

$$\text{der}(x, x_0) := y \quad (18)$$

defines  $x$  on  $[\tau_a, \tau_b)$  as follows.

Let  $(w_i)_{i \in {}^*\mathbb{N}_0}$  be a family of  ${}^*\mathbb{R}$ -valued maps defined as:

$$w_0(\tau) = x_0 + (\tau - \tau_0) \cdot y(\tau_0) \quad (19a)$$

$$w_{n+1}(\tau) = w_n(\tau_{n+1}) + (\tau - \tau_{n+1}) \cdot y(\tau_{n+1}) \quad (19b)$$

where

$$\tau_0 = \tau_a \quad (20a)$$

$$\tau_{n+1} = \text{Inf}_{[\tau_a, \tau_b)} \left( \{ \tau \mid \tau > \tau_n \wedge \text{event}_n(\tau) \} \cup \{ \tau_b \} \right) \quad (20b)$$

and

$$\begin{aligned} \text{event}_n(\tau) = & \\ & (\tau \in \text{Act}y) \vee \\ & \left( (w_n(\tau) \in x_0 + \varepsilon \cdot {}^*\mathbb{Z}) \wedge (w_n(\tau) \neq w_n(\tau_n)) \right) \end{aligned} \quad (21)$$

Defining the co-product

$$w = \bigoplus_{i \in {}^*\mathbb{N}_0} w_i \Big|_{[\tau_i, \tau_{i+1})} \quad (22)$$

then, finally:

$$\begin{aligned} x : [\tau_a, \tau_b) &\rightarrow x_0 + \varepsilon \cdot {}^*\mathbb{Z} \\ \tau &\mapsto w(\text{last}(\tau)) \end{aligned} \quad (23)$$

where

$$\begin{aligned} \text{last}(\tau) = & \\ \text{Sup}_{[\tau_a, \tau_b)} \{ \tau' \mid \tau' \leq \tau \wedge w(\tau') \in x_0 + \varepsilon \cdot {}^*\mathbb{Z} \} & \end{aligned} \quad (24)$$

The idea is the following:

- $w$  represents the “private” behaviour of the defined signal  $x$ : starting from  $x_0$  at  $\tau_a$ , it evolves linearly between two consecutive event instants ((19a) and (19b)) until  $\tau_b$ ;
  - as stated by (21), events affecting the behaviour of  $w$  have two possible causes:
    - $y$  (defining the right-hand side of the differential equation) has evolved perceptibly, i.e. its value has drifted by  $\pm\varepsilon$ , since the previous event (including initialisation),
    - $w$  itself has evolved perceptibly since the previous event (including initialisation);
  - each time an event affecting  $w$  occurs, its gradient is reevaluated, then  $w$  evolves linearly until the next event;
  - the “public” behaviour of  $x$  (i.e. as seen by an external observer) is a piece-wise constant approximation of its “private” behaviour  $w$  such that both maps coincide at event instants corresponding to perceptible changes of  $w$ , as stated by (24).
- Figure 7 illustrates the process (the  $w_i$  appear as black linear slopes, and  $x$  is the blue slope):
- blue bullets indicate events resulting from the evolution of  $w$  itself;
  - red bullets indicate events resulting from the evolution of  $y$  (notice that they are not necessarily “synchronised” with  $\varepsilon$ -steps);
  - green bullets indicate “skipped targets” (i.e. events that would have resulted from the sole evolution of  $w$  but that have been “intercepted” by an event caused by  $y$ ).

Figure 7: Semantics of a differential equation.

Notice that we have defined the semantics of a differential equation on an interval of the form  $[\tau_a, \tau_b)$  instead of defining it on the whole time-line  ${}^*\mathbb{T}$ . The reason is that we want differential equations to be defined modularly, as required in particular by behavioural abstraction: it should be possible to define signals where ideal phases alternate with high-fidelity ones.

Clearly, the set of continuous signals is closed under the application of continuous functions. Therefore any family of signals defined solely by means of differential equations and by algebraic constraints like

$$y = f(x_1, \dots, x_n) \quad (25)$$

only contains continuous signals. Regarding (25) we have in particular:

$$\text{Act}y \subseteq \text{Act}x_1 \cup \dots \cup \text{Act}x_n \quad (26)$$

meaning that such an algebraic constraint acts as an “activity filter”.

### 4.3 Behavioural abstraction support

Below, we suppose given an additional positive infinitesimal constant  $\delta$ .

We model a reset equation constraining a continuous signal  $x$  on  $[\tau_a, \tau_a + \delta)$  by means of the following differential equation:

$$\text{der}(x, x_0) := \frac{x_1 - x_0}{\delta} \quad (27)$$

where  $x_0$  is the value of  $x$  at  $\tau_a$ , and  $x_1$  is the “target value” to be reached by  $x$  at  $\tau_a + \delta$  as a result of the reset operation.<sup>6</sup>

<sup>6</sup>In Modelica, this is given by the second argument of `reinit` (see Listing 1 for an example).

Notice that the right-hand side of (27) is constant and infinite. By the definition of a differential equation given in Section 4.2,  $x$  reaches  $x_1$  (more precisely: the first element of  $x_0 + \varepsilon \cdot {}^*\mathbb{Z}$  that is greater than or equal to  $x_1$ ) after  $\delta$  units of time (i.e. the length of  $[\tau_a, \tau_a + \delta)$ ). Notice that this definition of a reset equation involves a *duration* (i.e. the time spent by the signal to reach its target value). Since this duration is infinitesimal, we actually observe the desired behaviour: the reset is infinitely fast compared to any standard phenomenon.

Recall, however, that we want to support proper composition of such abstraction mechanisms. In order to refine the above definition to achieve this goal, we first associate with each continuous signal defined in the model an *abstraction level*  $n \in \mathbb{N}_0$ <sup>7</sup> which represents the maximal number of nested reset equations that might contribute to the definition of the signal:

- a independent signal that is not reset in the model has the abstraction level 0;
- a signal that is reset in the model by equations involving only signals whose abstraction level is at most  $n - 1$  has abstraction level  $n$ ;
- a signal that is defined by an algebraic constraint inherits the highest abstraction level among those of the signals appearing in its definition.

Notice that, in a language implementing our semantic model, the abstraction level defined as above can always be statically computed by elementary data-flow analysis for an arbitrary model without circular dependencies between reset equations.

We are now in the position to refine (27) as follows. A signal  $x$  with abstraction level  $n$  and the current value  $x_0$  is reset to  $x_1$  at  $\tau_a$  by means of the following differential equation activated on  $[\tau_a, \tau_a + \delta^n)$ :

$$\text{der}(x, x_0) := \frac{x_1 - x_0}{\delta^n} \quad (28)$$

The idea is that signals with higher abstraction levels should reset infinitely faster than others: by taking successive powers of  $\delta$ , we achieve precisely this effect.

What about the Zeno effect under behavioural abstraction in such a semantic model?

Notice that we can assume that continuous signals do not diverge in value during integration (otherwise the model is considered singular) and let the highest level of abstraction in a given model be  $n$ . By (28), this

<sup>7</sup>A standard natural number.

means that in this model, the fastest reset terminates in  $\delta^n$  units of time. Hence, integration of each signal terminates in at most  $\lceil (\tau_{end} - \tau_0) / \delta^n \rceil$  steps, where  $\tau_0$  and  $\tau_{end}$  denote respectively the start time and the end time of the integration. Thus, provided that the maximum abstraction level in the model is finite, continuous signals always diverge in time.

#### 4.4 Application Example

Let us consider again the model of Figure 4, where we suppose that the behaviour of the voltage source and of the fuses have been abstracted. How does our proposal fare in such a case?

Before we answer this question, we need to examine the case of conditional equations.

Conditional equations are used to express “mode changes” in physical models, typically leading to equation *switching*, as in our electrical model example. As a consequence, conditional equations potentially lead to the exact same issues encountered with reset equations. Same symptoms, same medication: we just need to find a way to introduce the concept of infinitely fast transition in the semantics of conditional equations. This is achieved as follows.

Suppose that  $c : *T \rightarrow \{F, T\}$  is a boolean signal whose value is F until the event instant  $\tau_0$ , after which it takes the value T. Suppose also that  $x : *T \rightarrow x_0 + \varepsilon \cdot *Z$  and  $y : *T \rightarrow y_0 + \varepsilon \cdot *Z$  are two given physical signals. Then the semantics of a conditional real function can be defined as:

$$\text{if } c \text{ then } x \text{ else } y \stackrel{def}{=} \lambda \cdot x + (1 - \lambda) \cdot y \quad (29)$$

where

$$\lambda = \begin{cases} 0 & \text{on } \{\tau \mid \tau \leq \tau_0\} \\ \frac{\tau - \tau_0}{\delta} & \text{on } \{\tau \mid \tau_0 < \tau \leq \tau_0 + \delta\} \\ 1 & \text{on } \{\tau \mid \tau > \tau_0 + \delta\} \end{cases} \quad (30)$$

It can easily be shown that signals defined by conditional real functions are continuous signals.

Coming back to our example, what happens when the voltage source makes a step? The voltage  $\text{src.v}$  gradually evolves from its start value 0 to its maximum value 1. During the rise, it traverses the surface corresponding to

$$\text{src.v} = f1.iMax \cdot (r.R + f1.R + f2.R)$$

because, given our parameter settings and the values of the internal resistances of both fuses before the first melt, we have:

$$f1.iMax \cdot (r.R + f1.R + f2.R) = 0.500000001$$

Figure 8: Solution of the system of dynamic equations resulting from the abstraction of the ramp voltage source.

which belongs to  $[0, 1]$ .

But, according to (13n), this is precisely the voltage required to induce a current equal to the rated current of f1 in the circuit. Consequently, f1 melts, but not f2. Figure 8 illustrates the result of interpreting the model with our semantics.

## 5 Conclusion and Future Work

In this paper, we have extended the pioneer work of [2, 16] by proposing a non-standard operational semantics supporting compositional behavioural abstraction. As demonstrated by [1], non-standard semantics can be used to give rigorous interpretation of hybrid modelling languages such as Modelica.

The most obvious practical application of our work would certainly be the design and development of a simulator that would conform to our semantic model: one of us (S. Furic) is currently working in this direction in the course of the French funded project AGéSys.

## 6 Acknowledgements

We are indebted to Albert Benveniste, Benoît Caillaud, Marc Pouzet and Timothy Bourke for having launched the topic: their impressive work and their availability for exchanging on modelling language semantic topics has greatly helped us in this work. Many thanks also to Ramine Nikoukhah, for his help in understanding hybrid modelling issues and for having brought to our attention the central role of some synchronous language concepts, especially those of the SIGNAL language. Many thanks also to Belgacem Ben Hedia and to Étienne Hamelin, from CEA for the many interesting discussions. This paper results in large parts from the

fruitful collaboration between CEA and LMS Imagine in the course of the ITEA2 project OpenProd.

Ernst-Reuter-Platz 7, 10587 Berlin

## Abstract

This paper introduces a rocket model and discusses the advantages of refining it using a variable-structure approach to remodel critical parts. Both versions of the model are implemented in Modelica and were simulated using Dymola as simulation environment. The DySMo framework, which supports the simulation of variable-structure models in common simulation environments, was used to facilitate the redesign. The general benefits of the variable-structure approach are presented, and on the basis of the rocket model we present that simulation time and the data volume of the simulation can be reduced while maintaining the accuracy of the simulation results.

*variable-structure modeling, simulation speed, data reduction, reduce equation stiffness, rocket launch*

## 1 Introduction

In this paper, we regard the benefits of modeling a moon bound rocket using variable-structure to increase the simulation speed and to reduce the amount of saved simulation data.

The aim of our simulation is to predict the trajectory of the rocket, beginning with the ignition on earth's surface up until it reaches the moon as destination. The rocket is multi-staged, and as such consists of three booster modules and a payload module without means of propulsion. The model takes into account the chemical reactions in the boosters combustion chambers, which generate the thrust, the gravity of both earth and moon as well as atmospheric influences. First, we introduce a classical implementation of the model, which we will then compare to a redesigned version that uses the variable-structure approach.

The classical model calculates all components during the entire simulation. However the time frame

of the chemical reactions and of the rocket's movement are very different, which results in a stiff system of equations. This stiff equation system necessitates small step sizes, although a great part of the equation set would permit rather large time steps. Additionally, the chemical reactions only need to be calculated as long as the thrust of the rocket has not reached a steady state.

As a result, the simulation of the classical model generates an exceeding overhead of unnecessary simulation data and calculations. The ability to enable and disable equations during runtime, holding certain values constant for a given period of time, would allow to reduce this overhead. However, Modelica requires a constant set of equations and does not allow to change the equation system while simulating. All equations have to be solved during the whole simulation. In special cases and with the use of some workarounds the equation system can be manipulated to a certain degree, but not in the extend we want to use in this paper.

In section 2, we introduce the concept of variable-structure models and discuss different approaches to implement and simulate them. We will then give a detailed overview over the rocket model as well as the redesigned version in section 3. We compare the simulation results of both models, regarding performance and accuracy as well as the volume of generated data, in section 4.

## 2 Variable-Structure Modeling

The aim of variable-structure modeling is to improve models by introducing the means to change their equation and variable set during simulation. This is realized by encapsulating certain sets of equations and variables into different models, to which we refer as *modes*, and implementing a way to switch between them. Each transition is triggered by a predefined

switching condition. The mode switch is then realized by storing the end values of certain variables and using them to initialize variables of the next mode. The decision, which end values are used to initialize variables of the subsequent mode, has to be made by the modeler.

Variable-structure models are the topic of numerous publications, although they are often referred to by different names. In [6, 8] they are introduced as 'Multi-models', whereas they are referred to as 'Structurally dynamic systems' in [4] and 'Variable structure systems' in [10]. As they feature discrete mode switches as well as continuous equation systems they are often considered a variant of hybrid systems. A noteworthy method of formally specifying hybrid systems is the DEVS formalism, introduced in [9, 7].

Currently, altering the set of equations at runtime is not easily achieved using common Modelica simulation environments, which we want to use for the rocket simulation. However, several approaches to introduce variable-structure to a Modelica model have been devised, an overview is given in [1]. One way is presented in [2], where conditional statements are used to enable and disable certain equations based on disjunct conditions, which distinguish the current mode of the model. Such an approach is classified as *Maximal state space*, as the models state space is static and holds all states regardless of the current mode. This may lead to complicated mode switching procedures, as more than just the equations relevant at the current time have to be taken into account. Additionally, it may prove difficult to add new modes to an existing model. We followed another approach, termed *Hybrid decomposition*, where each mode is implemented as a separate model and the simulation switches between these models based on switching conditions. Mosilab [5] and SOL [10] are two approaches which enable the user to create variable-structure models. But since they are based on own languages it would be necessary to re-implement the rocket model in the specific language. In our approach we want to use common simulation environments. A framework to use common simulation environments is DySMo [3]. This framework is implemented in Python and allows a user to define a variable-structure model. The framework then handles the switches between the different modes automatically. In this framework Simulink, Dymola and OpenModelica are integrated. The communication with the tools is based on a communication interface integrated in Python. New interfaces can easily be added to the framework and then be used as simulation

environments for the variable-structure model.

A basic overview of the sequence used in the framework for switching between different modes is illustrated in Figure 1. Each of the gray boxes is a method defined in the communication interface from the specific simulation environment for the currently active mode.

As a first step, all modes are compiled, which is necessary for the Modelica simulation environments.

When all modes are compiled, the simulation parameters (determining start time, stop time, solver, etc.) are set in the framework.

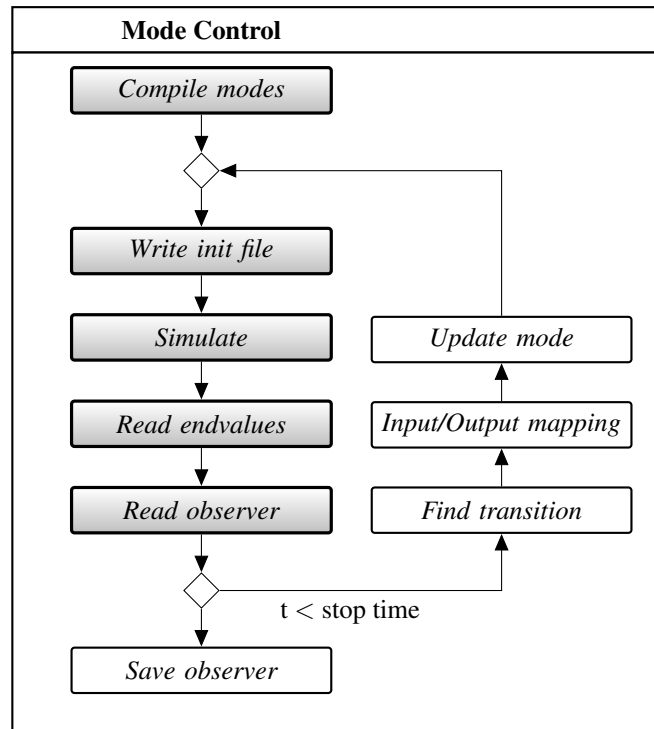

Figure 1: Schematic view of the steps to simulate a variable-structure model in DySMo

After this initial setup, the simulation of the first mode, using the appropriate executable and initialization file, is started. Each mode contains a certain number of stop conditions, which define when a simulation is terminated. When such a stop condition is reached, a variable *switch\_to* is set, which indicates the next mode of the simulation. Then the simulation terminates. The framework now reads the simulation results of the recently terminated simulation, and maps those endvalues to the starting values of the variables of the subsequent mode. Finally, the mode is updated to the new mode and a new simulation is started.

When the final stop time of the simulation is reached, the simulation terminates and the saved sim-

ulation data is stored in a file.

Using DySMo allows us to introduce variable structure to an existing model without having to completely re-model it, as only minor changes have to be made to add the stop conditions and make the desired adjustments to the equation sets of each mode. Furthermore, in certain modes we are able to greatly reduce the state space to only hold the needed information. This approach shown here is of course only suitable and sensible for models with a small number of modes. If many mode switches occur this framework is not suitable and in the future, creating and simulating variable-structure models should be integrated into Modelica or other languages. But since this is not the case yet, we want to illustrate the positive effects these kinds of models have with the DySMo prototype.

### 3 Rocket Model

In this section we introduce the classical as well as the redesigned model in greater detail. Both models were implemented in Modelica and simulated using Dymola. The object-oriented, component-based nature of Modelica allowed us to separate our model into different components which facilitated the variable-structure redesign.

Figure 2: Components of the rocket model and properties that are calculated by them

**Basic mathematical description of the rocket**  
 Since the complete Model consists of many equations, it would be too long to explain all equations in detail. However we give a short overview about the most

important physical laws necessary to create the rocket model.

As the main interest was the trajectory of the rocket, we needed Newton's law of motion

$$F(s, t) = F_{prop} + F_g - F_d = m \cdot \ddot{s}.$$

The remaining task was to determine  $F$ . In our model the force consists of three parts. The aerodynamic drag ( $F_d$ ), the gravitational force ( $F_g$ ) and the propulsive power ( $F_{prop}$ ). The gravitation force is dependent on the planets (*Earth* and *Moon*) and their masses. Also the position and mass of the rocket have an influence.

The aerodynamic drag is essentially

$$F_d = \frac{1}{2} c_w \rho A v^2$$

and is only calculated while the rocket is still in the atmosphere of the earth.

The remaining force is calculated by simulating the combustion of hydrogen in the combustion chamber. Therefore many thermodynamical and chemical laws come into play. We will mention only a few.

It is possible to model the change of concentration during a chemical reaction

with ordinary differential equations

$$\begin{aligned} \dot{C}_A &= -k C_A C_E, \\ \dot{C}_D &= k C_A C_E \text{ etc.} \end{aligned}$$

where

$$k = B T^{n_f} \exp\left(-\frac{E}{RT}\right).$$

Moreover we assume the ideal gas law

$$p = n \frac{RT}{V}.$$

It is then possible to determine the temperature using

$$\rho c_v \frac{dT}{dt} = \sum_{k=1}^r (-\Delta u_k) w_k$$

plus vaporization and heating terms. Here  $\Delta u_k$  is the reaction energy of reaction  $k$ . For a chemical reaction  $i$  where two substances  $A$  and  $B$  react, the coefficient  $w_i$  is defined as  $w_i := k_i C_A C_B$ . This energy leads to pressure which leads to a massflow through a throttle with

a certain velocity. At the end the propulsive power can be calculated with

$$F_{prop} = \dot{m}v.$$

The original and the variable-structure model were separated into different components, namely the rocket body, the propulsion stage and two celestial bodies, as shown in Figure 2. The figure already gives a short overview of what different calculations are necessary in each component.

### 3.1 Original Model

Basically, the rocket body calculates the movement of the rocket by taking into account the forces it is exposed to. The propulsion stage is responsible to calculate the thrust the rocket produces. It contains three booster modules that are used in succession. Each of the booster modules has a specified amount of fuel available and calculates the chemical reactions for the combustion of the solid propellant. This combustion builds up a pressure in the combustion chamber, through which the thrust of the rocket is determined. After starting a new stage the thrust is build up quite fast and afterwards is almost constant. These chemical reactions necessitate the solver to employ very small step sizes, as they take place very rapidly. Whenever the fuel of a booster module runs out, the propulsion stage will reinitialize using the next booster module available. Once the last booster module is emptied, the rocket will no longer generate thrust.

The celestial bodies are used to represent the moon and the earth. They supply the gravitational forces influencing the rocket. Air resistance and wind are also calculated in the earth component, as the rocket is subjected to these while passing through the atmosphere of earth. The moon, however, has no atmosphere, but is used as orientation point for the rocket.

All calculated forces are passed to the rocket body, where the movement of the rocket is calculated. The mass of the rocket changes substantially during the course of the simulation, as fuel is burned up and booster modules are discarded. The current mass of the rocket is determined by adding up the masses of the rocket body component, all remaining booster modules and the remaining fuel. When compared to the chemical reactions calculated in the propulsion stage of the model, the position of the rocket changes at a very slow pace.

The original rocket model takes about 50 seconds to simulate with the Dassel solver. The solver has to resort to a very small step size in order to simulate the

propulsion stage accurately, even though the propulsion is no longer needed after a steady state is reached or once the rocket runs out of fuel. As each simulation step generates data for all variables of the model, the overall data volume of a simulation measures about 1.5GB and postprocessing this data becomes rather tedious work.

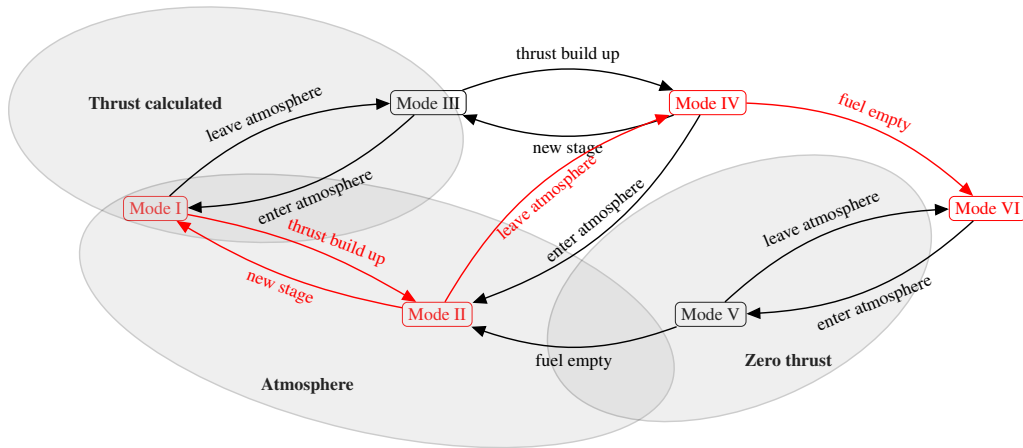

### 3.2 Variable-structure Redesign

When introducing variable structure to a model, the first step is always to identify the modes that are to be implemented, or, to put it another way, to determine in which way the model could benefit from variable structure. As already discussed, the rocket model has a stiff equation set, which necessitates very small step sizes for the simulation to be reasonably accurate. However, only during the ignition of each booster module it is necessary to calculate the chemical reactions inside the combustion chamber with such accuracy. Afterwards, the thrust is almost constant and regarding the chemical reactions is not necessary anymore.

Furthermore, the rocket has to travel a great distance without any thrust at all to reach the moon. The result is that the simulation runs with a very small step size for a long time while the variables feature only minimal changes.

The aim of our redesign is to eliminate this problem by holding the thrust constant once it has fully build up and take the equations for the chemical equations out of the model. After fuel runs out, the rocket either switches to another booster and builds up the thrust anew (regarding the chemical reactions), or it switches to a mode where thrust is assumed as zero if no further rocket stage is available. This leads to three different modes for the propulsion stage: building the thrust by regarding the chemical reactions, having constant thrust, or no thrust at all.

Another improvement is to calculate air resistance only while traveling through earth's atmosphere. This leads to two earth models, one that contains an atmosphere and one that does not. This sums up to six combinations of submodels, and therefore six modes, which are shown in Figure 3. Conditions for transitioning between the modes are also shown. At the bottom of the figure the actually performed mode switches from our model are listed. We can see that at the beginning of the simulation the rocket alternates between the modes I and II. This is due to the fact that only during the last propulsion stage of the rocket it is able to clear the atmosphere and therefore switch to

Mode switches: I -> II -> I -> II -> I -> II -> IV -> VI

Figure 3: Division of the rocket model into six submodels used as modes for the variable-structure redesign

mode IV, which has constant thrust and does not calculate the atmosphere anymore. This mode is active until the rocket's fuel is burnt up, in which case mode VI becomes active and sets the rocket thrust to zero for the remainder of the simulation.

It is noteworthy that, considering the given model, the modes III and V are never used. For mode III to be active the rocket would have to leave the atmosphere when it is in mode I. Meaning that the thrust of the current stage is not build up yet and the rocket left the atmosphere. With the given set of parameters this does not occur and therefore mode III is never used. Mode V is not used either, it would require the rocket to run out of fuel before it leaves the atmosphere, which it does not. We modeled these modes nonetheless, as they could be relevant if the simulation parameters were altered (consider for example starting from the moon which would necessitate mode III).

For the chosen approach, all six modes had to be implemented in Modelica, since Modelica does not allow to specify the necessary changes inside the submodels. Switching conditions were added to each mode, which define the modeID of the next mode and terminate the current simulation. In the DySMo framework the mode switches then have to be defined. This means that the initialization for each transition has to be regarded. For convenience, the modes for the rocket were implemented in such a way that variables are called the same if possible and therefore only a name matching is necessary for each switch. The framework then handles the occurring mode switches automatically and saves the simulation data. Each mode is only compiled once and then the executable is used in case

Figure 4: CPU time needed for the simulation in Dymola

the mode needs to be simulated again (as modes I and II are). This saves execution time since less compilations are necessary and therefore less communication with Dymola.

## 4 Results and Discussion

By redesigning the rocket model in a way that takes advantage of variable-structure modeling we intended to reduce the stiffness of the equation set, to speed up the simulation and to reduce the excessive amount of generated data without losing accuracy. In this section, we will discuss if these goals were reached, as well as the drawbacks of our approach.

Figure 4 shows the needed CPU time of the simulation runs in Dymola. Only the first 180 seconds after the launch of the rocket are shown to visualize the CPU time of the mode switches.

Three different simulation runs can be seen in this figure.

1. original model (black)
2. model with modes I, II, IV and VI
3. model which starts with the original model until the fuel runs out

At the beginning the CPU time is basically the same, the slight alterations could not be avoided. As can be seen the model with the many mode switches is considerable faster than the other ones. This becomes evident when the first switch occurs and the thrust is considered constant.

As can be seen when mode VI is reached only about half the time was needed for the simulation. When mode VI is reached the CPU time's increase is rather insignificant. The CPU time needed is about 0.4 seconds for the entire simulation. The CPU time for the original model increases constantly and needs about 50 seconds for a simulation time of 150 000 seconds.

So far, we only took into account the needed time for the simulation, but we also have to account for the time it takes to switch modes and to compile the additional models. The overall time it takes to simulate the redesigned model including all necessary steps is 4 seconds, of which only 0.4 seconds consist of actually simulating the model. The majority of the time, 3.1 seconds, is used to compile the models in Dymola. The framework, employed to switch between modes, accounts for the remaining 0.5 seconds. Still, the necessary time to simulate was significantly reduced compared to the 50 seconds it takes to simulate the original model.

Since the longest time was necessary for the compilation and the major speed advantages were seen when mode VI is active, we build another model, which is basically the original model until the fuel runs out. Then a switch to the last mode occurs. The result is also shown in Figure 4. Here we can see that we lose time compared to the first variable-structure model, but when the fuel is empty the CPU time becomes almost constant. Since only two modes need to be compiled and only one mode switch occurs the overall time necessary for this model is about 2.5 seconds, with switching, compiling and CPU time. Which is even faster than the originally designed variable-structure model. This shows that choosing the correct modes is not an easy task and needs to be done carefully.

Even though the needed time to simulate the rocket launch could be reduced, if the simulation results would be less accurate this improvement would lose meaning. In Figure 5 we can see two of the simulation

Figure 5: Rocket position comparison

results plotted on top of one another (the third simulation did show the same behavior). It is evident that the difference between both results is not discernible. Both results are essentially the same.

Another issue we had with the original model was the huge volume of generated data, 1.5GB, which resulted from storing variable data of every time step combined with the very small step sizes necessary to maintain accuracy for the stiff equation system. When simulating the redesigned model we are left with 8 result files; one for the simulation of each mode. When combined, the size of those files is about 1MB of information. Using the two mode model the simulation data of the two result files adds up to 30MB. It is evident that the major part of the original data was not needed to accurately calculate the trajectory of the rocket.

Dymola does support an option to choose the amount of data to be stored during a simulation run, but changing the setting for the original model resulted in failed simulations. It seems that this setting has an effect on the solver in Dymola. Imagine it would be possible to choose the amount of stored data: Due to the different time scales of the model we would have to find a compromise between storing many values of very fast changing variables while the thrust is built up and less values of slow changing variables during the flight to the moon with maximum thrust. With this compromise we could reduce the amount of data but may also lose information about data of the chemical reactions.

A problem we encountered with the variable-structure model was that the solver of Dymola seems to be influenced by the start time of the model. Whenever we started a simulation at a time other than zero, the simulation failed. The rocket model does not depend on the starting time, as the *time* variable is not used in the model. Thus, the solver should have been able to start at any given time and still calculate the same results. This was not the case for this model though. Therefore, we had to start each mode's simu-

lation at zero seconds and later add a time offset to get correct results.

## 5 Summary

In this paper we have shown that modeling with variable structure is worthwhile. We accomplished our goal to lessen the necessary time to simulate the flight to the moon without loosing accuracy and were able to significantly reduce the volume of generated data. We have also shown that it is not a trivial task to choose good modes and that when choosing different modes it is even possible to save more simulation time without disadvantages. Using variable-structure models seem to be a good choice for stiff equations in case the stiffness can be taken out for parts of the simulation.

## Abstract

This paper proposes an efficient approach to model stochastic hybrid systems and to implement Monte Carlo simulation for such models, thus allowing the calculation of various probabilistic indicators: reliability, availability, average production, life cycle cost etc. Stochastic hybrid systems can be considered, most of the time, as Piecewise Deterministic Markov Processes (PDMP). Although PDMP have been long ago formalized and studied from a theoretical point of view by Davis (*Davis 1993*), they are still difficult to use in real applications. The solution proposed here relies on a novel method to handle the case when the hazard rate of a transition  $\lambda$  depends on continuous variables of the system model, the use of an extension of Modelica 3.3 and on Monte Carlo simulation. We illustrate the approach with a simple example: a heating system subject to failures, for which we give the details of the modeling and some calculation results. We compare our ideas to other approaches reported in the literature.

*Keywords: Stochastic hybrid system; PDMP; dynamic reliability; state-dependent hazard rate; continuous time state-machine; Monte Carlo Simulation.*

## 1 Introduction

Usually, Modelica models are deterministic; they are built to simulate the nominal behavior of the systems they represent. In order to challenge the functioning of these systems in diverse situations, or in the presence of a varying environment, a degree of randomness is sometimes added to the system inputs.

But the kind of models this paper is dedicated to is quite different: here, *the random behavior can be due to the system itself, mainly because of failures and repairs of components*. The purpose of reliability, and more generally, of dependability studies is to

calculate probabilities of undesirable events such as the failure of the mission of a system, or to estimate the probability distribution of some performances of the system: total production on a given time interval, maintenance cost, number of repairs etc. Usually, dependability studies are performed with dedicated methods and tools, based on discrete (and often even Boolean) models of systems: fault trees, Markov chains, Petri nets, etc.

However, in some situations, a purely discrete representation of a system cannot be a good enough approximation: this is the case of hybrid systems, having both discrete and continuous parts, with strong interactions between the two. Reliability analysts call the study of such systems "dynamic reliability".

Below are two examples showing the need for powerful tools for dynamic reliability studies:

In the probabilistic safety analysis of nuclear power plants, so-called "level 1" studies, that are those aiming at assessing the probability of a core melt, rely on discrete (mainly Boolean) models. But after a core melt, components are subject to physical stresses (temperature, humidity and radioactivity) that may modify their behavior and increase very much their failure rates, and this should be taken into account in "level 2" studies that try to assess the risks of radioactivity release in the environment. Even for level 1 studies, there is a competition in time between the decay of the thermal power that must be evacuated and the failures of components, and the coarse decomposition of scenarios according to large time intervals in which failures can happen can be excessively pessimistic.

Another example of system associated to very high stakes and whose behavior cannot be captured correctly without a stochastic *hybrid* model is the electrical grid. In this system, transients with extremely different time scales can happen and evolve to blackout situations. For example, after the failure of a line, the intensity increases in the remaining

lines; it can augment their temperature which, because of dilatation, makes them come closer to the ground. This increases the probability of a new fault due to a contact between a line and a tree.

Recent results have shown that numerical schemes can solve PDMP with a small size, however Monte Carlo Simulation remains the only possible method for quantification in larger cases.

The purpose of this paper is twofold: it shows how to *model* a hybrid stochastic system and it gives an *efficient* Monte Carlo scheme that *works even in the case of failure rates varying with the continuous variables of the system*.

## 2 A review of formalisms used for hybrid system modeling

In this section, we will first give the theoretical model called PDMP (Piecewise Deterministic Markov Processes). Then we will explain the limits of PDMP and why these limits are not a real problem as long as we intend to model *physical* systems (and not, for example, financial systems). Finally we will see how some existing formalisms (including Modelica) can be used to represent PDMP.

### 2.1 The theoretical model PDMP

The state at time  $t$   $(x(t), m(t))_{t \geq 0}$  of a hybrid system is composed of two parts: a continuous one,  $x(t) \in \mathbb{R}^n$  and a discrete one,  $m(t) \in \mathbb{N}$ .

$x(t)$  usually models physical variables such as temperature, pressure, volume, flow rate, etc., whereas  $m(t)$  is the index of the state of the discrete "part" of the system: to each value of  $m(t)$ , one can associate discrete states (such as working or failed, open or closed etc.) to each component of the system.

What makes the resolution of dynamic reliability problems difficult is the existence of bi-directional interactions between  $x(t)$  and  $m(t)$ . Here are some examples of such interactions:

- $x(t)$  acts on  $m(t)$ . When a physical variable reaches a threshold, it can provoke a discrete change: explosion of a tank because of high pressure, evaporation of steam because of high temperature, reaction of the instrumentation and control system. A physical variable can also make a discrete event happen earlier or later: for example, a failure rate may increase with the temperature.
- $m(t)$  acts on  $x(t)$ . The opening or closure of a valve, the failure of a pump changes the differential equations governing physical variables.

From a mathematical point of view, PDMP contain all the ingredients needed to model stochastic hybrid systems such as those exemplified above (Davis 1993).

The general equations governing the evolution of the PDMP whose state is described by  $(x(t), m(t))_{t \geq 0}$

$$\frac{dx(t)}{dt} = g(x(t), m(t))$$

$$\Pr(m(t + \Delta t) = j / m(t) = i, x(t)) = \lambda(i, j, x(t)) + o(\Delta t)$$

Here,  $\lambda(i, j, x(t))$  denotes a function that defines the hazard<sup>1</sup> rate from state  $i$  to state  $j$  for the discrete part of the system:  $\mathbb{N} \times \mathbb{N} \times \mathbb{R}^n \xrightarrow{\lambda} \mathbb{R}$ . In other words, it defines the probability that a transition occurs from discrete state  $i$  to state  $j$ .

### 2.2 Scope and limits of PDMP

The scope of PDMP is quite large: it generalizes all discrete models used in dependability analysis, even those considered as *non markovian*, (like for example Petri nets with arbitrary probability distributions for delayed transitions) due to the modeling "trick" explained below.

Thanks to the insertion into  $x(t)$  of the time elapsed since the beginning of the life of an aging component, it is possible to model the probability distribution of the time to failure of this component, whatever this distribution may be.

For example, here is how we can transform a non markovian process with two states modeling a component with a Weibull distributed lifetime into a markovian process, thanks to the addition of time in the definition of the state:

- the "usual" definition ( $m = 1$  corresponds to a working state, and  $m = 0$  corresponds to a failed state):

$$\Pr(m(t) = 0) = 1 - \exp\left(-\left(\frac{t}{\alpha}\right)^\beta\right) \quad (1)$$

In this expression,  $\alpha \in \mathbb{R}^{+*}$   $\alpha$  is the scale factor and  $\beta \in \mathbb{R}^{+*}$  is the shape parameter of the Weibull distribution.

- definition with a PDMP whose continuous variable represents the time:

$$\frac{dx(t)}{dt} = 1 \quad \text{because } x = t \quad (2)$$

<sup>1</sup> Here, reliability analysts would rather use the term "transition rate" instead of "hazard rate". These two expressions are synonyms, but we use the second one because it is the most neutral. It is the quantity defined in eq. (6).

$$\Pr(m(t + \Delta t) = 0 / m(t) = 1, t) = \frac{\beta}{\alpha} \left( \frac{t}{\alpha} \right)^{\beta-1} \exp\left(-\left(\frac{t}{\alpha}\right)^\beta\right) + o(\Delta t) \quad (3)$$

$$\Pr(m(t + \Delta t) = 0 / m(t) = 0, t) = 1 \quad (4)$$

In equation (3), we use the *hazard rate* of the Weibull distribution.

This kind of representation by a PDMP can be generalized to any lifetime distribution; the remarkable case when the hazard rate is in fact constant corresponds to the exponential distribution (see section 3.1).

The large expressive power of PDMP unfortunately comes with a heavy additional burden for analysts: as one can see from the very elementary example given above, PDMP are not at all easy to manipulate. In fact, they are both difficult to specify, and to solve by methods other than Monte Carlo simulation.

How about their limits? Of course, PDMP do not address all the needs for reliability studies of systems involving uncertain dynamics. Neither random continuous inputs nor measurement noise can be captured. Still, PDMP offer a first interesting step beyond classical dynamic dependability models with discrete space. PDMP are interesting in that they do not require the modeling and simulation of full fledge stochastic differential equations. Their Monte-Carlo simulation can be performed at reduced cost, as we shall see.

### 2.3 Modeling in practice

Modeling hybrid systems has long been a concern for the study of purely deterministic systems.

For relatively simple models, the graphical representations used in control and signal processing can suffice. They allow the graphical construction of transfer functions, using assemblies of elementary blocks representing integrators, differentiators, multipliers, adders, thresholds etc.

For more complex models, a higher level of abstraction is needed. This can be achieved by the encapsulation of algebraic, differential and discrete equations in objects corresponding to physical components. This is the solution made possible by Modelica. Thanks to Modelica libraries, it is possible to quickly build models of mechanical, electrical, fluid etc. systems, encompassing thousands of equations. However, so far this kind of representation has not been extended to allow a convenient modeling of **stochastic** hybrid systems.

Thanks to a comparison between various existing modeling languages for PDMP done in (Bouissou

and Jankovic 2012) and (Bouissou et. al. 2013), the missing features in Modelica 3.3 can be identified:

- Asynchronous state machines in which transitions are triggered by events (instead of synchronous state machines triggered by a clock)
- Transitions that can be associated to random delays (this is the most important and delicate point)
- Allowing several instantaneous transitions from one state having specified probabilities of firing.

Section 4 will describe the two first points in detail<sup>2</sup>, but before that, we will give what is in fact the main point of this paper: a smart algorithm allowing to perform Monte Carlo simulation on PDMP. This algorithm is usable whatever the interactions between the discrete and continuous parts of the process and is very economical in terms of CPU usage.

## 3 Making the Monte Carlo simulation of a PDMP efficient

### 3.1 State of the art

The state of the art Monte Carlo simulation method for PDMP is described in (Zhang et al. 2008). This paper recalls the mathematical definition of PDMP as it was set up by Davis and gives an iterative simulation algorithm that determines the successive times of process jumps due either to a random event or to the fact that the continuous part of the system reaches the boundary of the currently valid domain for the differential equations.

Starting from the initial state of the system, the first jump date is the minimum of the dates of the set of events corresponding to:

- Boundaries crossings: the corresponding dates are obtained by solving the current set of differential equations until one of the continuous variables crosses a threshold;
- Random events. In most cases, there is a competition between several transitions associated to individual probability distributions of the times to firing of these transitions (like in a stochastic Petri net). For example, several components can fail at any moment, but if their failures are independent, one will fail first, and this will determine the instant of the first jump date.

When the random processes are independent from continuous variables, it is easy to determine, at  $t=0$ ,

<sup>2</sup> The third point will *not* be developed in this article, both because of a lack of space and because it is not related to the two other points.

the dates of all random events (details given hereafter). But if they are not, their determination is more difficult. We will first recall the definition of the hazard rate, associated to the distribution of any random variable such as the time to a failure or a repair then explain a method able to find in one run, without any backtrack, the date of the first event in the system, whatever its nature (random or boundary crossing).

Given a random time  $T$  whose *cumulative distribution function (cdf)*  $F$  is defined as

$$F(t) = \Pr(T < t) \quad (5)$$

the corresponding *hazard rate*,  $\lambda(t)$ , is defined as:

$$\lambda(t) = \lim_{\Delta t \rightarrow 0} \frac{\Pr(T < t + \Delta t | T > t)}{\Delta t} \quad (6)$$

The hazard rate can then be expressed as

$$\lambda(t) = \frac{F'(t)}{1 - F(t)} \quad (7)$$

that is

$$\frac{dF(t)}{dt} = (1 - F(t))\lambda(t) \quad (8)$$

For Monte Carlo simulation, the time to the next event,  $T$ , is determined by drawing a uniform random number,  $r$  in  $[0,1]$ , and solving:

$$F(T) = r$$

When  $\lambda$  is constant, the solution to the differential equation (7) is:

$$F(t) = 1 - e^{-\lambda t}$$

and

$$T = -\frac{\ln(1 - r)}{\lambda} \quad (9)$$

Figure 1: The "inverse cdf" technique for drawing a random number according to a given distribution

In figure 1, this approach is visualized (here:  $t_{start}$  is the time instant when the random number  $r$  is drawn,

and  $t_{fire}$  is the time instant of the stochastic event, so  $T = t_{fire} - t_{start}$ , the blue curve is the cumulative distribution function  $F$ ).

When the hazard rate of a transition depends on continuous variables  $x$ , so,  $\lambda(t, x(t))$ , the cumulative distribution function  $F$  can be obtained by integration of eq. (7) and is equal to

$$F(t) = 1 - e^{-\int_0^t \lambda(u) du} \quad (9)$$

Then, the usual and "naïve" way to proceed is to integrate the differential equations up to a "large enough" time, draw a uniform random number  $r$  and calculate  $T$  as  $F^{-1}(r)$ .

This process involves solving the differential equations of the model during a sufficiently large time interval and calculation of  $\lambda(t)$  which is dependent on variables of the model. A numerical method is then used for integration of  $\lambda(t)$  followed by calculation of  $F(t)$ . After this, the integrator of the differential equations needs to be rewound to  $t_{fire}$ , an operation normally not present in numerical integration methods.

### 3.2 New method for state dependent hazard rates

Instead of this complex and slow procedure, a new method has been developed that utilizes the fact that  $F$  is monotonically increasing and the zero crossing solver for events available in modern integration routines can be used to find the next event time  $t_{e,i+1}$ . The complete set of equations can be defined in the following way:

**At event**  $t = t_{e,i}$ :

$$\begin{aligned} m(t_{e,i}) &= g(m(t_{e,i-1}), t_{e,i}) \\ F(t_{e,i}) &= 0 \\ r(t_{e,i}) &= \text{random}() \end{aligned}$$

**for**  $t_{e,i} < t < t_{e,i+1}$ :

$$\begin{aligned} 0 &= f(\dot{x}, x, y, t, m(t_{e,i})) \\ \dot{F} &= (1 - F) \cdot \lambda(\dot{x}, x, y, t, m(t_{e,i})) \\ t_{e,i+1} &= \min_{t > t_{e,i}} t, \text{ such that } F \geq r(t_{e,i}) \end{aligned}$$

**where**

$$t \in \mathbb{R}, x(t) \in \mathbb{R}^{n_x}, y(t) \in \mathbb{R}^{n_y}, F(t) \in \mathbb{R}$$

$$m(t_{e,i}) \in \mathbb{N}, f(\dots) \in \mathbb{R}^{n_x + n_y}, \lambda(\dots) \in \mathbb{R}$$

This system consists of a continuous-time DAE (Differential Algebraic Equation system) defining the physical model, together with a state machine. The active state of the state machine is characterized by

the integer variable  $m$ . The DAE is a function of this active state  $m$ , and of continuous-time states  $x$  and algebraic variables  $y$ .

At an event instant  $t = t_{e,i}$  a transition to the next state of the state machine occurs, the cumulative distribution function  $F$  is re-initialized to zero, and a random number  $r$  is drawn.

Afterwards the DAE together with the differential equation for  $F$  is integrated until

$$F(t) - r(t_{e,i}) = 0$$

This means that the zero crossing of  $F(t) - r(t_{e,i})$  triggers a state event<sup>3</sup> and the corresponding (stochastically determined) time instant is the next event instant  $t_{e,i+1}$ .

For notational convenience this description was given for a special case. It is easy to generalize for several state machines where one or more stochastic and/or deterministic transitions are defined at the active states.

Remark: the above approach can be seen as a generalization of the simulation of nonhomogeneous Poisson processes (Sheldon 1990). Indeed, two methods of generating a Poisson process with known time-varying hazard rate function  $\lambda(t)$  are proposed in Section 5.5 of this reference, of which the second one can be seen as a basis of our method: it is proposed in Section 5.5 to compute

$$F(t - t_e) = 1 - e^{-\int_0^{t-t_e} \lambda(u) du}$$

and then to invert the equation  $F(t - t_e) = r(t_e)$  for  $t$ , where  $r$  is a random number drawn at the last event time  $t_e$ . We propose to differentiate the above equation, thus making clear that the time-varying intensity  $\lambda(t)$  can be given on-line. With this observation, we can now allow that  $\lambda(\dot{x}, x, y, t, m)$  is a function of the variables of a DAE describing the physical system,  $F$  is computed by integrating the differential equation for  $F$  together with the system DAE, and the stochastic event time is computed as the state event where  $F \geq r$  becomes true. We discovered our method independently, however, and this reference was subsequently pointed to us by Pierre Brémaud.

## 4 Modeling PDMP in Modelica

In this section it is shown how PDMP can be modeled in Modelica and how Monte Carlo simulations can be carried out over such models. Furthermore,

<sup>3</sup> State events are supported by modern ODE and DAE solvers; the solver will automatically iterate around the time instant where this function crosses zero, will backtrack, and will find the event time up to a certain precision.

with the novel technique from section 3.2 it is possible to model hazard rates that depend on the states of continuous variables in an efficient way.

### 4.1 Overview

In Modelica 3.3 support for hierarchical, synchronous, clocked, state machines (Elmqvist et al. 2012) was added. Such state machines are evaluated at clock ticks of sampled data systems, and are now the preferred way to model state machines in Modelica. In a prototype of Dymola, this state machine type was extended to model also continuous-time state machines (Elmqvist et al. 2014) and is the basis for the PDMP implementation in Modelica.

The basic mechanism is a generalization of transitions in the Modelica synchronous state machines, as sketched in the following figure:

Figure 2: Transition between two states in a state machine

A transition in a Modelica 3.3 synchronous state machine fires, if its source state is “active” and the transition “condition” becomes true. If transition flag “immediate=true”, the transition fires immediately (so at the same clock tick). If “immediate=false”, the actual firing occurs at the next clock tick, so it is delayed. This approach is generalized in the following way for continuous-time asynchronous state machines:

- If “immediate=true”, the behavior is as before, so the transition fires immediately (at the current model evaluation).
- If “immediate=false”, by default a new event iteration is triggered and the transition fires at the next event iteration (so with an infinitesimal small delay that breaks algebraic loops).

There are several useful ways to delay a transition, such as by a fixed time period (e.g. firing after 2ms), or by a time period that is defined stochastically in different ways (as needed for a PDMP). Since there are many possibilities, it seems not possible to pre-define this behavior in a language element, but it needs to be configurable by a user.

In the following sub-sections, the different ingredients needed for such a Modelica extension are discussed.

### 4.2 Random number generation

In order to draw random numbers for the triggering of stochastic transitions, a random number generator is needed. A standard random number generator in a programming language is an impure function and is typically called as “`r = random()`”, so the function has no arguments and returns for every call a different random number, typically in the range  $0 \leq r \leq 1$ . It is clear that such a function cannot be implemented as a Modelica function, because Modelica functions are “pure”, and return always the same value, when called with the same input arguments. There are the following remedies:

- (1) Explicitly pass the internal memory (usually called “seed”) of the random number function as input and output arguments:

```
(r, seed) = random(pre(seed))
```

As a result, the random function can return a different (`r, seed`) value only at an event instant, as it should be, because the operator `pre(..)` can only be used in a discrete equation. It is therefore guaranteed that the random number function cannot be called during continuous integration which would give severe problems with the integration method.

- (2) Use an external Modelica function as interface to a C-function, `r = random()`, and mark this function as impure:

```
impure function random
  output Real r;
  external "C" r = random();
end random;
```

The “`impure`” keyword introduced in Modelica 3.3 guarantees that the random function can be basically only called in a when-clause, so at event instants.

Calling a random number generator in any simulation environment is tricky, because there are different requirements and depending on the analysis, simulation runs should (a) use different random number sequences in every simulation run, as for Monte Carlo simulations, or (b) should use the same random number sequences in specific simulations, as for Optimization over Monte Carlo simulations (Looye, Joos 2006) or when developing a model.

Figure 3: Two options for the pseudo random generator

Taking into account the above observations, a Modelica model was designed to define the random properties globally: The user has to drag model “GlobalSeed” in the model and can then select from two options: in the first case (by default), for every simulation run a different initial seed is selected. In the second case, defined by a flag, initial seeds can be explicitly defined and every simulation run will use the same random number sequence. The selected seeds are displayed in the icon.

In a model, the random number generation function is called in the following way:

```
protected
  outer GlobalSeed globalSeed;
  Real r "random number";
equation
  when condition then
    r = globalSeed.random();
  end when;
```

Since `globalSeed.random` is defined as an impure function, it can only be called in a when clause, so only at an event instant. Every call returns a different random number in the range  $0 \leq r \leq 1$ .

### 4.3 Delayed transition blocks

As already mentioned, there are many ways to define the delay of a transition. In order to keep this user configurable, it is proposed to define the delay by a Modelica block, with one Boolean input and one Boolean output signal, which has the following properties:

The input signal of such a block, called `enableFire`, signals when the source state is active and the transition condition becomes true. The signal is then set to `true`, until it is explicitly reset (either because the transition fired, or the source state became inactive, e.g., due to the earlier firing of another transition).

Figure 4: Behavior of a delay block

The delay block triggers an event after a defined “delay time” and at this time instant the output signal `fire` is set to `true`. This raising signal triggers the firing of the transition. Immediately, when the source

state becomes inactive, `enableFire` and `fire` are both reset to `false`.

Based on this principle, a small library of delay blocks has been implemented. The two deterministic delay blocks `FixedTimeDelay` and `VariableTimeDelay` define the delay by a fixed or variable deterministic time delay, respectively. The core part of the `FixedTimeDelay` block implementation is (`t_start` is the time instant when the input `enableFire` is rising<sup>4</sup>):

```
if enableFire then
  fire = time >= t_start + delayTime;
else
  fire = false;
end if;
```

Therefore, a time event is triggered after the defined `delayTime` and the output `fire` changes to `true` at this time instant. Conceptually, the equations in a transition are defined as:

```
algorithm
  when initial() then
    enableFire := stateActive and
                  condition;
  elseif stateActive and condition then
    enableFire := true;
  elseif not stateActive then
    enableFire := false;
  end when;

equation
  if immediate then
    fire = enableFire;
  else
    delayBlock.enableFire = enableFire;
    fire = pre(delayBlock.fire);
  end if;
```

Note, the output `fire` of the delay block needs to have an infinitesimal small delay via the `pre(...)` operator in order to break algebraic loops.

#### 4.4 Randomly delayed transitions

The approach sketched in section 3 for fixed (not state-dependent) hazard rates leads the following implementation in Modelica, where the implementation of eq. (9) can be easily identified:

```
outer GlobalSeed globalSeed;
Real r, t_next;
parameter Real hazardRate;

equation
  when enableFire then
    r = globalSeed.random();
    t_next = time - log(1-r)/hazardRate;
  end when;
```

<sup>4</sup> At the time instant where `enableFire` becomes true, the actual value of the variable delay time is inquired and this value is used as delay time.

```
if enableFire then
  fire = time >= t_next;
else
  fire = false;
end if;
```

Since the condition `time >= t_next` is a purely time dependent condition, a Modelica tool will determine the time instant of the fire time in advance and will directly (and therefore efficiently) integrate to this time instant.

Other stochastic distributions can be implemented in a similar way, provided that the distribution of the time to the firing is invariant once the `enableFire` Boolean has become true.

#### 4.5 State dependent randomly delayed transitions

In this section the implementation of the innovative approach from section 3.2 is sketched: the corresponding delay block can be defined in Modelica as:

```
outer GlobalSeed globalSeed;
Real r;
input Real hazardRate(min=0);
equation
  when enableFire then
    r = globalSeed.random();
    reinit(F,0); // start at F=0
  end when;

der(F) = (1-F)*hazardRate;
if enableFire then
  fire = F >= r;
else
  fire = false;
end if
```

The expression `F >= r` defines a state event and will therefore trigger a search process to determine the time instant when this condition becomes true up to a certain numerical precision. At this time instant an event is triggered.

#### 4.6 Asynchronous state machines

As already mentioned, in a prototype of Dymola the Modelica 3.3 synchronous state machines have been extended to continuous-time (= asynchronous) state machines. For all details see (Elmqvist et.al. 2014). As a very short summary: the states of a state machine might be non-clocked Modelica models or blocks. The “active” state is always simulated together with the rest of the DAE system and all outgoing transitions from this state are monitored. If one of these transitions fires, an event is triggered, the active state is changed and simulation continues with the new active state. All de-activated state models or blocks are “frozen”, so all variables in these objects

keep their values until these states become again “active”.

In Modelica 3.3 a transition is defined with the following built-in operator (see Modelica 3.3 specification, section 17.1):

```
transition(from, to, condition, immediate, reset,
           synchronize, priority)
```

Here “from” and “to” are the instance names of the blocks used as source and target state of the transition, “condition” is the firing condition and “immediate” is the flag that defines whether the transition is immediately firing or is firing at the next clock tick (the remaining arguments are not important for the following discussion).

This “transition” operator holds in principal also for continuous-time state machines. However, the case for “immediate=false” needs to be differently defined: As sketched in the previous sections, a wide variety of useful delay definitions can be provided by different blocks. Therefore, one approach would be to use a replaceable block as additional argument in the transition operator. Example:

```
transition(“state1”, “state2”, true, false, true, true, 1,
           redeclare FixedHazardRateDelay
           delay(hazardRate=0.03));
```

This call would use block “FixedHazardRateDelay” for the block instance “delay” with the given modifier. Built-in operators in Modelica have the syntax of a function call. However, a block, being replaceable or not, cannot be passed to a function, and therefore, this construct seems to be unnatural to a built-in operator. It would be possible to pass a function object, such as:

```
transition(“state1”, “state2”, true, false, true, true, 1,
           delay = function FixedHazardRateDelay
                 (hazardRate=0.03));
```

However, with a function object, it would not be possible to define stochastic transitions that depend on continuous-time states (see section 4.5) because a differential equation needs to be solved in the object and state events need to be triggered.

It is therefore proposed to define the transition built-in operator with a syntax that is close to the function object:

```
transition(“state1”, “state2”, true, false, true, true, 1,
           delay = block FixedHazardRateDelay
                 (hazardRate=0.03));
```

Informally, the semantics is that the provided block (here: FixedHazardRateDelay) with its modifier is instantiated in the scope of the source state, so this block is only active and running, when its source

state is active and otherwise is “frozen”. If a delay block is not explicitly given, the default block will just implement the equation

```
fire = pre(enableFire);
```

so an infinitesimal small delay will be introduced.

Unfortunately, such a built-in operator is uncommon in Modelica (having a replaceable block as an argument to a built-in operator) and it is unclear whether this complicated definition should be introduced into the Modelica language specification.

For this reason, another approach is used in the prototype: The desired delay block is instantiated inside the source state. In the transition, the output of the delay block is utilized. The implementation in the source state is basically straightforward by instantiating from the desired delay block:

```
FixedHazardRateDelay delay(
    enableFire=enteringState(),
    hazardRate=0.3);
```

An issue is to define, when the random number shall be drawn (that is, when the input enableFire has a rising edge). In the prototype, enableFire is defined to have a rising edge, when the source state is entered. This is inquired, with the (not yet standardized) built-in operator “enteringState()”, that is available as a prototype in Dymola. As transition condition simply “<source-state>.delay.y” is used.

## 5 Case study

### 5.1 Preamble

The test case we are going to use to illustrate our ideas was first used to screen a number of potential tools and approaches adapted to dynamic reliability (Bouissou and Jankovic 2012), (Bouissou et al 2013) It has the advantage that it is easy to understand.

Although this test-case is very simple it has been quite difficult to solve it with tools that were initially designed only for modeling deterministic systems (and this includes Modelica tools). We intend to solve a more complex test-case in the future, such as the well-known “heated tank” problem used by T. Aldemir in (Aldemir 1991), that has been solved since then with many different approaches e.g. (Lair et al. 2010), (Zhang et al. 2008), (Broy et al. 2011), (Zhang et al. 2013).

### 5.2 The “heated room” test case

Consider a room containing a heater. A temperature sensor with a hysteresis switches the heater on when the ambient temperature falls below 15°C and switches it off when the temperature reaches 20°C.

The outside temperature is constant: 13°C. At time  $t = 0$ , the temperature of the room is 17°C, and the heater is on.

The flow of energy (power) traversing the walls is proportional to the difference of temperature between the inside and the outside of the room. When the heater is on, it injects a constant power in the

$$\frac{dT}{dt} = 0.1 \times (\text{Outside\_temperature} - T) + 5 \times (\text{heater\_is\_on})$$

room. Let us suppose that the isolation of the room and the heater power are such that the differential equation giving the evolution of the temperature is as follows (with  $t$  in hours, and  $T$  in °C):

In this expression, *heater\_is\_on* is an indicator function, with the value 1 if the heater delivers power and 0 otherwise.

If the heater was not subject to failures, the trajectory of temperature as a function of time would be a deterministic succession of portions of exponential functions, alternatively convex and concave, "oscillating" between 15 and 20 °C.

But in fact, the heater has a constant failure rate  $\lambda = 0.01/h$ , and a constant repair rate  $\mu = 0.1/h$ . How does this random behaviour affect the evolution of the temperature?

## 6 Modelica models for the case study

The system consists of 5 classes: *globalSeed* (described in section 4.2) *heaterController*, *heater*, *outsideWeather* and *heatedRoom*. There is only one object of each class.

Figure 5. Structure of the Modelica model

In this case we can have a causal model, where each box has outputs calculated from its inputs. This is why the links are all directed.

The box *outsideWeather* just contains a constant parameter: the outside temperature, set to 17°C; this value is sent to *heatedRoom*. In *heatedRoom* there is the differential equation:

```
equation
  der(T) = 0.1 * (Outside_Temperature - T)
          + 5 * Heater_is_on;
```

The box *heaterController* just contains a hysteresis taken from the Modelica standard library. The two bounds (minimal and maximal temperatures respectively set to 15 and 20) are defined in this box. The output is a Boolean sent to the box *heater*; this Boolean is true whenever the heater is supposed to heat.

### 6.1 Heater model with stochastic transitions

With the method sketched in section 4, the heater is modelled as a continuous-time state machine where stochastic delay blocks with constant hazard rates are used inside the states (Figure 6).

For example “working” is the state when the heater is working. Inside this state a vector of delay blocks with fixed hazard rates are defined and the hazard rates are displayed in the icon ( $\{0.01\}/h$ ), so defining here 0.01 failures per hour. This state is instantiated with one delay block, and the transition from “working” to “notWorking” is just referencing the output of this delay block (`working.delay[1].y`).

Figure 6: The heater model with a continuous-time state machine. In every state an instance of a delay block with constant hazard rate is present. In the transitions, the outputs of these delay blocks trigger the firing of the transitions.

This output becomes true after the stochastic delay defined by the hazard rate (a random number is drawn when state “working” is entered). In this case the state machine switches to “notWorking”. The repair rate is defined as 0.1 failures/h and the state switches back to “working” again, after this stochastic delay. The output of the heater model is true, if the state machine is in state “working” and the input of the heater (the signal coming from the controller) is true. The result of one simulation of the overall system is shown in figure 7.

## 6.2 Monte Carlo Simulation

The above model can directly be used to simulate *one realization* of the random process corresponding to the life of the system. To perform a Monte Carlo simulation to estimate, for example, the mean temperature as a function of time, it is necessary to generate a large number of such trajectories using different initial seeds for every simulation. This task can be performed in Dymola by using appropriate script functions (that are based on the algorithmic part of the Modelica language). A special Modelica/Dymola script has been implemented for this case to run the simulations and store the desired fractiles<sup>5</sup>. In figure 8, the mean value of the room temperature is shown, as well as the 1% and 99% fractiles at each time point respectively. 10 000 simulations were performed with 500 output points per simulation. On a notebook, these simulations took 25s. Computing the result values for figure 8 took another 45s (the reason is that a very simple algorithm was implemented to compute the fractiles and a better implementation will give a considerable speed-up).

Figure 7: A single random trajectory of the temperature (containing one failure and one repair over 100 hours).

Figure 8: Statistics obtained from 10000 trajectories

<sup>5</sup> The computation of the 99 % fractile  $z$  from 10000 simulation runs means that at every grid point of the result 10000 result points are available and that 99 % of these are smaller than  $z$ . In other words, 1 % of 10000 values = 100 values are larger than  $z$ .

## 7 Comparison with approaches in the literature

The same problem (heated room) had been already modelled and solved with three other tools. The details about these experiments can be found in the two ESREL papers already mentioned.

The tool Vensim, which is well known in the domain of so called "system dynamics" was originally designed for modelling deterministic differential equations. Its graphical input interface is extremely limited, does not allow encapsulation of models, nor reuse by another means than copy-paste. This tool is not usable for real size systems, the building of models being much too error prone.

The tool KB3, based on the Figaro modeling language, is dedicated to the construction of discrete state stochastic models, for reliability and dependability calculations. With this tool it has been very easy to build a graphical model representing the heated room, using a library for hybrid stochastic Petri nets. The model was solved using the YAMS Monte Carlo simulator, able to process any Figaro model. The main concern with this approach is the impossibility to "separate" in the processing the calculations on the discrete and on the continuous part of the model. Thus it would probably be inefficient in terms of CPU consumption on a large model, just like the approach described in (Zhang et al. 2013), commented 15 lines below).

Finally, the tool PyCATSHOO based on Python libraries had also been tested. This tool is new and has no graphical interface. However, it uses an object oriented approach such as Modelica, with two distinct hierarchies, corresponding to the relations "is included in" and "inherits from". The PyCATSHOO models include a native notion of stochastic transition, since this tool was designed specifically for solving dynamic reliability problems. Its scalability is ensured by the use of state of the art libraries for solving differential equations and parallelisation of computations.

It will be interesting to make further comparisons of Modelica and PyCATSHOO models resolutions for larger systems.

In (Aldemir 1991) a more complex benchmark is described. From the solutions to this well-known benchmark (already mentioned in section 5.1), the one from (Zhang et al. 2013) is interesting, because here a general purpose continuous-time modeling environment (Simulink) is used together with a state machine (Stateflow) to solve a problem with a state dependent hazard rate. However in this reference, a fixed time step integration is utilized for the simulation and in every step the approximation is used that

the hazard rate is constant. The constant hazard rate is integrated over every time step and at the end of every time step random numbers are drawn to check whether the failures of components are to be triggered in the next time step, according to the current values of components failure rates. This technique is less precise and requires a lot more computations compared to the one explained in (Zhang and al. 2008). This *seems to be* the price to pay in order to be able to use high level models with a small modeling effort instead of ad hoc programs developed at a high cost in terms of manpower. But in fact, our new approach from section 3.2 is *an improvement* of the simulation strategy given in (Zhang and al. 2008), *without backtracking* and able to use error controlled, variable step-size integrators for the continuous part of the system and yet *it allows the use of high level models*, as usual in a Modelica environment.

## 8 Conclusions

In this paper we have pinpointed the need for considering probabilistic safety analyses in which the fault occurrence and propagation behavior can depend on the physical and control state of the considered system. Indeed, we advocated that reliability modeling should not be kept separate from modeling of physics and control, as it is today. One specific subtlety of the subject is that the joint consideration of reliability and physics require being able to consider state dependent hazard rates for time to failure distributions. As a first contribution, we provided an on-line procedure for Monte-Carlo simulation of such phenomena in the presence of coupling between fault events and system physics. Then, we proposed an extension of the Modelica language to support this kind of modeling. The extension has been meant minimal in that it most possibly relies on existing features. Not all probabilistic phenomena relevant to the joint simulation of reliability and physics are covered by our proposal, but we believe it is a first and significant contribution addressing a large part of the remaining open issues with current approaches.

# The Modelica BehaviorTrees Library: Mission Planning in Continuous-Time for Unmanned Aircraft

Andreas Klöckner

German Aerospace Center (DLR), Institute of System Dynamics and Control  
82234 Weßling, Germany, [Andreas.Kloeckner@dlr.de](mailto:Andreas.Kloeckner@dlr.de)

## Abstract

The paper introduces a continuous-time architecture and a Modelica library for mission planning based on behavior trees. It allows to study the long-time behavior of complex aircraft models in interaction with reactive mission plans by means of efficient simulations. The developed Modelica library is used in a mission example for a solar high-altitude aircraft and the advantages of the behavior tree formulation in both simulation speed and modularity are discussed. The architecture will further be used to deploy automatically coded mission plans to actual flight computers using the functional mockup interface.

*Keywords:* UAV; Mission Management; Behavior Trees; Autonomy; Artificial Intelligence

## 1 Introduction

Missions currently envisaged for Unmanned Aerial Systems (UAS) pose increasing demands on modeling, planning and simulation capabilities. For example, solar UAS are highly dependent on environmental conditions and must execute autonomous missions lasting several weeks (see Fig. 1).

Figure 1: The growing complexity of integrated unmanned aircraft systems, environmental conditions and long-term missions call for efficient and intuitive tools for mission design and simulation.

With growing complexity of the systems, integrated simulation schemes have to be employed, not only modeling the vehicle's flight dynamics but also its avionics systems or even aeroelasticity. Such models have to be as detailed as possible, while maintaining sufficient simulation speed to also run simulations of long-term missions. We have shown previously that Modelica is an excellent tool for this purpose [1].

Additionally, missions of increased complexity and diversity make use of a range of distinctly developed UAS capabilities such as collision avoidance, formation flying or physical interaction with the environment. In order to further improve a system's versatility, developers seek to employ the same system for a variety of purposes, providing as much autonomy to the system as possible (see e.g. [2]).

In order to face these challenges, a flexible, scalable and intuitive scheme for UAS control systems and mission plans has to be provided. Ögren recently proposed behavior trees for this purpose [3]. They are distinguished by their standardized structure providing a mission design scheme, which Champandard argues to combine important advantages of different schemes such as state machines and task planners [4].

However, conventional behavior tree implementations rely on periodically updating the tree's status based on its inputs. This *clocked* or *discrete-time* processing makes previous behavior tree formulations unsuitable for continuous-time simulation of long-term missions. The tree's update rate would have to be chosen high enough to correctly reflect the system's behavior. The smaller integrator time-steps and additional time events would in turn slow down the overall simulation speed considerably.

In order to combine efficient long-term simulations with the capabilities of behavior tree mission plans, a *continuous-time* formulation for behavior trees was thus developed and implemented in Modelica. The present paper describes this formulation and the resulting Modelica library:

- The conventional behavior tree formulation is characterized by discrete-time, sequential, top-down processing of the tree. The new scheme is laid out as continuous-time, event-driven, and bottom-up processing, see Sec. 3. This allows a simulator to choose large integration step-sizes as desired for long-term mission simulation. The formulation can be generalized to other languages supporting event notifications.
- Section 4 introduces the Modelica implementation of the modified system. A library of base tasks with clear internal and external interfaces allows the user to graphically design mission plans and also easily implement new task types. Additional infrastructure is provided to simplify communication with the tree. The processing of an exemplary simple task is shown in Sec. 5.
- The example shown in Sec. 6 show-cases the modular assembly of a mission plan for a solar UAS. The simulation speed of the controlled system is maintained. A comparison to a state-machine based approach using the StateGraph2 library [5] gives identical results.

## 2 Behavior Trees

Behavior Trees are a technique developed for artificial intelligence in computer games. They are first mentioned in this context by Damian Isla [6]. A good introduction is found in Millington's textbook [7]. The approach is introduced to the UAS world by Ögren [3].

Using behavior trees, complex missions are built up using atomic tasks. These can e.g. query the aircraft's state (conditions) or send commands to the underlying control system (actions). A typical combination of the tasks is to conditionally execute an action. A solar UAS e.g. might need to harvest solar energy by maximizing its flight altitude, if a surplus of energy is available. In behavior trees, this is expressed using a sequence of sub-tasks as shown in Fig. 2a.

The task of maximizing potential energy could then be further composed of two alternatives: Either the maximum altitude is already reached or the aircraft has to climb. A set of alternative approaches to a common goal is expressed using a selector as shown in Fig. 2b.

A sequence executes all its sub-tasks in the given order until all sub-tasks are finished successfully. The selector also executes its sub-tasks in the given order, but returns successfully with one successfully finished sub-task. The two basic composite tasks can thus be compared to logical AND and OR operators.

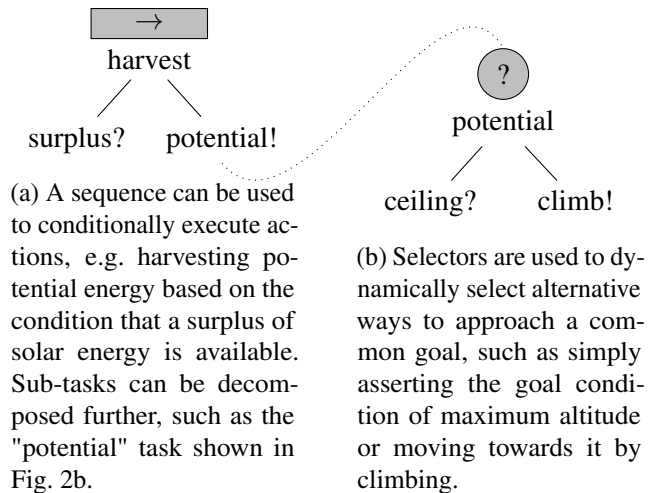

Figure 2: In a behavior tree, simple tasks are connected to a tree in order to achieve more complex goals.

The main advantage of behavior trees for UAS mission management is their standardized and intuitive structure. All atomic tasks describe self-contained and goal-directed behaviors. Higher-level plans are built by intuitively decomposing complex goals into sub-goals. Since all tasks have a common interface and the switching of tasks is determined by implicit logics, the user can modularly interchange arbitrary tasks in the tree. The plans are thus very scalable and human-readable on all levels of the hierarchy. Additionally, behavior trees are inherently memory-free and work with persistent statuses. They thus execute the correct task immediately after a restart or online modification.

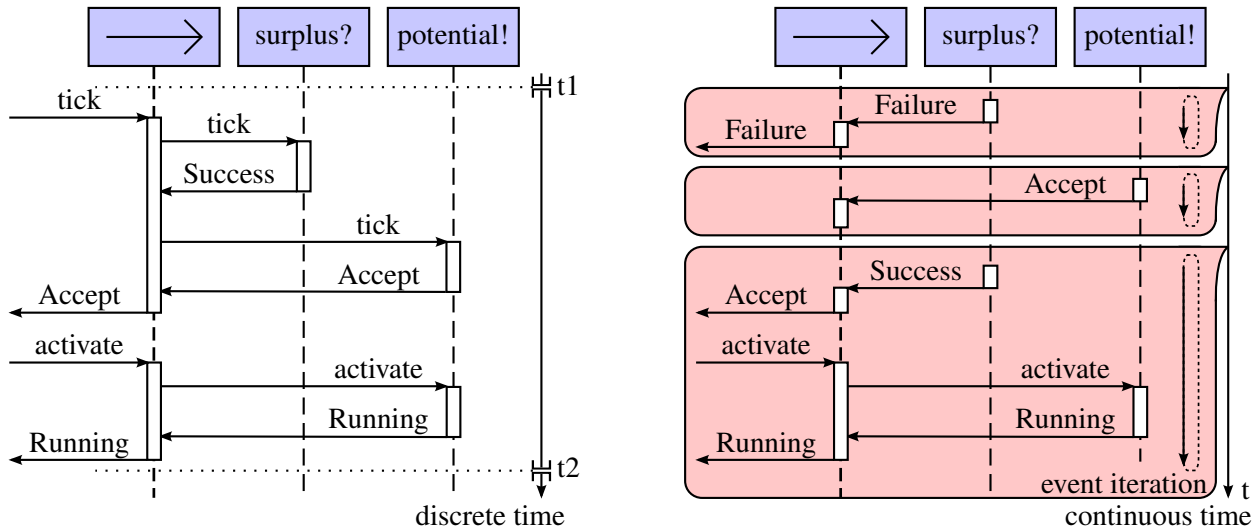

In previous studies, I have augmented behavior trees with state-machine-like entry and exit hooks [8]. The necessary notion of transient tasks is complemented in that paper with an introduction to the processing of basic behavior trees and further discussion of advantages as well as prospects of behavior trees for UAS mission management. A first step towards logical verification and validation of behavior trees is also covered by previous research [9]. Here, the formalism is refined for continuous system simulation.

## 3 Continuous-time Processing

Conventional behavior trees are processed at a fixed update rate. At each instance of time, a tick is issued to the top-most node of the tree. A tick requests a task to report its status back to the superior task. The standard statuses of a task are Success, Failure and Running.

The tick is propagated in a top-down manner through the tree to its leaf nodes. Each composite task, such as a sequence or a selector, sequentially ticks its sub-tasks to determine their statuses. Figure 3a uses a sequence

(a) In conventional processing, a tick is propagated from the root node of the tree down to the leaf tasks. After all sub-tasks have been ticked, a task returns its own status to its superior task. If necessary, additional activation routines are executed subsequently. This processing is done in each discrete time step.

(b) The proposed continuous-time processing relies on the sub-tasks notifying their superior tasks of status changes. In Modelica, these notifications are generated in event iterations and passed up the tree. Activation procedures are still triggered from the top. This processing can be done in continuous-time.

Figure 3: The processing of tasks in behavior trees is conventionally done sequentially in discrete time. In the new processing scheme, status notifications are passed through the tree in continuous time. Both variants are contrasted here in form of sequence diagrams showing processing of the example sequence from Fig. 2a.

diagram to illustrate the process of ticking the example sequence from Fig. 2a. The sequence is not running at first. In the illustrated time-step, it asserts a surplus of solar energy and then decides to accept being activated. It is subsequently activated by its superior node, and then activates its harvesting sub-task in turn. The separate decision and activation parts of the process are a consequence of the activation/deactivation procedures introduced previously [8].

The downside of this straight-forward processing is that a tick must be issued to the root node with a sufficiently high repetition rate in order to react adequately to changes in the environment. On the Modelica side, this is solved using discrete-time events. These in turn slow down long-term continuous simulations, which cannot make use of large integrator step-sizes anymore and have to handle additional integrator restarts.

In order to overcome this downside, I introduce the bottom-up approach for the decision part of the processing shown in Fig. 3b. Instead of periodically querying the sub-tasks' statuses, the superior task is notified by its sub-tasks about status changes. The superior task may then adapt its own status to the new situation and propagate the new status towards the root of the tree. The activation part of the processing is not changed.

Using this scheme, the example sequence starts with a Failure status, because it cannot assert a surplus of solar energy. The harvesting sub-task can then asynchronously decide to accept being activated. This does not require any status change of the sequence, such that the change event is not passed up the tree. Finally, the surplus sub-task notifies the sequence of its new Success status. The sequence then passes on its Accept status to the higher levels of the tree and is activated as in conventional processing. Each of these status notifications is processed in an event iteration.

If the behavior tree processing is changed in the proposed way, it is relieved of most of the discrete-time events. Instead, state events will be triggered in Modelica whenever a task changes its status. This allows for continuous-time simulation. Additionally, status changes of the behavior tree are resolved instantly as if the tree had an infinitely high update rate. The additional cost of iterating state events is moderate, because typical behavior tree mission plans change their status at a much larger time-scale than the simulation of the controlled system.

The new processing scheme additionally addresses the known limitation of behavior trees in handling events like a finite state machine as pointed out in pre-

vious work [8]. With the presented processing, the foundations are laid to implement event-based behavior trees in any programming language supporting event notifications. Additional work will have to be spent on adding internal or external storage to the tree in order to convert instantaneous events to permanent statuses.

## 4 Modelica Implementation

In Modelica, all tasks are implemented as models extending from a super-class Task, in which the common properties of all tasks are defined. The Task model in particular implements the status switching logics of the tasks. The status cycle used in this work is an extended version of the one introduced previously [8]. It makes a distinction between transient tasks and non-transient tasks. Transient tasks such as conditions can be evaluated without activation. Non-transient tasks such as an action must be activated in order to evaluate them.

All possible statuses of a task are defined in a Status enumeration. It defines the following eight statuses:

**Success and Failure** are the standard transient statuses and indicate, if the task (usually a combination of conditions) evaluates successfully or not.

**Accept** indicates that the task will accept being activated. It marks the entry point to the non-transient part of the status cycle. A task can only enter the non-transient part of the status cycle, if it is activated by its superior task. This status was called Activating in [8].

**Activating** now designates a task, which was properly activated by its superior task and is currently performing initialization procedures. This status can be used to execute the entry hook of the task. It is introduced here in order to allow for time-consuming initialization procedures. These were not possible previously.

**Running** denotes a properly initialized, non-transient task during its nominal execution.

**Finished and Aborted** are the non-transient equivalent statuses to Success and Failure. They indicate, if a task has finished running successfully, or if it failed during its execution. These statuses mark the exit point from the non-transient part of the status cycle. A task can only leave these statuses, if it is deactivated by its superior task.

**Deactivating**, equivalently to Activating, designates a task, which was deactivated by its superior task and is currently performing finalization procedures. It can be used to run the task's exit hook.

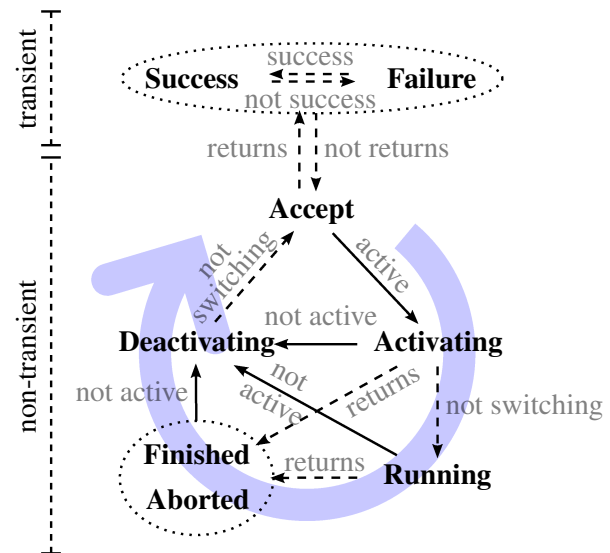

Figure 4: The status of a task is triggered by the internal trigger flags returns, success and switching ( - - ) or by (de-)activation through the active flag ( — ).

Figure 4 summarizes the complete status cycle. The task may internally determine status changes marked with dashed arrows. The status changes marked with solid arrows can only be initiated by the superior task through activation or deactivation.

Until the task is activated it can choose its status freely from Success, Failure and Accept. This allows transient tasks, especially conditions, to be evaluated without activation. As soon as the task enters the non-transient part of the status cycle by being activated, it is basically bound to iterate its status in the marked clockwise direction. The task can finally leave the non-transient status cycle only if deactivated by its superior task and after passing the Deactivating status.

In order to relieve task designers from coping with the correct implementation of the status cycle, three additional trigger flags are introduced. These indirectly trigger a task's status:

**returns** determines, if the task can be evaluated in the sense of returning a successful or unsuccessful status or if the task needs to be activated first.

**success** determines the correct status, if the task has a returning status.

**switching** is used to mark initialization and finalization of tasks. It can be used e.g. while powering up resources needed by the task.

The task's status can now be uniquely determined using these trigger flags and an additional active flag provided by the superior task. The trigger flags are also illustrated in Fig. 4 by the labels of the arrows.

The appropriate equation is common to all tasks and a base Task model is thus provided (see Listing 1). It contains the status switch logics, the three internal trigger flags returns, success and switching as well as a public uplink connector to the superior task. In this way, the status dynamics of all tasks are forced to be consistent and new task types can be conceived by simply assigning values to the trigger flags.

Listing 1: The basic Task interface contains an uplink to the superior task, three additional status triggers and the status switch logics. The function `f()` implements the status cycle shown in Fig. 4.

```

partial model Task
  Uplink uplink;
protected
  Status status = uplink.status;
  Boolean active = uplink.active;
  Boolean returns;
  Boolean success;
  Boolean switching;
equation
  status = f(pre(status),
            active,
            returns, success, switching);
end Task;

```

A Condition is e.g. defined by Listing 2. It can always be evaluated to Success or Failure and thus fixes the returns flag to true. The success flag determines whether to return Success or Failure. It can be filled by arbitrary conditional equations, e.g. using an additional BooleanInput. Because a condition cannot be activated, the switching flag must actually only be filled in order to balance the model.

Listing 2: Defining a new Condition task is done by binding the trigger flags to boolean expressions.

```

model Condition
  extends Task;
  BooleanInput u      "A boolean input";
equation
  success = u;      //is used as condition
  returns = true;  //and always returned
  switching= false; // => Not used!
end Condition;

```

All inter-task communication described in Fig. 3 is handled by the Task's UpLink connector and corresponding DownLink connectors of the superior tasks. The UpLink connector is outlined in Listing 3. The status variable carries the status information, while the active flag is used by the composite tasks to activate or deactivate their sub-tasks. Using these connec-

tors as public interfaces, single tasks can be connected in a tree to almost arbitrarily complex mission plans.

Listing 3: The BehaviorTrees UpLink connector for connecting sub-tasks to their respective superior task passes the sub-task's status up the tree and receives an active flag from the superior task.

```

connector UpLink
  output Status status "The task status";
  input Boolean active "(De-)Activation";
end UpLink;

```

Using the interfaces described above, a library of basic tasks is provided. The library's structure is shown in Fig. 5. It includes the most common tasks encountered in behavior trees such as Condition, Action, Selector and Sequence. The Root task is needed to steer the overall execution of the tree.

Additionally, a communication structure is provided in order to simplify the information flow between the tree and its environment (Blackboard). The system relies on a global memory block using Modelica's inner/outer functionality. Continuous-time Real variables can be written to the system using the SetReal block. Each slot is provided with a name and an active flag. The GetReal block retrieves the currently active value with a given name from the blackboard. Using this structure, it is possible for several tasks to write to the same input of the controlled system. It especially allows to also encapsulate continuous-time controllers in tasks and to switch between them automatically based on the current behavior tree status.

Figure 5: The BehaviorTrees library contains a number of standard task implementations. It also provides infrastructure to facilitate communication with the tree.

## 5 Processing of a Sequence

In this section, the processing of the last event shown in Fig. 3b is detailed with respect to the implementation described in the previous section. The Sequence task uses the implementation shown as pseudo-code in Listing 4. It first processes the sub-tasks' statuses to determine its own status triggers. These can then be processed by the standardized status cycle implementation as shown in Fig. 4. If the sequence is active, it passes on this flag to its first accepting sub-task.

Listing 4: The Modelica pseudo-code for the implementation of a Sequence Task determines the status triggers and steers the active flag of its sub-tasks.

```

model Sequence
  extends Composite "Task with sub-tasks";
  equation
    returns      = not any substatus[:] is
                  Accept, Activating, Running;
    success      = all substatus[:] are
                  Success or Finished;
    switching     = any substatus[:] is
                  Activating, Deactivating;
  // <-- Apply status cycle from Task
  if active then
    subactive[first accepting] = true;
  end if;
end Sequence;
    
```

Initially, the surplus sub-task has the status Failure and the potential sub-task has the status Accept. The sequence consistently returns Failure.

When the surplus status changes to Success, the sequence's returns flag changes to false. Applying the status cycle, the sequence changes its status to Accept and passes on this status to its superior task.

According to the switch logics contained in the superior tasks, the sequence's active trigger is then changed to true. The sequence passes on this value to its first accepting sub-task, the potential energy harvesting. This action then changes its status to Activating, which in turn changes the sequence's switching trigger to true. According to the status cycle, the sequence also assumes Activating status and passes it up the tree.

Eventually, the potential sub-task generates a new event, when it switches its status to Running. The sequence adapts to this change by changing its own switching flag to false, applying the status cycle, and passing its new Running status to its superior task.

Figure 6 shows a sequence diagram of this sequence of events. The single final event from Fig. 3b is split in three events here. Depending on the superior tasks

and the sub-tasks, these events can also happen immediately one after the other. An action without activation procedure e.g. immediately leaves the Activating status. This combines the latter two events into one.

Figure 6: The detailed processing of a sequence activating its potential sub-task includes the status triggers.

## 6 Application Example

The described system is used for show-casing its applicability to actual UAS mission scenarios. To this end, a mission plan is built for an electric high-altitude solar-powered aircraft. This plan is used to steer the integrated simulation model developed in previous work [1]. The aircraft is implemented as the non-linear inverse of a point-mass model of the flight dynamics with two controlled propellers. It has 26 individually controlled solar panels. The total number of continuous-time states for the aircraft is 72.

The plan is divided in a longitudinal and a lateral part. The lateral part steers the aircraft towards a holding position and commands a holding pattern at this point. This part is not described here in detail. The longitudinal part of the plan is shown in Fig. 7. It consists of two sub-goals. The first is to ensure that a maximum of solar energy is stored in the aircraft. The second includes the main mission, such as operating a communication relay at the holding position. In this example, it is simplified by issuing an altitude holding command.

The energy-maximizing plan is comprised of two alternative plans. One is used to harvest solar energy. It

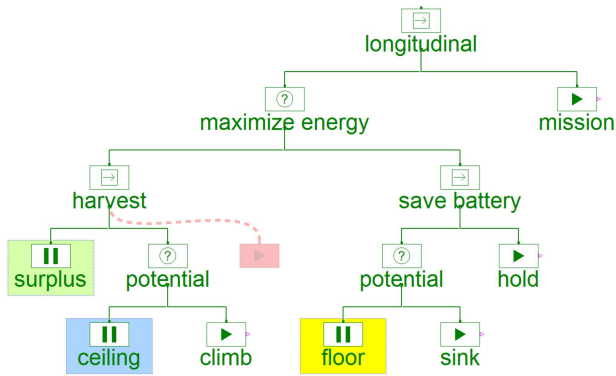

Figure 7: The BehaviorTrees mission plan uses encapsulated inputs and outputs specialized for the specific UAS application. The conditions are marked with colored frames for comparison with the transitions in Fig. 8. The plan's modularity is shown by introducing a new sub-task of the harvest task (shaded, dashed line). Only one additional connection is required for this extension.

is described already in Sec. 2 as the introductory example. It commands the aircraft to climb to its maximum altitude, whenever a surplus of solar energy is available. The second alternative ensures that a minimum of energy is used, if no energy can be stored. To this end, the aircraft first descends to a minimum altitude and holds this altitude in a way, which minimizes battery use. This type of using altitude to store potential energy is called a "jojo" mission. It is important to notice, that in this plan formulation, the main mission is only allowed to be executed, if no energy task of higher priority needs to be executed.

Figure 8 shows a StateGraph2 [5] implementation equivalent to the behavior tree. It consists of the four states *mission*, *climb*, *sink* and *hold* as well as numerous transitions with conditions equivalent to the behavior tree logic. The corresponding state graph transitions and behavior tree conditions are marked with colored frames in Fig. 7 and 8 respectively. It can be noted, that some transitions have to be reused multiple times in order to replicate the behavior tree's results.

The advanced modularity of the behavior tree can be appreciated even more, when an additional task is introduced. Figures 7 and 8 also include a sketch of loading a fuel cell as an additional energy harvesting task. While the behavior tree only requires one additional connection, the state graph has to be extended with a number of transitions. The extension is done here in an ad-hoc way and optimizations of the state machine are possible. However, the typical mission

designer will appreciate the facilities to create ad-hoc plan changes in an efficient way such as provided by the BehaviorTrees library.

The results of both the BehaviorTrees and the StateGraph2 mission plans are shown in Fig. 9. A full day of flight (86400 s) is shown including a full jojo mission between 6000 m and 13000 m of altitude. The results of both mission plans are identical: The simulation starts before sunrise, such that the aircraft holds its lower altitude limit. When the sun rises at about 07:50, the batteries start charging. Only when the batteries are fully charged at about 11:30, the aircraft climbs to its mission altitude. With decreasing solar energy in the early evening, the aircraft starts to sink to its lower altitude limit again.

Figure 9 also shows the related current productions. The repeated switching with critical battery stems from highly different power demands for the altitude holding and sinking tasks in combination with discontinuous commands from the mission plan. Providing fully continuous switching will alleviate this behavior.

In order to compare the computational complexity of the different implementations, the required CPU time on a standard laptop computer and the generated number of time- and state-events are given in Tab. 1. The values are compared for the discrete-time formulation of the behavior tree and the continuous-time BehaviorTrees modification. The tree is ticked once per minute in the discrete-time case. The important reduction of both time events and execution time can be seen. The continuous-time formulation saves about 80 % of the simulation time and removes all time events. For completeness, the execution times of the StateGraph2 implementation are also given, as well as the results from simulating only the aircraft model with the recorded command inputs for the same period.

Table 1: The execution measures of the different configurations are determined for a single simulation experiment of the discrete-time and the continuous-time behavior tree as well as the state graph implementation and a direct simulation with recorded inputs. CPU time, number of time events and number of state events are extracted from the simulation log file.

Configuration	CPU time	time- / state events
Discrete	368 s	1442 249
Continuous	72 s	0 247
State graph	76 s	60 242
Direct inputs	66 s	25 183

Figure 8: The StateGraph2 mission plan consists of four places corresponding to the actions of the BehaviorTrees mission plan. The conditions of the behavior tree are translated into transitions. They are marked with colored frames for comparison with Fig. 7. It can be seen that the state machine implementation requires a number of redundant transitions. The complexity of this implementation becomes more visible, when an additional task is introduced similarly to the one included in Fig. 7 (shaded, dashed lines).

(a) The altitude results for a full day of flight are identical for both mission plans.

(b) Also, the energy production and consumption patterns are equal for both simulations.

Figure 9: Both mission plans are simulated with an integrated aircraft model for a full day of flight. The results are identical for both plans.

## 7 Conclusions and Outlook

The conventional discrete-time formulation of behavior trees can be argued unsuitable for long-term UAS mission simulation in Modelica because of its forced update rate. A continuous-time formulation is thus devised and implemented in the Modelica BehaviorTrees library. The formulation allows the simulator to choose large step-sizes, allowing for long-term mission simulation with behavior tree mission plans in Modelica. The approach relies on passing event notifications between composite tasks and their sub-tasks.

The new formulation also addresses the limitations of previous behavior tree formulations with respect to event-handling. It provides the capability needed to process behavior trees based on events also in languages other than Modelica. By providing a suitable data storage, the approach can be used to create event-driven behavior trees also in real-time environments such as flight computers.

The Modelica library described in this paper presents clear public and internal interfaces, allowing the user to design mission plans graphically on the one hand and to implement new task types on the text layer on the other hand. The behavior tree infrastructure is complemented with a communication infrastructure allowing to conveniently pass signals from and to the plan without direct connections.

A plan implemented with the BehaviorTrees library gives identical results compared to an equivalent plan using the StateGraph2 formalism. The simulation speeds confirm that long-term simulations are possible with both methods. However, the plan's modularity is increased using the BehaviorTrees facilities as compared to a StateGraph2 implementation.

The comparison of results and timings should be regarded as an initial qualitative result. It indicates that behavior trees can indeed conveniently be used to steer a solar-powered high-altitude aircraft on long-term missions. Quantitative evaluations and comparisons to conventional state machines and discrete real-time implementations still need to be carried out. Formal validation and verification need to be addressed in order to guarantee consistent behavior between the continuous and discrete formulations.

The BehaviorTrees library is currently only used in internal studies and research projects. A commercial, or open-source, release is currently not planned but not ruled out either. The library will be further developed in the scope of a doctoral project and interested users are invited to contact the author for further information.

Future versions of the library will make use of the new synchronous elements provided by the Modelica 3.3 specification. These should provide for even better performance and robustness. Comparisons to pure Modelica 3.3 state charts should give similar results as the comparison to StateGraph2: Similar performance with improved modularity. Additional improvements can be made with respect to repeated switching by providing for continuous switching, where possible.

In summary, the prospects of using BehaviorTrees mission plans in Modelica are excellent, both in usability and in performance. The approach can be valuable not only for UAS applications, but also for other fields such as vehicle test automation. Future research effort will additionally be spent on deploying such mission plans to actual flight computers using automatic code generation and the functional mockup interface.

## Abstract

An electrical machine library, developed within the framework of the European project *Actuation 2015*, is presented in this paper. The library has been developed adopting a multi-level approach, in order to minimize the models complexity and reduce the computational time. Multi-level approach consists in creating several models of the same electrical machine topology, with different levels of complexity. Indeed, model complexity increases at higher model levels and each model takes into account specific physical effects. In addition to the fundamental behavior, the presented models address physical effects such as losses, magnetic saturation, torque ripple and fault conditions. The interchangeability among model levels is ensured by using common interfaces. An overview of the library structure is given; however, particular attention is paid on the permanent magnet synchronous machine (PMSM) models, since they are becoming increasingly widespread in aerospace applications. The PMSM models description and simulation results are provided, in order to highlight the implemented physical effects and confirm the models effectiveness.

*Keywords: Permanent Magnet Synchronous Machine, Multi-Level, Losses, Magnetic Saturation, Torque Ripple, Fault conditions.*

## 1 Introduction

According to the concept of the More Electric Aircraft (MEA), an increasing number of hydraulic actuators for primary and secondary flight control surfaces are being replaced by Electromechanical Actuators (EMAs), in order to improve efficiency, weight and maintenance of the aircraft [1]. For this reason, EMAs are becoming an attractive research area and part of the research work is focused on developing virtual testing environments and analysis tools. Indeed, EMAs' manufacturers require simulation tools capable of analyzing EMAs performance and exploring different design configurations. In response to

these requirements, a suitable simulation and analysis tool for EMAs, named *Actuator* library, has been developed within the framework of the European project *Actuation 2015*.

The multidisciplinary architecture of EMAs could lead to a large simulation time or even numerical non-convergence due to the model complexity [2]. In order to avoid these issues, the idea of implementing several models of the same component (i.e.: inverter, electrical machine, gear box etc...), with different levels of complexity has been exploited. Hence, a multi-level approach has been adopted, with the aim of keeping the models as simple as possible, since a good model is a wise trade-off between realism and simplicity.

The model levels are categorized by the complexity of the physical effects implemented within the model. In particular, higher model levels take into account more complex physical effects. Considering that several models of the same component are available within the library, the interchangeability among the model levels is crucial, in order to investigate different physical effects by simply replacing the model level. For this reason, the interchangeability has been ensured by using common interfaces among the model levels.

In this paper, the *Electrical Machines* library, which is part of the *Actuator* library, is presented. The *Electrical Machines* library has been implemented using Modelica [3], as modelling language, and Dymola, as simulation environment. This library is organized as three packages and each of them considers a specific machine topology, such as PMSM, synchronous reluctance machine (SRM) and direct current (DC) machine. Each one of these packages contains the sub-package *Examples*, which provides several case studies, helpful for highlighting the features of each modelling level. Due to space constraints, not all the machine topologies included in the *Electrical Machines* library will be considered in this paper. Indeed, the presented work is mainly focused on describing the

PMSM models as these machines are characterized by an excellent efficiency, together with a high power density [4]. These features make PMSMs very attractive for aerospace applications [5]. Whilst initially resistance to the adoption of these machines was shown by airframes to the possibility of unsuppressed short-circuit currents, it is now more accepted that through fault tolerant design and health monitoring schemes these machines offer an optimum solution.

In the next sections, an overview of the `Electrical Machines` library is presented along with a description of the model interfaces. Moreover, details of the PMSM modelling levels and the physical effects (i.e.: losses, magnetic saturation, torque ripple and fault conditions), taken into account, are given. Simulation results obtained using Dymola are also included.

## 2 Library Structure

An overview of the `Electrical Machines` library is provided in this section and figure 1 shows the library structure.

Figure 1: Structure of the `Electrical Machines` library as part of the `Actuator` library.

The machines considered in this library are PMSM, SRM and DC machine. The PMSM type covers a number of topologies from non-salient surface mount to high reluctance interior permanent magnet (IPM) machines. The library is organized in three packages,

one for each machine topology earlier mentioned, plus the package `Basic`, which considers a generic alternating current (AC) electrical machine. According to the multi-level approach previously introduced, several models with different level of complexity are included within each of the four packages. The level of complexity is related with the physical effects that the model takes into account. In other words, a higher level of complexity implies the modelling of more complex physical effects, such as non-linear effects.

The package `Basic` contains only one model level (model `Basic`), which is the simplest model for an AC electrical machine. Indeed, model `Basic` is defined by means of the torque constant and its behavior is ideal (losses and non-linear effects are neglected). Package `PermanentMagnet` includes the three-phase PMSM models and three model levels, such as `Standard`, `Saturation` and `Fault` models, are provided. Three-phase SRM models are organized in the package `Reluctance` and two model levels (`Standard` and `Saturation`) are implemented. Finally, the package `DirectCurrent` considers the DC machine models with independent excitation. This package consists of two modelling levels (`Standard` and `Saturation`). As previously underlined, the sub-package `Examples` is provided for each of the mentioned packages, in order to support the user in both familiarizing with the models and exploring their features.

It is worthy to remark that the contribution of this work is mainly focused on the package `PermanentMagnet` and all the considerations presented in the coming sections are made considering PMSM.

## 3 Models Interfaces

As mentioned earlier, every model belonging to a level is replaceable with one belonging to another level. This feature has been achieved by adopting common interfaces, which are defined in `Actuator.Electrical.Interfaces`. The adopted model interfaces can be classified according their function in:

- electrical interface;
- mechanical interface;
- thermal interface.

All quantities accessible at the mentioned interfaces are shown in physical units.

Considering AC electrical machines (packages `Basic`, `PermanentMagnet` and `Reluctance`), the electrical interfaces adopted are the `PositivePlug` and `NegativePlug`, since the stator winding is assumed as three-phase winding. In particular,

the AC machine models have been built up considering a wye-connected stator winding, with floating neutral point. The adopted electrical interfaces allow connecting the AC machine to a power converter or to a driven voltage source (`SignalVoltage`). In the case of the DC machine models, `PositivePin` and `NegativePin` have been used as electrical interfaces, for both armature and field windings (the DC machine excitation is independent).

All the machine models adopt `Flange` and `Support` as mechanical interfaces and they are included in the models by extending the `PartialOneFlangeAndSupport`. The developed electromagnetic torque and the load torque are applied on the machine `Flange`, while the reaction torque is available on the `Support`, in case the machine housing is not grounded.

The `PartialConditionalHeatPort` is used as thermal interface for all the machine models and housing temperature and heat flow are available at the heat port.

## 4 Model Basic

The model `Basic` is included in the package `Basic` and it is the simplest model for a generic three-phase AC machine. The machine behavior is described through the torque constant, which establishes the relationship between current and electromagnetic torque. Copper, iron and mechanical losses are not considered at this level, as well as, effects such as magnetic saturation, torque ripple and fault conditions are neglected.

Data records have been used to organize the model parameters and for the model `Basic` the required parameters are:

- Phase resistance ( $R$ );
- Magnetizing inductance ( $L$ );
- Pole pairs number ( $pp$ );
- Torque constant ( $k_t$ );
- Rotor's moment of inertia ( $J_r$ );
- Stator's moment of inertia ( $J_s$ ).

The stator's moment of inertia will be used by the model only when the machine housing is not grounded. Since plugs are used as electrical interfaces, the model `Basic` is fed using phase quantities ( $abc$ ) and Park's transformation (invariant amplitude transformation) [6] is adopted for implementing the model in the rotating reference frame ( $dq$ ), according to the following equations:

$$\begin{aligned} v_d &= R \cdot i_d + L \cdot \frac{d}{dt} i_d - \omega_e \cdot L \cdot i_q \\ v_q &= R \cdot i_q + L \cdot \frac{d}{dt} i_q + \omega_e \cdot L \cdot i_d + \frac{2 \cdot k_t}{3 \cdot pp} \cdot \omega_e \end{aligned} \quad (1)$$

where  $\omega_e$  is the electrical speed in  $rad/s$ . The electromagnetic torque ( $\tau_e$ ) developed by the model `Basic` is given by:

$$\tau_e = k_t \cdot i_q \quad (2)$$

The electrical equations are implemented in the *Modelica Text Layer*, while the mechanical model is realized in the *Modelica Diagram Layer*, using an object-oriented approach. In figure 2, the *Modelica Diagram Layer* of the model `Basic` is shown. Model `Basic`, as well as all the other machine models presented in the `Electrical Machines` library, is reversible. This means that the model `Basic` can work reversibly as motor or generator.

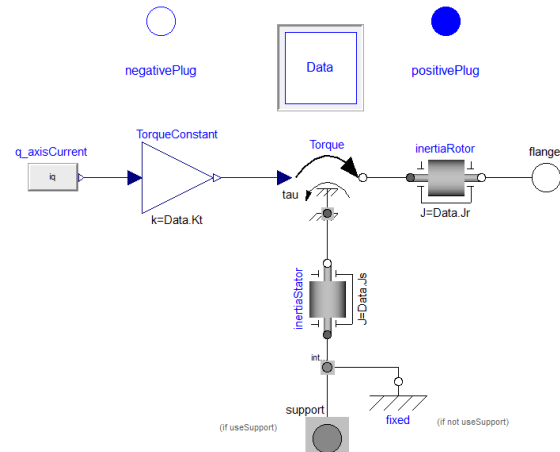

Figure 2: *Modelica Diagram Layer* of the model `Basic` included in the `Electrical Machines` library.

In order to verify the model `Basic` functionality, the simple EMA architecture, reported in figure 3, has been implemented and simulated in Dymola. The chosen EMA architecture consists of an inverter, which supplies a PMSM mechanically coupled to a 500  $rad/m$  transmission ratio roller screw, through a gearbox with transmission ratio equal to 5. The inverter is fed using a 270 V DC link and the PMSM parameters are: 14 pole pairs, 56.2  $g \cdot m^2$  rotor inertia, 0.05  $\Omega$  phase resistance, 2 mH magnetizing inductances and 2.1  $Nm/A$  torque constant. Control unit (*controller*) implements the conventional position control, hence the position is controlled by a cascaded structure, where the inner loop controls the  $q$ -axis current, the outer loop controls the speed and finally the outermost loop controls the position. During the simulation, the controlled sur-

face is moving 0.02  $m$  forward and backward, while an external load force of -80000  $N$  (equivalent to -32  $Nm$  load torque on the PMSM shaft) is acting on the flight surface. The simulation results are shown in figure 4. In particular the mechanical quantities (position, speed and torque) of the PMSM are reported and a good agreement between actual and reference position is highlighted.

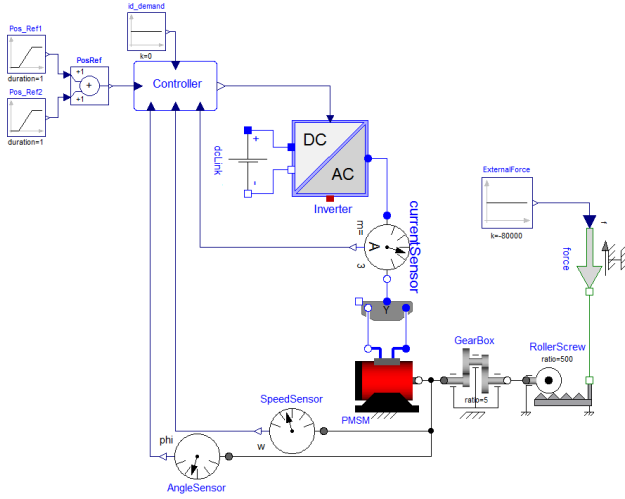

Figure 3: EMA architecture simulated in Dymola, using the model Basic.

Figure 4: Simulation results obtained using the model Basic under position control: mechanical rotor position (top), mechanical rotor speed (middle) and developed torque (bottom).

## 5 Model Standard

The model Standard, included in the package PermanentMagnet, is based on a lumped parameters approach and it describes the behavior of PMSMs taking into account torque generation, losses and thermal model. Non-linear effects, such as magnetic saturation, torque ripple and fault conditions are neglecting at this level.

The model is developed in the rotating reference frame synchronous with the rotor ( $dq$ ) and Park's transformation (invariant amplitude transformation) is used to pass from the  $abc$  to the  $dq$  reference frame. Figure 5 reports the equivalent circuits in the rotating reference frame.

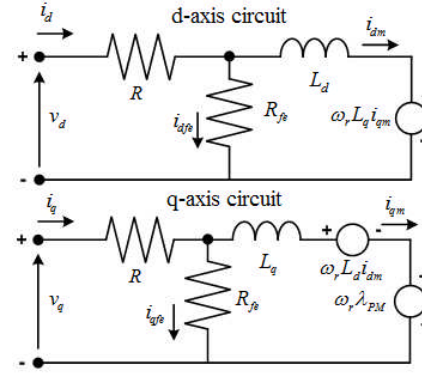

Figure 5:  $d$  – and  $q$  – axis equivalent circuits implemented within the model Standard.

These equivalent circuits take into account the iron losses using an equivalent iron losses resistance ( $R_{fe}$ ), placed in parallel with the series between the magnetizing branch and the electromotive force term [7]. Applying the Kirchhoff's voltage law (KVL) at the main loop of the circuits in figure 5, the following equations can be written:

$$v_d = R_t \cdot i_d + L_d \cdot \frac{d}{dt} i_{dm} - \omega_e \cdot L_q \cdot i_{qm} \quad (3)$$

$$v_q = R_t \cdot i_q + L_q \cdot \frac{d}{dt} i_{qm} + \omega_e \cdot L_d \cdot i_{dm} + \omega_e \cdot \lambda_{PM}$$

where  $R_t$  is the phase resistance (which is function of the winding temperature),  $\lambda_{PM}$  is the permanent magnet flux,  $L_d$  and  $L_q$  are the  $d$  – and  $q$  – axis magnetizing inductances respectively. These parameters ( $R$ ,  $L_d$ ,  $L_q$  and  $\lambda_{PM}$ ) are provided by the model user, through the model's mask. On the other hand, applying the Kirchhoff's current law (KCL) at the circuit nodes results:

$$\begin{aligned} i_d &= i_{dfe} + i_{dm} \\ i_q &= i_{qfe} + i_{qm} \end{aligned} \quad (4)$$

According (4), the total currents ( $i_d$  and  $i_q$ ) are split into iron losses currents ( $i_{dfe}$  and  $i_{qfe}$ ), given by (5), and magnetizing currents ( $i_{dm}$  and  $i_{qm}$ ). The formers flow through the equivalent iron losses resistance, while the latter are responsible of the torque generation.

$$\begin{aligned} i_{dfe} &= \left( L_d \cdot \frac{d}{dt} i_{dm} - \omega_e \cdot L_q \cdot i_{qm} \right) / R_{fe} \\ i_{qfe} &= \left( L_q \cdot \frac{d}{dt} i_{qm} + \omega_e \cdot L_d \cdot i_{dm} + \omega_e \cdot \lambda_{PM} \right) / R_{fe} \end{aligned} \quad (5)$$

In order to complete the PMSM model, the electromagnetic torque equation has to be explicit. In general, the torque developed by the PMSM is the sum of two terms: the field torque due to the permanent magnets and the reluctance torque due to the machine saliency. PMSM model Standard includes both these torque terms, hence the behavior of surface mounted (SMPM) and interior permanent magnet (IPM) machines can be simulated. The electromagnetic torque is given by (6):

$$\tau_e = \frac{3}{2} \cdot pp \cdot \left[ \lambda_{PM} \cdot i_{qm} + (L_d - L_q) \cdot i_{dm} \cdot i_{qm} \right] \quad (6)$$

where  $pp$  is the pole pairs number, which is provided by the model user.

Model Standard is a power balanced model and the losses taken into account are copper, iron and mechanical losses. Copper losses ( $P_{cu}$ ) are a function of the current and the winding resistance, according to the following equation:

$$P_{cu} = \frac{3}{2} \cdot R_t \cdot (i_d^2 + i_q^2) \quad (7)$$

The coefficient  $3/2$  arises from the adoption of the amplitude invariant Park's transformation. As previously said, the phase resistance  $R_t$  is function of winding temperature ( $\theta_w$ ), through the equation:

$$R_t = R \cdot \left[ 1 + \alpha \cdot (\theta_w - \theta_{ref}) \right] \quad (8)$$

where  $R$  is the phase resistance at the reference temperature ( $\theta_{ref}$ ) and  $\alpha$  is linear temperature coefficient, which depends on the winding material (i.e. copper or aluminum).

Iron losses ( $P_{fe}$ ), both hysteretic and eddy current, are a function of voltage and frequency as well as the material composition. These losses are calculated as equivalent copper losses:

$$P_{fe} = \frac{3}{2} \cdot R_{fe} \cdot (i_{dfe}^2 + i_{qfe}^2) \quad (9)$$

Equivalent iron losses resistance is obtained considering the specific iron losses ( $C_p$ ) and the stator mass ( $m_s$ ):

$$R_{fe} = \frac{(2 \cdot \pi \cdot 50)^2 + \lambda_{PM}^2}{C_p \cdot m_s} \quad (10)$$

Both these parameters ( $C_p$  and  $m_s$ ) are provided by the model user, using the model's mask. Specific iron losses gives the iron losses in 1 Kg mass of a given magnetic material, when it is subject to a flux density of 1 Wb/m<sup>2</sup> at 50 Hz.

Finally, mechanical losses ( $P_{mec}$ ), due to friction and windage, are functions of rotor speed and they are included in the model using the equivalent viscous friction torque ( $\tau_f$ ):

$$\tau_f = B \cdot \frac{\omega_e}{pp} \quad (11)$$

$$P_{mec} = \tau_f \cdot \frac{\omega_e}{pp} \quad (12)$$

where  $B$  is the friction coefficient. The stray losses are neglected in the model Standard, due to their small amount compared to the other losses.

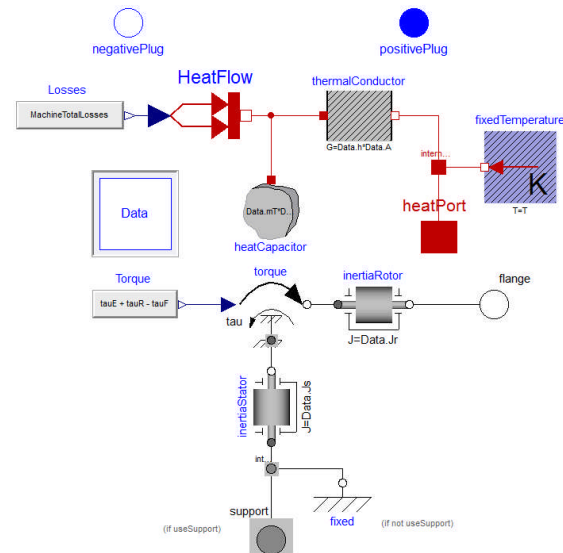

Figure 6: Modelica Diagram Layer of the model Standard included in the Electrical Machines library.

Total losses are applied in input to the thermal model adopting the component PrescribedHeatFlow. The implemented thermal model considers the PMSM as a whole block and it is composed by a heat capacitor and a thermal conductor. The heat capacity ( $C$ ) is defined as:

$$C = c_p \cdot m_T \quad (13)$$

where  $m_T$  is the total motor mass and  $c_p$  is the equivalent specific heat capacity, which depends by the motor materials (mainly copper and iron). However, the convective thermal conductance ( $G$ ) between windings and housing is given by:

$$G = h \cdot A \quad (14)$$

where  $A$  is the convection area and  $h$  is the heat transfer coefficient, which depends upon the cooling system adopted. Both these parameters, together with  $m_T$  and  $c_p$  are provided by the model user. The winding and housing temperatures are respectively available on `port_a` and `port_b` of the thermal conductor. Finally, the heat flow is available at the heat port of the thermal model (`heatPort`). Equations (3)-(14) are implemented in the *Modelica Text Layer*, while the mechanical and thermal models are included in the *Modelica Diagram Layer*, as shown in figure 6.

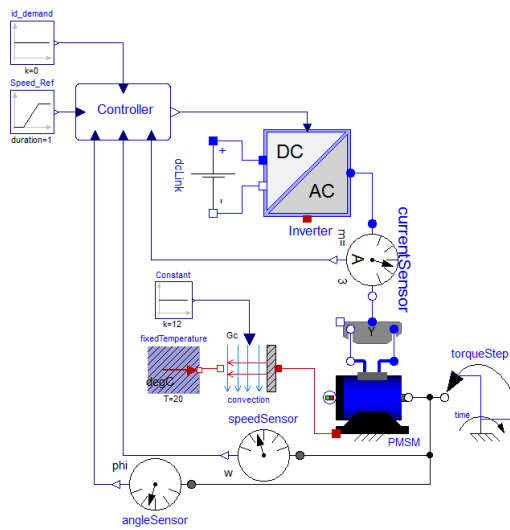

Figure 7: Speed control scheme simulated in Dymola, using the model Standard.

Model Standard has been simulated under speed control using the block diagram reported in figure 7, with the purpose of highlighting the PMSM losses and the thermal behavior. The PMSM parameters are:

- pole pairs number 14;
- rotor's moment of inertia  $56.2 \text{ g} \cdot \text{m}^2$ ;
- phase resistance  $0.05 \text{ } \Omega$ ;
- $d$  – and  $q$  – axis inductance  $2 \text{ mH}$ ;
- permanent magnet flux  $0.1 \text{ Wb}$ ;
- specific iron losses  $1.1 \text{ W/kg}$  (M300);
- stator mass  $3 \text{ kg}$ ;
- friction coefficient  $0.0002 \text{ Nm} \cdot \text{s}$ ;
- motor mass  $5 \text{ kg}$ ;
- specific heat capacity  $424 \text{ J/(kg} \cdot \text{K)}$ ;
- convection area  $0.75 \text{ m}^2$ ;
- heat transfer coefficient  $12 \text{ W/(K} \cdot \text{m}^2)$ .

During the simulation, the mechanical speed reference signal is a ramp from  $0 \text{ rpm}$  (at  $0.01 \text{ s}$ ) to  $1500 \text{ rpm}$  (at  $1.01 \text{ s}$ ), while the  $d$  – axis current

reference signal is kept equal to  $0 \text{ A}$ . Once the speed reaches the steady state value ( $1500 \text{ rpm}$ ), a load torque step of  $-25 \text{ Nm}$  is applied at  $1.5 \text{ s}$ . Figure 8 shows the PMSM losses (copper, iron and mechanical losses) together with the electrical and mechanical powers. In steady state, the machine efficiency is equal to  $93.45\%$ .

Figure 8: Simulation results obtained using the model Standard under speed control: mechanical rotor speed (top), PMSM losses (middle) and PMSM power (bottom).

The trends of the windings and housing temperatures, over a working period of  $1 \text{ hr}$ , are reported in figure 9.

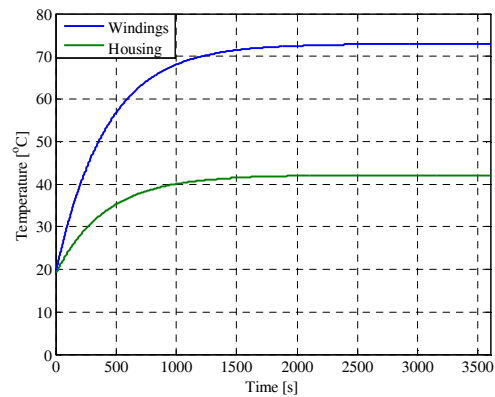

Figure 9: Simulation results obtained using the model Standard: winding and housing temperatures.

## 6 Model Saturation

The model Saturation, included in the package PermanentMagnet, has been obtained as an extension of the model Standard. Therefore it takes into account all the physical effects already presented in the model Standard section, plus the magnetic saturation and the torque ripple. As with the model Standard, the model Saturation is also developed in the rotating reference frame ( $dq$ ) and Park's transformation (amplitude invariant trans-

formation) is used to pass from the  $abc$  to the  $dq$  reference frame.

Figure 10: Field torque component against  $q$ -axis current: analytical curve (blue line) and finite element results (green dots).

In ferromagnetic materials, the relationship between the field strength and flux density is not a straight line (i.e. constant permeability), but it is defined through the magnetization curve. Since ferromagnetic materials reveal a variable permeability according to the field strength, the magnetization curve has a knee point. Past this knee point, further increases in the field strength do not result in proportional increases in flux density. The PMSM performance is affected by the magnetic saturation; in particular, it influences both the permanent magnet flux and the inductances. Since the permanent magnet flux and the inductances are a function of the operating point, the developed torque (both field and reluctance terms) is not proportional to the current anymore.

In the model Saturation for PMSM, the magnetic saturation is taken into account considering only its influence on field torque term (i.e. permanent magnet flux), while the reluctance torque term (i.e. magnetic saliency) is not affected by the magnetic saturation. In the presence of magnetic saturation, the curve of the field torque term against the  $q$ -axis current (torque-current curve) has a trend, like shown in figure 10. The torque-current curve can be included in the model Saturation using two approaches:

- the look-up table;
- three given points, which identify the torque-current curve.

In the former case, the data stored inside the look-up table may be obtained by finite element simulations. In the latter case, the model user provides the following data:

- $q$ -axis current at the knee of the torque-current curve ( $I_{qm\text{knee}}$ );

- field torque at the knee of the torque-current curve ( $T_{\text{knee}}$ );
  - field torque at the saturated region of the torque-current curve ( $T_{\text{sat}}$ );
- and the developed torque is analytically calculated using (15).

$$\tau_e = \frac{\sqrt{c_1 \cdot i_{qm}^4 + i_{qm}^2}}{c_2 + i_{qm}^2} \quad (15)$$

where  $i_{qm}$  is the actual magnetizing current along the  $q$ -axis, while  $c_1$  and  $c_2$  are the torque function coefficients. These coefficients are expressed as shown below.

$$c_1 = T_{\text{sat}} \quad (16)$$

$$c_2 = \sqrt{\frac{I_{qm\text{knee}}^4 \cdot T_{\text{sat}}^2 + I_{qm\text{knee}}^2 - I_{qm\text{knee}}^2 \cdot T_{\text{knee}}}{T_{\text{knee}}}} \quad (17)$$

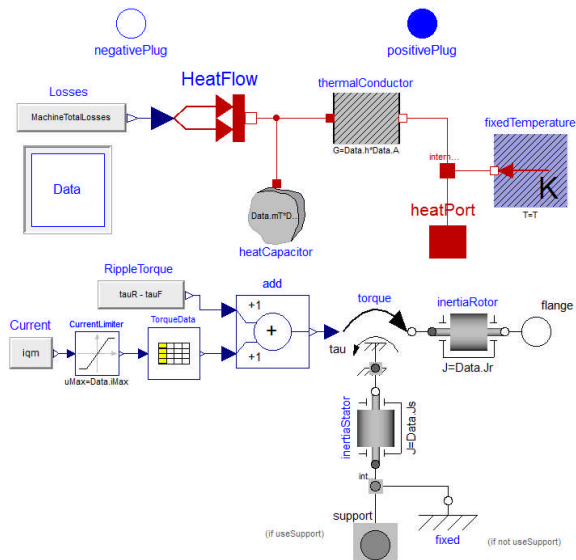

Figure 11: Modelica Diagram Layer of the model Saturation included in the Electrical Machines library.

In addition to the magnetic saturation, the model Saturation, also implements the torque ripple, which is function of the electrical rotor position ( $\vartheta_e$ ). In particular, the model Saturation allows to superimpose a sinusoidal torque ripple ( $\tau_{\text{ripple}}$ ) on the developed electromagnetic torque ( $\tau_e$ ). The torque ripple waveform is defined according (18).

$$\tau_{\text{ripple}} = A_{\text{ripple}} \cdot \sin\left(\frac{f_{\text{ripple}}}{f_n} \cdot \vartheta_e\right) \quad (18)$$

where  $A_{\text{ripple}}$  is the ripple amplitude,  $f_{\text{ripple}}$  is the ripple frequency and  $f_n$  is the PMSM rated frequency. These parameters are provided by the model user by

means of a dedicated mask.  $A_{ripple}$  and  $f_{ripple}$  are function of [8]:

- stator winding (concentrated or distributed, single or double layer);
- motor geometry (slot opening, tooth shape, etc...);
- air-gap flux density quality (harmonic content);
- load conditions.

Equations (15)-(18) are implemented in the *Modelica Text Layer*, while the look-up table is placed in the *Modelica Diagram Layer*, as shown in figure 11.

Figure 12: Simulation results obtained using the model Saturation under speed control: mechanical rotor speed (top), developed torque (middle) and  $q$  – axis current (bottom).

In order to verify the magnetic saturation influence on the PMSM performance, model Saturation has been simulated under speed control within Dymola. PMSM parameters are the same adopted for the simulation test shown in the previous section, while the magnetic saturation parameters are:

- $q$  – axis current at the knee equal to 5 A ;
- field torque at the knee equal to 10.5 Nm ;
- field torque in the saturated region equal to 30 Nm .

These parameters define the torque-current curve reported in figure 10 (blue line). During the simulation, the mechanical speed reference signal is a ramp from 0 rpm (at 0.1 s) to 2000 rpm (at 0.2 s), while the  $d$  – axis current reference signal is kept equal to 0 A. Once the speed reaches the demanded steady state value (2000 rpm), a load torque ramp from 0 Nm (at 0.3 s) to -25 Nm (at 0.5 s) is applied, in order to emphasize the magnetic saturation effect. Figure 12 shows the simulation results. In particular, the comparison between the  $q$  – axis currents flowing into the PMSM, with (green line) and

without magnetic saturation (blue line), is highlighted. When the magnetic saturation is considered, in order to develop the same electromagnetic torque (as in the absence of magnetic saturation), a higher  $q$  – axis current is required. Even during the acceleration phase, the  $q$  – axis current draw is higher when the magnetic saturation is taken into account. This is due to the analytical implementation of the torque-current curve (15). Indeed, torque-current curve is not a straight line in the linear region (see figure 10).

Figure 13: Simulation results obtained using the model Saturation under position control: mechanical rotor position (top), mechanical rotor speed (middle) and developed torque (bottom).

Figure 13 reports the simulation results obtained when the PMSM is position controlled and the torque ripple is considered. Torque ripple parameters have been set equal to 0.5 Nm amplitude (2% ripple) and 11200 Hz frequency. During the simulation, a -25 Nm load torque is applied. The enlargement in figure 13 (bottom plot) highlights the superimposition of the torque ripple on the developed torque. Torque oscillations, due to the ripple, have repercussions on both mechanical speed (middle plot) and  $q$  – axis current.

## 7 Models Fault

Models including fault conditions have been implemented only for PMSM (package Permanent-Magnet), since the presence of permanent magnets is the source of concern in the event of fault conditions. Indeed, fault condition is supplied by the back electromotive force due to the permanent magnets [9]. PMSM models including fault conditions have been implemented in the phase reference frame ( $abc$ ), since asymmetric faults are considered as well. Winding short-circuits, winding open-circuits and permanent magnet demagnetization are the three

fault conditions considered during the failure modeling. For each of the mentioned fault conditions a specific model has been developed, in order to keep low the model complexity. The realized models are listed below:

- model `ShortCircuit`, which implements single- and three-phase short-circuits;
- model `OpenCircuit`, which considers single- and three-phase open-circuits;
- model `Demagnetization`, which takes into account the permanent magnet demagnetization.

As suggested in [10], the winding faults have been implemented by means of ideal electrical switches. Such switches are driven by Boolean variables in order to open or close the phase windings and inject the fault conditions. Figures 14 and 15 show the *Modelica Diagram Layer* of model `ShortCircuit` and model `OpenCircuit` respectively.

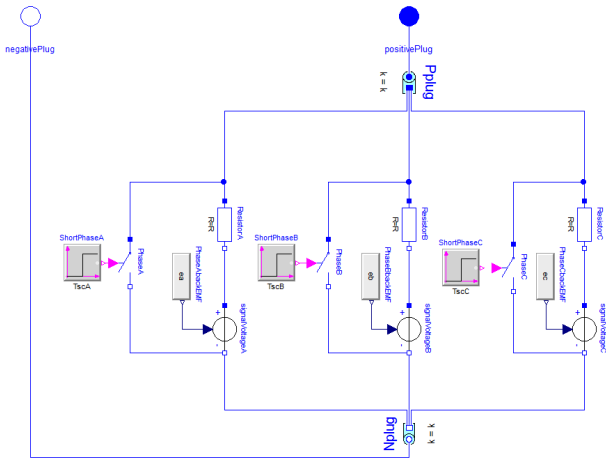

Figure 14: *Modelica Diagram Layer* of the model `ShortCircuit` included in the Electrical Machines library.

Figure 15: *Modelica Diagram Layer* of the model `OpenCircuit` included in the Electrical Machines library.

Demagnetization is caused by increasing of temperature inside the permanent magnet and/or high current values. In the model `Demagnetization`, the fault condition is considered as consequence of the fault

(i.e. permanent magnet flux reduction) neglecting the causes that led to the fault.

Figure 16 shows the Dymola block diagram used for testing the models including fault conditions. In particular, PMSM is current controlled (with  $i_q = 10 A$  and  $i_d = 0 A$ ) and its rotor is speed driven at a constant  $500 rpm$ . For the sake of brevity, only the simulation results regarding model `ShortCircuit` and model `OpenCircuit` are reported here. Moreover, the PMSM parameters are the same as those adopted in the model `Standard`, within section 5. Using model `ShortCircuit`, a three-phase short-circuit (symmetric fault) has been injected at  $0.3 s$ . By this time, the mechanical speed and currents have reached the steady state values. The corresponding simulation results are reported in figure 17. From the top plot, it is evident that the rotor speed is kept constant even after the fault injection. The middle plot shows the braking torque ( $T_{br}$ ) and its the steady state value is equal to  $-3.57 Nm$ . The same value can be obtained applying the formula reported in [11] and written below:

$$T_{br} = -\frac{3}{2} \cdot pp \cdot R \cdot \lambda_{PM}^2 \cdot \omega_e \cdot \frac{R^2 + \omega_e^2 \cdot L_q^2}{(R^2 + \omega_e^2 \cdot L_d \cdot L_q)^2} \quad (19)$$

Figure 16: Block diagram implemented in Dymola, for testing both model `ShortCircuit` and `OpenCircuit`.

Since the three-phase short-circuit is a symmetric fault, the current components in the  $dq$  reference frame can be defined (see bottom plot). The steady state values of the  $dq$  current components are  $i_{qsh} = -1.7 A$  and  $i_{dsh} = -49.9 A$ . These values are in line with those obtained applying the analytical formulas reported in [11].

$$I_{dsh} = -\frac{\omega_e^2 \cdot \lambda_{PM} \cdot L_q}{R^2 + \omega_e^2 \cdot L_d \cdot L_q} \quad (20)$$

$$I_{qsh} = -\frac{\omega_e \cdot \lambda_{PM} \cdot R}{R^2 + \omega_e^2 \cdot L_d \cdot L_q} \quad (21)$$

Figure 17: Simulation results obtained using the model `ShortCircuit`, in case of three-phase short-circuit: mechanical rotor speed (top), developed torque (middle) and  $dq$  currents (bottom).

Figure 18: Simulation results obtained using the model `OpenCircuit` in case of single-phase open-circuit: mechanical rotor speed (top), developed torque (middle) and  $abc$  currents (bottom).

In figure 18, the simulation results obtained using model `OpenCircuit` are reported. In this case, a single-phase open-circuit (asymmetric fault) is injected into phase  $a$  at  $0.3$  s. After the fault injection, the developed torque (middle plot) becomes oscillating, since the PMSM currents are unbalanced. The pulsating torque component is shown alongside the demanded torque under healthy conditions ( $21$  Nm). Its frequency is twice the operating frequency of the PMSM. Since the stator winding is assumed wye-connected, with a floating neutral point, and the current in phase  $a$  is null, due to the

phase opening, the phase currents in phases  $b$  and  $c$  must be shifted by 180 degrees. The described situation can be observed in the bottom plot of figure 18.

## 8 Conclusions

An electrical machines library developed using Modelica has been presented in this paper. Particular attention has been paid to the PMSM models, since PMSMs are becoming widespread in aerospace applications, due to their inherent features. A multi-level approach has been adopted, in order to keep the model complexity low and reduce the computation time. The interchangeability among modelling levels has been ensured by using common interfaces. All the models are power balanced and can work as either a motor or generator. The main physical effects taken into account are losses, thermal behavior, magnetic saturation, torque ripple and fault conditions. Physical effects included in the models have been discussed and their implementation has been detailed. The effectiveness of the various modelling levels has been proven through simulation results obtained in several operating conditions.

## Abstract

More electrically powered aircraft reveals some significant advantages such as weight decrease, reduced maintenance requirements and increased reliability and passenger comfort. However, the development of the future more-electric aircraft (MEA) systems is a very challenging task. Its complexity may be handled by a model supported design approach for the total aircraft design process. A key factor of applying model based design is dedicated modeling and simulation techniques for all design phases. The highest complexity can be seen in the systems validation and verification phase where the aircraft system is integrated from the supplier's models.

While the capability to conveniently model complex physical systems with Modelica is generally accepted, the capability to perform large scale model integration and analysis as part of a validation and verification process remained unproven. In this paper we give evidence of Modelica/Dymola to be suitable for the virtual testing of complex energy systems in the future MEA design process. We demonstrate the modeling and the simulation results of component stand-alone tests as well as the tests of an integrated aircraft power network.

*Keywords:* V&V; electrical network; simulation; aircraft

## 1 Introduction

The model based design approach is a key factor for more efficient aircraft design with its growing demand to optimize the complex physical systems containing mechanical, electrical, hydraulic, thermal, control, electric power or process-oriented sub components [15]. Especially the more electric aircraft concept relies on incorporating high quality system models in the complete aircraft design process [1]. The process itself briefly can be divided into 4 major phases: con-

cept phase, system specification phase, system development phase and system verification phase [5].

- **Concept phase:** During concept phase a two-fold iterative optimization is performed on aircraft manufacturer side. This includes aircraft concept and global energy system architecture optimization.
- **System specification phase:** In this phase, a frozen energy system concept is provided by the aircraft manufacturer. Additionally, more detailed aircraft data about structure, cabin, light physics, engine and electrical power generation are available. The selected system suppliers conduct full concept definition where all the requirements and risks are understood. The aircraft manufacturer's requirements is transformed to the level of equipment suppliers by the system suppliers. Stability studies and failure analysis of aircraft electrical network are typical activities during the system specification phase.
- **System development phase:** In this phase preliminary and detailed design of equipment takes place. Verification and validation for artifacts are done, which are produced during this phase.
- **System verification phase:** The objective in the system verification phase is to demonstrate the maturity of the systems in a realistic integration and verification of more-electric aircraft systems, capable of covering all phases of the development process. The virtual integration platform for energy systems allows addressing integration issues prior to their physical integration on the test rigs and also extend test coverage. Power quality investigation of the integrated network will be of the interest in this phase. The typical tasks of the aircraft manufacturer in this phase are: monitor supplier system development by verification of system performance and functions, integrate sys-

tems in physical and functional aircraft, verify integrated systems and validate simulation models versus test results.

The model types and level of detail change for every phase. For example an advanced concept phase tool like ENADOT [14], applicable for optimal architecture design of the electrical energy system, in general does not demand more detailed electrical circuits than resistive elements. In contrast, the aircraft electrical network validation and verification process strongly relies on software for detailed and numerical complex modeling, simulation and analysis of network components and systems. Substantial efforts were made to reach platform independence and link simulation tools each with special strengths and dedicated for specific domains. Especially the FMI standard was a major step forward and was verified to improve an aircraft systems design process. Nevertheless, for the sake of performance and transparency, industrial processes often rely on a single common tool.

The software used in an aircraft project for the systems integration validation and verification (V&V) process is defined by the airframer for all model suppliers and contributors. While Modelica has found attraction in the automotive sector, it is not the standard for detailed simulation in aeronautic industry yet. Inspired by the success in the prior design phases, a study was performed in the context of the CleanSky project [4] to evaluate the potential and performance of Modelica and the commercial tool Dymola for electrical V&V. In this paper we give an overview of the necessities of the infrastructure which had to be developed. Necessary tools are addressed and lessons learned from the study are documented. It is the aim of this paper to rise awareness of the needs to conduct V&V studies. This paper quotes parts of [7, 6] with special focus on the Modelica community.

In chapter 2 the general procedure for model V&V is presented. The following paragraph gives an overview of the models and library structure. Some results and lessons learned from simulation are documented in the “simulation” chapter. It is concluded by an overview of the methods and tools developed for the study.

## 2 Procedure of virtual testing

In this chapter we want to reveal the general procedure of the V&V process. Details were published in [7].

Today, virtual testing of the integrated aircraft energy system is becoming an indispensable task in the

system verification design phase. The virtual testing procedure enables integration of the system by software before the real physical integration on the test rigs and extends test coverage. The behavior of the integrated system is estimated to be representative since component models are verified by in-house hardware tests at the suppliers. Each component is delivered as detailed (behavioural) and abstracted (functional) model.

The virtual testing process can be briefly divided into two steps. First, each subsystem or component model shall be tested for correct operation by so-called component standalone tests. A standalone test usually consists of a bunch of single tests such as power connection, power disconnection, power consumption at steady state, current harmonic analysis and so on, for one component. Standalone tests are required for both functional and behavioral models.

Once standalone tests for all components and subsystems are successful finished, in the next step simulations and tests of the total integrated system model are performed. Finally, specific analysis and post-treatment tasks can be performed based on the simulation results of the integrated models.

## 3 Modeling

To illustrate the type of system under investigation, a typical MEA energy system is depicted in figure 1. The system is powered by the variable frequency generator which controls the bus voltage by the generator control unit (GCU). The AC voltage is rectified by an auto transformer rectifier unit (ATRU) which feeds the environmental control system (ECS), DC loads and the direct current charging unit (DCCU) connecting low voltage DC loads. Low level AC voltage loads are supplied by an auto transformer unit (ATU).

### 3.1 Functional/behavioural model

As written before, different modeling levels apply for different test scenarios. Today, aircraft industry utilizes a three multi-level approach for the design of the aircraft system [10].<sup>1</sup>

The models are split into three types:

<sup>1</sup>To improve the international common understanding of modeling levels and modeling needs, SAE Aerospace organisation will publish a document titled “AIRCRAFT ELECTRICAL POWER SYSTEMS. MODELLING AND SIMULATION. DEFINITIONS.” in the near future

Figure 1: Electric network architectures for More Electric Aircraft

- Architectural models consist of algebraic equations and are used for steady-state power consumption calculations.
- Functional models reflect the low frequency behavior of the original system till around one third of the base grid frequency excluding switching ripples. Functional models are derived from behavioral models by state space time averaging of high frequency periodical switching waveforms. Typical applications are stability studies [12, 11] and control design. For the AC network in research often a dq equivalent network representation [9] is chosen. For an industrial project this might be further restricted to an equivalent one phase DC system. While this simplifies the system essentially by neglecting the AC phase information, no calculation of reactive power is possible .
- The behavioral models reflect both low and high frequency dynamics including switching effects. Behavioral models are based on equations derived from the subsystem structure and electrical circuit. The behavior at the terminals should be equivalent to the real hardware up to frequencies in the hundred kilohertz. Applications include power quality simulation and analysis of transient effects [8, 16].

The table 1 presents an overview of model requirements in all aircraft design phases.

For the system verification phase, functional models

are used for long term studies of the integrated system. Behavioral models are mainly used for detailed investigation of transients as power on phases.

### 3.2 Electrical components

The library of components and systems developed for the project can be seen in figure 2. The structure follows the needs of the V&V procedure: All models are implemented as a “behavioural” and “functional” representation.

All models have to be verified by associated standalone tests. The Modelica language concept showed to be beneficial in organizing integrated libraries with both, models and scripts. For example, in figure 2 the test routines for the 230VAC/115VAC auto-transformer rectifier model are emphasized. Scripts can contain procedures for parameter setting, simulation commands and post processing and documentation features. The newly developed scripts are addressed in chapter 5.3.

In the project it was confirmed, Modelica language and the Modelica standard library are capable of modeling all subsystems sufficiently. While the Modelica electrical library is known to be of limited size compared to design environments specialized for electrics, it was found out most components can be modeled by generic objects (e.g. rectifier unit) or they are very specific and need to be written textually by equations anyway (e.g. the generator). The only type of model which was missing showed to be a detailed magnetic hysteresis model. Magnetic hysteresis is of special importance for electrical power systems since the initial magnetizing effect of electrical transformers at power connection can lead to short-time excessive currents flowing into the transformer. This effect is called “inrush current” and investigated in [6]. The Modelica magnetic hysteresis model [17] was developed from JTI resources and will be part of the Modelica standard library in the future.

As an example for the library the ATU model is shown in figure 3 which is one of the critical magnetic elements. The component tests include harmonic current test, inrush current test, power connection and power disconnection test. The harmonic current analysis aims to determine disturbances due to the equipment on different frequency levels. Fast Fourier transformation (FFT) is performed after simulation of the ATU model reaches steady state condition (figure 4).

Design phase	Typical task	Required model
Concept	Architecture optimization	Level 1
System specification	Stability studies	Level 2/3
System development	Control design	Level 2/3
System verification	Virtual testing	Level 2/3

Table 1: Model requirements in different aircraft design phase

### 3.3 Integrated aircraft power system

The stand alone test are essential prerequisites to debug the single components for stable simulation before the integration. After successful stand-alone tests for all components, various scenarios for testing the complete electric power network can be performed. To demonstrate the capability of Modelica/Dymola to deal with large scale power systems, the proposed electric power network depicted in figure 5 has been simulated in Dymola at both behavioral and functional levels. The behavioral model is reduced by Dymola to a simulation model with 69 continuous time states. The linear system to be solved reduces to one equation system of order 18. The initialization system was reduced to five independent nonlinear equation systems where the largest was of order 33. While the numbers by itself seem not to be very impressive, complexity comes from the switching system.

In the demonstrated electric power network, the ATRU is connect to grid at 0.0025 second. After the pre-charging ATRU with 25e-3 second, the DC output of the ATRU is connected with the HVDC network. The PMSM which has a 20e-3 second pre-charging time is connected with the HVDC network at 0.055 second. After the power inverter in the PMSM is activated, a constant speed command is given for the PMSM under a constant load. AC currents and voltages of the VFG is recorded in the figure 6 for behavioral model and in figure 7 for the functional model. In the simulation results, it is clear to see the inrush currents at the moment of switching on ATRU and DC ripple at the ATRU output. These values are very important indicators for the stability study for the electric power network in MEA. [12]

## 4 Simulation and lessons learned

### 4.1 General

As benchmark of the study, the components and especially the large aircraft power systems had to be simulated to demonstrate the performance and robustness of Dymola's numerical solver for such a usually very

stiff power system and suffering from huge amount of event handling actions due to switching components.

In the study it could be demonstrated Modelica/Dymola is capable of simulating all component and integration tests. Compared to the traditional simulation platform for V&V tests, numerical speed showed to be excellent for the smaller component tests and competitive for the large integration test and might be further improved. Also it was detected, simulation speed is overwhelmingly dependent on the model quality and the experience of the designer. Stable and fast operation of the components with non-specialized integration algorithms as DASSL was almost mandatory for the successful large system integration.

From the example in the previous chapter it was seen, the complexity of the initialization in many cases prevents simulation already before start. As a workaround the designer may test initialization with the steady state option.

### 4.2 Identification of modeling errors

A typical problem for large scale simulation is abortion, slow progress of simulation or chattering caused by modeling problems. For a limited number of modeling errors, the simulator's log usually gives important hints while they are not easy to interpret. For example, in the V&V study dynamic state selection was indicated by the simulator for a (working) component model. For the large scale test this inhibited numerical problems. This phenomenon and a workaround for the magnetic system is documented in [ifeec]. As a second example, for the generator model standalone test algebraic loops were indicated in the simulator's log. Algebraic loops can occur for feedback loops with feedthrough part, which can not be simplified by the symbolic routines. While algebraic loops are unusual for standard electric circuits they appear easily for saturated elements. In the V&V study the equation system conditioned by the algebraic loop accounted for numerical problems. While it does not necessarily help, there is the option to cut the loop by insertion of a first order delaying element.

Figure 6: Simulation result of integrated electric power network: VFG current and HVDC voltage (behavioral level)

Figure 7: Simulation result of integrated electric power network: VFG current and HVDC voltage (functional level)

In practice the most common error is a stiffness of the equation system which can be traced back to modeling problems. Stiff means the eigenvalues of a linearized system have a real part which is negative and large in magnitude, compared to the reciprocal of the time span of interest [3, chapter 5]. For this problem usually no distinct warning is generated by the simulator. For small systems experienced designers may detect the sources of the problem by inspection. For larger systems built from verified components, new stability problems may arise while troubleshooting by inspection may fail due to the complexity.

The problem of modeling errors and its identification shall be illustrated via the circuit depicted in figure 8.

Figure 8: Example of switching circuit with inductance

The inductance on the right hand side is powered via the the transistors by positive or negative voltage. The most simple implementation of the transistor is a switching resistor with the levels high or low resistance, controlled by a Boolean input signal (e.g. Modelica.Electrical.Analog.Ideal.IdealClosingSwitch). For a pulse width modulation scheme, the inductor is powered by the upper or lower transistor where the control signal  $C_n$  is always the opposite of  $C_p$ . Since an overlapping operation of the transistors would result in a short circuit, for real systems the turn over of the complementary control signals includes a dead-time where both transistors are in high resistance mode. In simulation, a sudden interruption of the current path in the dead-time period results in a high voltage peak in the inductor due to  $v = Li$ . The inductor's flux vanishes slowly (stiff) due to the high switch resistances. This might sound like a simulation problem but in fact this is even a physical problem: For real transistors those voltages would also occur and could severely damage the semiconductor. This effect has to be prevented in design by a free wheeling diode or a "snubber circuit" in case of an inductive source. In the study this problem occurred for the motor inverter unit. As a counteraction the snubber circuit (a capacitance in parallel to the switch) was foreseen. While inserting tiny resistances/capacitances in the circuit is a well known but poor method to solve simulation problems, here the application adds physical meaning.

An other problem which can be related to physics is the "floating ground" problem. In the example, only the voltage difference of the voltage source is defined but the absolute levels of the connectors are calculated from the circuit. This may again result in chattering of the simulation if state variables are sensitive to this floating ground. The mathematical background of the problem is a ill-conditioned Eigenvalue vector and a high numeric sensitivity of the state. As in simulation "floating grounds" are problems of the real physical system as well which can lead to malfunctions of

the circuit. Both, circuit designer and model designer should be aware of it and should consider a direct connection to ground or a connection to ground via a large resistor. Floating ground problems often are shown in the simulator's translation log while the user may be overwhelmed by the amount of information at first.

For large systems there remains the problem of identification of the source of the stiffness. In the course of the study the following approach showed to be successful (Dymola specific):

1. DLR's Modelica Linear Systems 2 library is a very powerful tool to analyze a model. Since version 2013 its functions are embedded in Dymola's main window. The command "Full linear analysis" linearizes the system and gives the eigenvalues. A stiff system exhibits at least one large eigenvalue. The participation factors relate the states variables to the eigenvalues which identifies the critical components. In the example in figure 8, a large eigenvalue could be related to the inductor's state variable "current". The problem of the circuit can be detected by observing the current paths in the system.

Often the stiffness does not appear in the original system but in the course of the simulation. The "Full linear analysis" command can be invoked to linearize at a specified simulation time. For this, the next rules apply:

2. Simulation needs to start successfully. If the system does not initialize correctly a simulation from a no-load condition and successive connection of the loads may be successful. For Dymola, the "Dassl" solver generally shows a good compromise between accuracy and speed. For stiff systems there exist special solvers as "RadauIIa" (see [3, chapter 5] for example). In many cases the perpetual use of the solvers for stiff systems only conceals problems of the models which may return for slightly more complex systems. Nevertheless, for the identification of the problem it generally is a good idea to use a solver as "RadauIIa" to get the simulation running.
3. Simulation to the critical condition/time: The first step is to identify the critical condition by simulation. In many cases the critical time is the last successful simulation step. Then the "Full linear analysis" command is evoked with linearization at the critical time. Follow instructions 1..
4. If the simulation stops in the course of the simulation before an anticipated critical time or if no

evidence can be found at the last successful simulation step, a condition with similar critical conditions might be found in the earlier simulation. By observation of the "CPU time" (simulation time at each simulated time step) stiff conditions can be identified by steeper periods in the plot of the CPU time vs. simulated time.

## 5 New developments

In the course of the project, some deficiencies were identified for the implementation of the models and the automation of the results within a single environment. The following tools and scripts were newly developed to overcome the obstacles:

### 5.1 Signal processing tool

In an industrial design process, a tool chain must fulfill higher demands on automation, ergonomics and single tools are preferred than in usual research projects. Especially, tools for signal post operation are needed integrated in the design tool and must be scriptable. In JTI, Dymola was selected as single simulation platform and there was co-funding in the project MODELSSA to extend it by the necessary features. Amongst other features, a library of signal analysis methods in time domain (e.g. min/max, period, duty cycle, root-mean-square) and frequency domain (like FFT, IFFT, total harmonic distortion) was developed. All features are accessible graphically from the user interface and scriptable. The features are documented in [3] and were presented on the Modelica conference vendor sessions.

### 5.2 Modelling of magnetic hysteresis

For efficient modeling of magnetic circuits, the free Modelica.Magnetics.FluxTubes library [2] was applied for this study. The library is well established and was proven by hardware design studies. Material properties can be taken into account by linear and nonlinear permeability. As an important extension in the frame of the Cleansky project, DLR commissioned and supervised the development of magnetic hysteresis models for Modelica. As an outcome, a high fidelity model based on Preisach's equations was embedded (the original publication goes back to 1935, for implementation see [13] for example). For the study of inrush currents which was industrially motivated it was preferred to use another more efficient one. The so called "Tellinen hysteresis model" showed to

model the flux density  $B$  versus magnetic field strength  $H$  relationship of a measured ferromagnetic material well via moderate complex equations and thus by efficient simulation speed. Details and comparisons about the first release of the magnetic hysteresis models for Modelica were published in [17].

### 5.3 Dedicated scripting for tests

Most simulation tools provide basic post processing functions but with a limited perimeter. Thus, specific analysis functions usually have to be developed for the simulation platform using a post treatment language. Also systematic design and test automation often demands user specific scripts. When performing simple/single simulations, it is sufficient to select menu commands or to type commands in the command input line of the command window. But wanting to perform more complex actions as part of an industrial process (e.g. automatically repeat more complicated parameter studies a number of times) it is much more convenient to use the scripting facility. The goal is often to fully automate the simulation. Just to name some features, the script facility makes it possible to load model libraries, set parameters, set start values, simulate and plot variables.

Dymola supports easy handling of scripting, both with functions and script files (.mos files). Whether a function or a Modelica script file (.mos) should be used is up to the user, essentially the same functionality can be obtained with both. When a function should be the final result, a function is created, and the functionality is then created as an algorithm in this function using the Modelica Text layer of the function as an editor. When a Modelica script file (.mos) should be created, the command input line can be used for input, creating a command log that can be saved as a script. Scripts can be nested; functions can be nested and a Modelica script file may run other Modelica script files.

The test scripts were customized by DLR from existing commands of Modelica language and Dymola functions. The built in functions and model management tools of Dymola were found to be sufficient for the study. Among others, the following scripts and tools were found to be necessary repeatedly for the V&V study:

- Transformation of input data: From input files data are edited into a Modelica compatible type. This function is of major relevance in an industrial process since input data might not be Modelica compatible and use of additional software

is undesirable in standardized processes. By help of some Dymola built in functions conversions from text files, Microsoft Excel sheets and more was performed. Matlab's matrix data format .mat is supported immanent.

- Transformation of output data: Same as for the import, the output features are important. Typical outputs programmed in functions were time domain results (.mat result files), tables (Excel) and generic data (.txt). For generation of frequency domain data, it was necessary to have the Fast Fourier Transformation (FFT) function executable by script. Thanks to the co-funding by the JTI project this function is now provided in Dymola. Application of the FFT function include parameter studies with tabulated output of total harmonic distortion (THD) or harmonic content at specified harmonics.
- Coherency test models: Test of linear dependence of signals in time domain by convolution. Coherency is an important criterion in verification tests to analyze the validity of models and model abstraction levels. It is applied for verification of models versus hardware test data or between different models. The script calculates coherency by application of the coherency function to two simulation or measurement waveforms.
- AC modulation envelope: The AC envelope function is the smooth curve outlining the extreme positions of a distinctive alternating wave with a fixed frequency. The modulation envelope shows its amplitude variation in frequency domain. The AC amplitude is an important measure for the voltage quality which must be stabilized by the generator control. The developed function relies on peak finding and transformation of data to frequency domain by FFT.

As an example of an integrated test, the Dymola script for the worst case study of sympathetic effect is presented in Fig. 9. This script function firstly simulates the test bench till 5.791 second and records the simulation result in a "end.txt" file. This result will be always defined as initial condition for the following 20 time simulations with different connecting time for ATU2. A real variable Tatu2 is defined to vary the connecting time of ATU2 and has a time step  $\varepsilon = 0.000125$  second for each simulation loop. Simulation setups such as used integrator, simulation time are also defined in the script function. Additional scripts have been made

for post-processing. It is a big advantage for users, that a complex test like analysis of sympathetic effect can be easily formulated with Dymola scripting language in a very compact manner.

```
function Script_Case1_with_simulation_paper
import Modelica.Utilities.Flies.*;

protected
  Real Tatu2 = 5.791;

algorithm

  //performe simulation till steady-state
  translateModel("Case1");
  simulateModel("Case1",
    stopTime=5.79,
    numberOfIntervals=0,
    method="Radau",
    resultFile="Case1");

  //backup dsfinal
  copy("dsfinal.txt","end.txt",true);

  //do parameter studies about
  //switch on time of ATU2 with
  //time step 0.000125s

  for i in 1:1:20 loop

    Tatu2 :=5.791 + i*0.000125;
    importInitial();
    simulateExtendedModel("Case1",
      startTime=5.79,
      stopTime=5.8,
      numberOfIntervals=0,
      method="Radau",
      resultFile="dres_"+String(i),
      initialNames={"Tatu2"},
      initialValues={Tatu2},
      finalNames={"Tatu2"});

    //re-initialization
    Files.copy("end.txt","dsfinal.txt",true);

  end for;
end Script_Case1_with_simulation_paper;
```

Figure 9: Scripting for the worst case study of sympathetic effect

## 6 Conclusion

By the study, the applicability of Modelica and Dymola for large scale testing of aircraft electrical systems in V&V studies was demonstrated successfully. All demands on new functionality, additional models and specialized scripts could be met within the project.

It could be detected the reliability of simulation highly depends on mature models. The developed library therefore is an important base for propagation to a Modelica based V&V process in aircraft electrical systems simulation. Further effort should be made for robust initialization of the simulation.

## Acknowledgment

The research leading to these results has received funding from the European Union's Seventh Framework Programme (FP7/2007-2013) for the Clean Sky Joint Technology Initiative under grant agreement no. CSJU-GAM-SGO-2008-001.

## Abstract

The goal of the A2015 library presented in this paper is to develop a Modelica based, tool-independent standard for electromechanical actuators (EMA). This will contribute to the establishment of a “common language” throughout the development of EMAs for aircraft and helicopters and through the supply chain. All stages of the design and validation process (conceptual design, specification, development and validation) are covered. The modeling approach addresses specific aspects of the EMA design process not covered by existing tools. The library scope, engineering need and implementation are described. Modeling of selected EMA components is discussed in more detail. An application example of the library is given (linear actuator, A320 aileron)

*Keywords: Actuator, EMA; Library; Multi Physics*

## 1 Library scope

### 1.1 Introduction

Protecting the environment and providing efficient onboard energy supply is one of the top goals in the

development of future aircraft. A key technology towards the realization of these goals is the “More Electric Aircraft”. Various research initiatives have been launched in recent years to get closer to this goal. The ACTUATION2015 project [1] will complete this approach by focusing on Electro Mechanical Actuator (EMA) technologies. EMAs are mandatory in order to substitute hydraulic circuits, pumps and reservoirs. The objective of the ACTUATION 2015 project is to develop and validate a common set of standardized, modular and scalable EMA modules that address cost, reliability and weight requirements from the air framers. In the context of that project the A2015 simulation model library is developed to support and streamline the EMA design process.

### 1.2 Engineering needs

The focus of the ACTUATION2015 project is on aircraft families including business, regional and large commercial aircraft as well as helicopters. The actuation systems covered include primary and secondary flight controls, main landing gears and breaks. A further major focus is on modularization and scalability of EMA modules. All the needs and architecture differences of such systems and all dif-

ferent stages of the development process (conceptual design, specification, development, and validation) through the whole supply chain must be covered by a universal simulation model library.

Apart from covering the relevant physical effects and general system dynamics aspects, the library should support the development in terms of concept and performance assessments, sizing (as far as system aspects are involved), component requirements definition and fail case assumptions, system reaction and performance in case of failures (static and transient), and virtual design validation. Electromechanical actuators have mostly a reduced reliability compared with conventional hydraulic actuators. Therefore the library must allow assessing redundant actuator concepts.

Since simulations on system and subsystem level can't cover all computational needs of an EMA development, interoperability with established tools is vital. Because many tools support it, the FMI standard [13] is the natural choice for model exchange of Modelica libraries. The library does not provide distributed parameter models (for e.g. stress computations) and monitoring and state of health algorithms, because specialized tools for these tasks are already available.

### 1.3 Library architecture

In order to cover the described range of applications several models of different scope and level of detail are implemented for each of the core EMA components (multi-level approach, see e.g. [14]). Since each group of models shares the same interface they are easily replaceable. In the A2015 library five modeling levels are predefined, mostly associated with nonlinearities included and events triggered (for easier handling each level has an associated icon color):

1. Perfect (linear, no losses)
2. Linear, invertible
3. Nonlinear, invertible (e.g. using tanh instead of sign functions)
4. Hard nonlinear (state events are triggered by nonlinearities)
5. Fully switched (e.g. switching inverter, based on state events)

This scheme does not imply that for all components models of all levels are included, or for each level only a single model is included. Instead, the modeling level scheme is introduced to give the user a quick idea what kind of effects a certain model does include.

Naturally, the A2015 library follows a standardized model breakdown structure with common interfaces based on the Modelica Standard Library (MSL) and uses its predefined implementations of thermal flows and heat exchange, and mechanical support flanges [9]. Parameters are organized in records, signals are bundled in busses. In order to unify failure injection, a dedicated library is used [12].

## 2 Selected library components

The A2015 library contains model components from the following domains: Electrical (inverters, motors), mechanical (rotation to rotation and rotation to translation transformers), sensors (position, speed, force, etc.), thermal (heat sinks, housings), and control (e.g. force fight compensator). Selected components are described in this paragraph.

### 2.1 Fault Triggering Library

The development of health monitoring algorithms, but also the design of fault tolerant redundant actuators is aided by the possibility to easily trigger faults in the models.

The `FaultTriggering` library [12] is used as a standardized approach to trigger all failures implemented in the library. At the moment the motor, inverter, gear and nut screw models have predefined faults that can be enabled. Further model components will follow.

### 2.2 Inverters

This section gives an overview of the implementation of the multi-level Power Electronic Inverter modeling provided within the A2015 library. For further technical details see [3].

#### 2.2.1 Package Structure

As described previously, a multi-level modeling approach is used within the A2015 library. For the Power Electronic Inverters 5 levels of complexity are provided. The Inverters package is split into the `NonSwitching` and the `Switching` subpackages, see figure 1. The `NonSwitching` package provides models for levels 1 to 4 and the `Switching` package provides a level 5 model. A core feature of the A2015 library is that for each individual component every modeling level is fully replaceable with one another. In order for each modeling level within the Inverters library to be fully exchangeable a common interface is used for all 5 modeling levels.

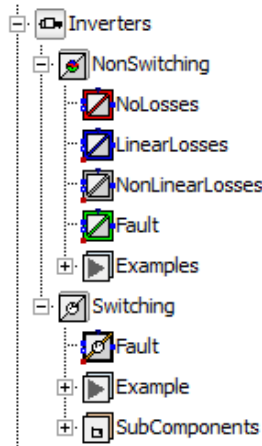

Figure 1: Structure of the Inverters package as part of the Actuator Library.

### 2.2.2 Losses

It is important to note that all the Power Electronic Inverter models are fully multi-directional. Therefore losses are fully implemented, regardless the direction of the power flow. Hence, if power flows from DC to AC the AC side power will be lower than the DC side power and vice versa. This is inherent within the model and will be calculated automatically even when the direction of power flow changes during simulation. Table 1 summarizes the losses included in each level of the Inverter models.

Level	Losses
1	None
2	Linear Losses
3	Non-Linear Losses
4	Non-Linear Losses
5	Conduction Losses

Table 1: Losses modeled within each level of the Inverters package.

Using the level 2 model the user may specify a constant efficiency for the Power Electronic Inverter under all operating conditions (a default value is provided, if no data is available). Levels 3 and 4 both use non-linear loss characteristics. The user can specify the power range of the inverter and the losses within the inverter over the specified power range. A default characteristic is also given, as shown in figure 2 below, however accurate characteristics are recommended to be added by the user if known. The default characteristics are per unit and are scaled within the model by the specified, or default, power range.

Figure 2: Default non-linear loss characteristics

Level 5 includes switches and Pulse Width Modulation in order to create the required electrical outputs. The losses included are the conduction losses due to the switch and diode resistances when conducting. Energy losses due to switching are neglected.

### 2.2.3 Faults

Another core aspect of the A2015 library is the inclusion of fault conditions within all component models. In the case of the Power Electronic Inverters these are mainly included in the level 5 model because failure of switches are the most likely failure conditions and no switches exist within the lower level models. Table 2 summarizes the fault conditions included in the Inverter models.

Level	Faults
1	None
2	None
3	None
4	Full-Bridge
5	Single Switch, Single Phase, Multi-Phase and Full Bridge

Table 2: Fault conditions modeled within each level of the Inverters package.

For level 4 a full bridge fault is implemented. When triggered the Power Electronic Inverter output becomes zero. This represents a full-bridge open circuit fault or deactivation of the Inverter. The level 5 model includes the ability to activate open circuit and short circuit faults. These can be injected for a single switch, multiple switches, a single phase, multiple phases and full bridge. The Fault Triggering library described in [12] is used in order to trigger the implemented faults. The actual faults can be injected at any time instance but must be predefined.

## 2.3 Motors

### 2.3.1 Package Structure

According to the machine topologies considered, the Electrical Machines package is divided in four sub-packages:

- Basic, which considers a generic AC machine
- PermanentMagnet, which includes the permanent magnet synchronous machine (PMSM) models
- Reluctance, which models synchronous reluctance machines (SRM)
- DirectCurrent, which contains the models of DC machines with independent excitation

An Example package is provided for each of the described sub-packages, in order to highlight the model features. The Electrical Machines package has been developed adopting a multi-level approach as described in chapter 1. Several model levels of the same machine type, with different physical effects taken into account have been implemented.

### 2.3.2 Model Interfaces

The interchangeability among model levels is ensured using common interfaces. Considering AC electrical machines `PositivePlug` and `NegativePlug` have been used as electrical interface. In case of DC machine models, `PositivePin` and `NegativePin` have been adopted as electrical interfaces, for both armature and field windings. All the machine models adopt `Flange` and `Support` as mechanical interfaces and contain a heat port providing housing temperature and heat flow.

### 2.3.3 Basic Model

The basic model is the simplest model for a generic AC machine. The machine behavior is described by a torque constant, which establishes the relationship between current and electromagnetic torque. Losses, non-linear effects and thermal behavior are not considered at this modeling level. The basic model, as all the other machine models, can work reversibly representing both motor and generator.

### 2.3.4 Standard Models

Standard models are based on a lumped parameter approach. They describe the behavior of the machine considering losses and thermal behavior, but neglecting magnetic saturation, torque ripple and fault conditions. Standard models have been developed for PMSM, SRM and DC machine. These models are power balanced. The losses taken into account are:

copper, iron [4], mechanical and for DC machine brush losses. Finally, standard models provide a machine thermal model, which gives the winding and housing temperatures, and the heat flow.

### 2.3.5 Saturation Models

Saturation models for PMSM, SRM and DC machines have been obtained by extending the standard models. The main features of the Saturation models are magnetic saturation and torque ripple. Magnetic saturation is taken into account using two approaches (which can be user-selected): look-up table and analytical implementation. In the former case, the torque-current curve data (may be obtained by a finite element simulations) are stored in a look-up table, within the model. In the latter case, the torque-current curve is implemented using three given points (current and torque at the knee and torque at the saturation region). Finally, Saturation models allow superimposing a sinusoidal torque ripple on the computed electromagnetic torque. The torque ripple parameters (amplitude and frequency) must be given by the user.

### 2.3.6 Fault Models

Models including fault conditions have been implemented only for PMSM, since the presence of permanent magnets (PMs) is source of concerns in the case of failures. Fault conditions such as winding short-circuits, winding open-circuits and PM demagnetization have been considered. For each of these cases a specific PMSM model has been developed in order to minimize the model complexity. The fault models are:

- ShortCircuit, which implements single- and three-phase short-circuits
- OpenCircuit, which considers single- and three-phase open-circuits
- Demagnetization, which takes into account the PM demagnetization.

As suggested in [5], the winding faults have been implemented by means of ideal electrical switches. In the demagnetization model, the fault condition is taken as a consequence of the fault (i.e. PM flux reduction) neglecting the causes that led to the fault.

## 2.4 Mechanical rotational (reducers)

The rotational mechanical models include gear reducers and torque limiters. As with the other components, multiple modelling levels are included for different accuracy needs.

### 2.4.1 Package Structure

The package structure is given in figure 3. Only selected packages are expanded to give a good overview of the used models.

Figure 3: Structure of the Rotational package.

### 2.4.2 Model properties

All rotational models are fully balanced models with optional support flange. Using this approach, the support torques can be modelled and used for housing design. Also all models are energetically balanced. All losses are available in the (optional) heat ports.

### 2.4.3 Gear reducers

The `GearReducer`, `EpicyclicReducer`, `GearedRotaryActuator` and `HarmonicDrive` packages model geared transmissions with following levels of detail:

- Basic: no losses
- Linear: losses dependent on speed
- Nonlinear: losses dependent on the speed using a hyperbolic tangent approach to approach the nonlinear friction effect at zero velocity.

### 2.4.4 Torque limiter

The torque limiter restricts the torques on a shaft to a safe level by transferring the rest torque to a support flange.

## 2.5 Mechanical translational (nut screws)

As illustrated by table 3, the most simple models of nut screws (NS) start from the MSL `IdealR2T` model to reproduce the functional effect of perfect power transformation between rotational and translational domains.

For the most simple case, end-stops and bearings are not explicitly considered in the NS model:

- When the displacement is out of physical stroke, a warning is generated or the simulation is stopped.
- Anti-rotation and anti-translation devices are included implicitly, assuming no translation of the drive shaft and no rotation of the actuator rod.

When using the support options, the NS model becomes a mechanical quadriport model which combines the rotation and translation of nut and screw. This enables the explicit modelling of anti-rotation and anti-translation outside the NS model [6]. Inertial effects are also to be added outside of the NS model.

Technological imperfections are progressively introduced and modelled with increasing complexity. Among all candidate topologies, the NS model structure is selected in order to meet major engineering needs for aerospace actuators. For this reason, it associates in series (from drive to load flanges):

- a perfect rotational to translational power transformer, with warning or error generated when the position is out of stroke
- an optional friction loss that applies to a rigid rod
- an optional and generic compliance that can represent in addition either backlash or preloading, depending on parameterisation.

### 2.5.1 Friction models

There are a lot of candidate options for friction modelling and parameterization [7]: efficiency (direct/indirect), parametric model of friction force (e.g. Coulomb or Stribeck), coefficient of friction with rod diameter and lead, etc. Using efficiency (direct and indirect) has been selected for non linear friction models because it is widely used by engineers. As a drawback, using efficiency exclusively does not allow to compute the no-load driving force or no-drive back-driving force. For non preloaded designs, a lossy rod model has been developed with the same structure as the MSL `LossyGear` [8].

For continuous models, the transition between sticking and sliding has been approximated by a hyperbolic tangent function in order to avoid triggering state events. In addition, removing any conditional statements has contributed to typically reduce the simulation time of the friction model by 25%. By setting negative values for the indirect efficiencies, irreversibility (impossible to back drive the NS) is parameterized without introducing an additional pa-

parameter for that case. When activated the thermal port of the friction model outputs the heat generated by friction.

### 2.5.2 Compliance models

In order to enable failure injection or design exploration, a non-linear model has been developed to reproduce backlash, pure compliance or preloading, depending on its parameterization. NS compliance has been modelled as a transmission device involving two unilateral elastic contacts that act in opposition. The compliance model structure was defined in order to maintain consistency with the MSL, as illustrated by table 3.

The MSL `Elastogap` model has been modified for non-linear continuous models in order to avoid any event triggering or conditional statements, even for structural damping. Each direction of contact between nut and screw has been modelled by a serial combination of a lossy-rod and an elasto-gap, with one elasto-gap being flipped. This choice has the major advantage of reproducing the friction force

due to preload without any modification of the friction model. For non continuous models, the strengthening length of contacts has been used as the unique parameter of preload and backlash, enabling continuous transition between these characteristics. Positive values correspond to backlash, zero values to pure elastic and negative values to preload conditions.

### 2.5.3 Fault triggering

The two major types of NS failure are jamming and free-run. Jamming has been modelled by increasing friction through modification of the friction model parameters. Free-run has been modelled by manipulation of the compliance model parameters: decreasing stiffness (linear model) or preload, then increasing backlash. The failure injection library can also be used to introduce progressive degradation through continuous evolution of friction and compliance parameters. This is of particular interest for virtual assessment of health monitoring strategies.

Properties of different nut screw models	MSL	Basic	Linear	Nonlinear Continuous	Nonlinear non continuous
Perfect power transformation					
Optionally activated ports of mechanical support	✓	✓	✓	✓	✓
Replaceable models and data records					
Warning or stop if out of stroke		✓	✓	✓	✓
Offset of displacement transformation		✓	✓	✓	✓
Optionally activated heat port	✓	✓	✓	✓	✓
Optional version for Failure injection (jamming or free-run)		✓	✓	✓	✓
Compliance			Linear spring	✓	✓
Friction loss	Direct/Inverse efficiency		Viscous damper	Direct/Inverse efficiency	Direct/Inverse efficiency
Irreversibility				✓	✓
Preload				✓	✓
Backlash				✓	✓
Effect of velocity on friction				Planned	Planned
Effect of temperature on friction				Planned	Planned

Table 3: Properties of A2015 library nut screw models

### 2.5.4 Model verification

All models have been designed to accept implementation in causal simulation software. In addition, their ability to run correctly for any causality case in the Modelica environment (any combination of two imposed variables out of drive torque, drive velocity, load force, and load velocity) has been addressed in detail.

### 2.5.5 Future work

The last part of the model development will include the consideration of the dependency of friction on velocity and temperature. Unfortunately, these effects are rarely documented in supplier's catalogues and are generally considered as confidential. However, it is intended to enable varying efficiencies versus velocity and temperature, either through a parametric equation or by a 3-D table.

## 2.6 Sensors

The A2015 library includes models for linear and angular position sensors, force sensors, torque sensors, current sensors, and temperature sensors.

They extend ideal sensor models from the MSL [9] and add effects and failures to the sensor output that are present in real sensor devices. Offset, non-linearity, saturation, and temperature dependency, as well as hysteresis, drift, and signal discretization are the effects taken into account. Most common sensor failures, such as open-circuit and short-circuit, will also be implemented.

The sensor models are parameterized according to typical data sheets in order to provide the end user with a practical library. This approach results in very general sensor models, independent from the sensor technology, which can be easily customized.

Figure 4 shows the structure of the Sensors package, which follows the general modeling approach for the whole library: different model levels (here: `Ideal`, `Linear`, and `NonLinear`) sharing a common interface, parameters included in records, and a bus connector predefined with the ideal and real signals of the sensor, and a status flag.

## 2.7 Controllers

### 2.7.1 Package Structure

This package contains blocks suitable for designing the control system of actuators [10]. The blocks can be combined with actuators of different modelling levels.

Figure 4: Structure of Sensors package

The structure of the Controllers package is shown in figure 5. Due to the function of the models within the package, the structure of the Controllers package follows a slightly different approach than other packages of the A2015 library.

The package consists of four sub-packages. The Continuous and Discrete sub-packages contain basic controller blocks built up from proportional, integrator and derivative blocks. The main purpose of the blocks in the Filters sub-package is to smooth control demand signals or filter measurements. The last sub-package contains blocks performing direct and inverse Park transformations. The package contains wrapper classes that allow the user to conveniently exchange blocks with similar functionality. The blocks in the library are parameterised via dedicated parameter records, organized in a separate sub-package.

### 2.7.2 Description of selected blocks

The PID controller variants include a symmetrical output saturation and integrator anti-windup (when applicable) and can be parameterised according to both the serial and parallel convention. They differ from the counterpart in the Modelica Standard Library in the implementation of the integrator anti-windup. Within the A2015 library, the integrator anti-windup is based only on the output of the integrator, not on the overall output. The output saturation is therefore implemented separately.

The filter blocks include both continuous and discrete time blocks, as well as general blocks that can be parameterised by specifying the numerator and

Figure 5: Structure of the Controllers package.

denominator of their transfer functions and also the well-known continuous time filter types available in the Modelica Standard Library (Butterworth, type I Chebyshev, etc). These model classes are wrappers for the blocks from the Modelica Standard Library in order to allow the user to switch between the different filter types.

A specialised force-fight compensator, the position, speed and current controllers are available as distinct standalone blocks. The measurements required by these blocks are collected via specialised sensor buses (see chapter 2.5). The user is free to select the controller and control demand filter types. These blocks can be connected to motor models via a three-phase interface and also to simplified motor models with one input. This is used in the two variants of the current controller, one of which performs space vector control.

### 2.7.3 Failure modes

The actuator control library also provides the user with a means for simulating the effects of various control failure scenarios. The following failure modes will be implemented: control output freeze, controller reset, short spikes in the controller output, non-return to zero error, runaway and no valid data faults.

## 3 Application example

To test the library and give a realistic example, a linear actuator based on an A320 aileron actuator has been modeled using the described library. The actuator model is set up using the base class `LinearGearedEMA`. This is a predefined base class for linear actuators which fully supports all redeclaration schemes of the library. It is extended by a position controller and an extra position sensor.

The final model can be seen in figure 6. In the model, the multi disciplinary approach of the library is directly visible. Electrical, mechanical and thermal effects are taken into account as well as the actuator control.

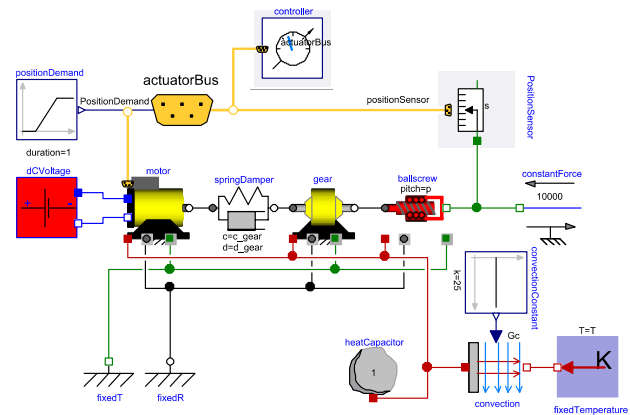

Figure 6: Overview of complete Linear EMA

### 3.1 Model structure

The mechanical model is built using a 2x1DOF approach. The rotational as well as the translational forces and support forces generated by each part are accessible outside the model. This may be used for the design of anti-rotation devices. The parameter data of the motor, gear, inverter, nut screw and controller are stored in parameter records. They extend from base records of these data to facilitate easy re-declaration in the models.

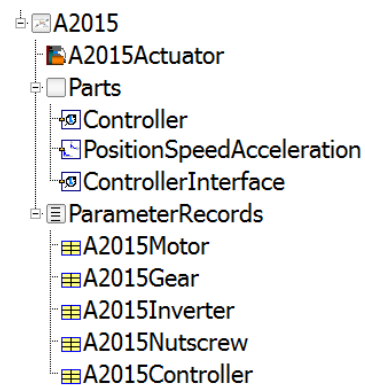

Figure 7: Overview of the library with the components for a specific linear EMA

In figure 7 an overview of the library for this specific linear EMA is given. All specific parts are combined in the package `Parts` and all parameters in the package `ParameterRecords`.

### 3.2 Simulation results

Simulation results of the described actuator can be seen in figure 8. The shown current response is the result of a position step input of 4.3 mm. In the Modelica model, the aerodynamic damping is neglected and a continuous controller is used. For comparison the simulation result of a discrete Simulink reference model is also plotted. Both simulations show a comparable dynamic response.

By modelling the controllers using the existing discrete blocks, it is possible to also model the effects of discrete controllers and increase the match between the model results.

To showcase the more advanced features of the library, an advanced model, including motor saturation and motor ripple is included. The effect of a motor ripple is visible from 1.15 to 1.3 seconds.

The shown simulation run takes 0.2 seconds of simulation time on an Intel® Xeon® E5-1620 Processor. The reference model in Simulink takes 6.5 seconds simulation time on the same machine. Including a sampled model using the same sample time as the Simulink model increases the simulation time to 1.7 seconds.

The frequency response of an actuator is also an important design criterion. It can be calculated using the `FrequencyResponse` package [11] by T. Bunte. The amplitude and phase response for 3 amplitude values (1, 5 and 10 mm) is calculated. The response from the input reference to the output rod is shown in figure 9. The frequency response of the same system with different amplitude changes depending on the stroke. This clearly shows the nonlinearity of the system. As expected, the system cannot follow the high frequencies at high amplitudes due to limitations on the motor current.

## 4. Conclusion and outlook

In this paper we have presented a library for modeling Electromechanical Actuators (EMAs). In the library, electrical machines, inverters, controllers, mechanical parts (rotational and translational) as well as sensors have been included. All model components have been set up using replaceable parameter sets and replaceable parts. The standardization of the interfaces of the components using partial classes

enables the user to build an EMA model as a modular system. This supports the exchange of models between partners and makes it possible to reuse these models for different simulation tasks without a structural redesign. The integration of component faults helps to quickly assess the actuator performance for failure cases.

To test the library, an existing Simulink model has been reworked into a Modelica model using mostly the components from the library. The results of the Modelica model show a good agreement with the Simulink reference model.

Figure 8: Simulation of actuator system

Figure 9: Frequency response of controlled actuator from position reference input to rod output.

The presented library is developed with a strong focus on Electromechanical Aircraft and Helicopter Actuators. This is not the only field the library can be used; It can help developers of all electromechanical actuators like automotive actuation (air path actuators for diesel engines, automatic hatch door actuation), automation systems (packaging machines) or printing systems.

Possible future library extensions include mass, volume, cost, etc. design optimization (by providing specialized modeling levels while maintaining the EMA model topology) and automated safety and reliability analysis.

The availability of the library in- and outside of ACTUATION 2015 is currently under clarification by the partners of ACTUATION2015.

## Abstract

A computational framework for the efficient analysis and optimization of dynamic hybrid energy systems (HES) is developed. A microgrid energy system with multiple inputs and multiple outputs (MIMO) is modeled using the Modelica language in the Dymola environment. The optimization loop is implemented in MATLAB, with the FMI Toolbox serving as the interface between the computational platforms. Two characteristic optimization problems are selected to demonstrate the methodology and gain insight into the system performance. The first is an unconstrained optimization problem that optimizes intrinsic properties of the base generation, power cycle, and electrical storage components to minimize variability in the HES. The second problem takes operating and capital costs into consideration by imposing linear and nonlinear constraints on the design variables. Variability in electrical power applied to high temperature steam electrolysis is shown to be reduced by 18% in the unconstrained case and 11% in the constrained case. The preliminary optimization results obtained in this study provide an essential step towards the development of a comprehensive framework for designing HES.

*Keywords: hybrid energy systems; dynamic simulation; optimization; renewable energy; FMI*

## 1 Introduction

Hybrid energy systems (HES), which may combine multiple energy resources to achieve improved performance or cost efficiency, have attracted consider-

able attention in the United States and internationally due to developments in renewable energy technologies as well as economic, political, and environmental concerns regarding existing energy infrastructures. One notable challenge to the design and deployment of HES is the difficulty in modeling the operation and performance of such systems. Traditionally, electricity is produced from baseload generation (e.g., nuclear and coal plants), which operate at near steady state conditions with little variability. In contrast, renewable energy sources (e.g., wind turbines and concentrated solar plants) are highly dynamic with very significant variability. The addition of a renewable component to the energy infrastructure creates an enormous increase in the number of possible operational situations that must be considered, and thus greatly complicates the design process. Although it is well understood that a large energy storage device capable of achieving high rates of charge and discharge is necessary for mitigating the variability of renewable energy sources, the design and control of HES makes little use of proper design optimization methodology. In this study, we seek to apply optimization methods in order to gain a better understanding of the complex dynamics governing HES, and to obtain insights towards how to properly design such systems to maximize performance and cost efficiency.

To achieve the desired improvements in HES design, appropriate simulation and optimization tools need to be selected. The Modelica language is well suited for studying complex systems such as HES due to its object-oriented structure and acausal approach to modeling. On the other hand, the MATLAB environment provides a variety of optimization methods,

including those available in the Optimization Toolbox. In numerical optimization, it is of critical importance to automate the simulation process, because manual iterations quickly become impractical as the problem size is increased. Since our HES model and optimization algorithms are implemented in different software environments, a suitable tool for coupling diverse numerical tools is required. For this purpose, we use Functional Mockup Interface (FMI), which has been successfully demonstrated for both model exchange [1] and co-simulation [2]. In the present framework, we apply the FMI for model exchange.

The organization of the paper is as follows. First, we introduce the computational framework established in this study, with a brief summary of the HES model formulation and optimization approach. We then present two benchmark optimization problems to demonstrate the established methodology, followed by a discussion of the simulation and optimization results. Finally, we offer some concluding remarks in addition to an overview of future research directions related to this topic.

## 2 Computational framework

An illustration of the computational framework established in this paper is provided in Figure 1.

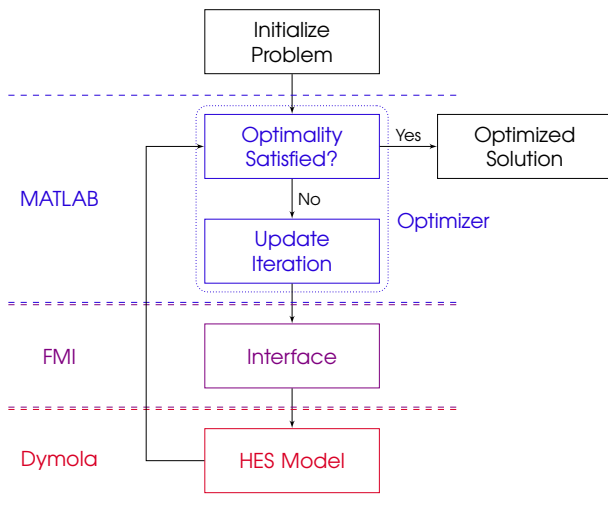

Figure 1: Schematic of computational framework.

Note that, as previously mentioned, the FMI is used to allow the MATLAB-based optimizer to modify inputs to the HES and setup additional simulations by building a Functional Mockup Unit (FMU) of the Modelica HES model. Also note that the optimization loop conducted in MATLAB may require a large num-

ber of iterations before converging to the optimized solution, and thus it is important that the HES model be sufficiently robust and flexible to handle a variety of potential operating scenarios. In the following section, we present the HES model considered in this work and discuss the concepts used in creating the model to ensure this robustness.

### 2.1 HES model

As mentioned above, the HES model considered in this work is implemented in the Dymola environment of the Modelica modeling language. As shown in Figure 2, the HES model has a configuration that includes multiple energy inputs and outputs. In this case, thermal and electrical energy in excess of the demand to the grid is dynamically distributed to a high temperature steam electrolysis (HTSE) process, which produces chemical products (hydrogen and oxygen) to complement the electricity produced by the HES. In a traditional hybrid energy system, multiple input energy sources are combined to provide a single output (MISO), i.e., electricity. The drawback of such a configuration is that in case the energy supply exceeds the demand, excess energy is either wasted or must be transferred to large storage devices, which are expensive. Therefore, the MIMO system can be expected to offer significant advantages in flexibility, utilization and efficiency over the MISO system, as reported in, for example, [3, 4].

Figure 2: Model of Advanced HES configuration, implemented in Dymola.

Note that the HES considered here contains two types of energy flows: thermal (in the form of heated helium) and electrical. The conversion of thermal to

electrical energy occurs in the Brayton power plant, where heated helium (the working fluid) carries thermal energy provided by a high temperature gas reactor (HTGR). Electrical power from the Brayton plant is combined with that produced by a wind turbine (the renewable source), which is regulated by an electrical battery. Two distribution centers, one for helium and one for electricity, are used to dynamically calculate the amount of each energy type to be distributed to the HTSE to match the necessary electrical power output to the grid. Note that the HES model in Figure 2 includes two types of arrows: the solid (blue) arrows represent energy flows (helium and electricity), while the dotted (red) arrows represent information flows. For example, the amount of electricity distributed to the HTSE unit is needed at the HTGR and helium distribution center to calculate the required mass flow rate of helium. Similarly, the electricity distribution center makes use of information about the electricity demand in the grid to calculate the relative amount of electricity to be dynamically distributed between the grid and HTSE. For computational simplicity, detailed components within the subsystems such as pipes, valves, turbines, etc. are not considered in this initial effort; the system dynamics are instead captured by a series of transfer functions, switches, logic blocks, and other signal-based elements. The plan is to eventually replace these with models that more accurately capture the relevant physics; this topic is discussed further in the *Conclusions and future work* section. We next detail the models for the individual subsystems and components in the present computational framework.

Figure 3: High temperature gas reactor model.

A schematic diagram for the HTGR is shown in Figure 3. The electrical power entering the HTSE ( $P_{htse}^e$ ) is provided by the electricity distribution center, and is the input to the HTGR. The HTGR model then uses this information to calculate the amount of high temperature helium that would correspondingly be needed by the HTSE. Also note that the total amount of helium entering the Brayton plant is controlled by the amount of electricity directed to the HTSE. In an actual reactor, the operating conditions and output should ide-

ally be constant, as fluctuations can cause excessive wear on the components and significantly shorten the lifespan of the system. Therefore, the variability in the HTGR generation will be an important component to the cost function used in the optimization of the HES in future work.

Revisiting Figure 2, we note that the mass of heated helium from the HTGR then enters the helium distribution center, where some of the helium is channeled to the HTSE for chemical production and the remainder is sent to the Brayton plant for electricity generation. As in the HTGR, the amount of electricity entering the HTSE is used as an input to the helium distribution center to calculate the flow of helium that needs to be directed to the HTSE to achieve near-stoichiometric conditions there. This is accomplished with the following equations:

$$\dot{m}_{brayton}^{He} = \dot{m}_{total}^{He} - \dot{m}_{htse}^{He} \quad (1)$$

$$\dot{m}_{htse}^{He} = K_{htse}^{He} P_{htse}^e \quad (2)$$

The Brayton plant is represented by a first-order transfer function

$$H_{brayton}(s) = \frac{K_{brayton}^e}{\tau_{brayton}s + 1} \quad (3)$$

where the gain  $K_{brayton}^e$  is a lumped quantity that accounts for efficiency and unit conversions, and the time constant  $\tau_{brayton}$  can be varied according to the design and operation of the Brayton plant.

The Brayton power plant is one source of electricity in the system; the other is a series of wind turbines, which serve as the renewable source in this HES configuration. Note that as shown in Figure 2, the wind power is not inputted directly to the electricity distribution center, but via a grid-scale battery. This is because the battery model does not model the charge and discharge behavior of the battery directly, but rather the operational impact of the battery on dampening excessive unsteadiness due to high variability in available wind power. The renewable power is modeled as a time-varying input signal to the battery based on available wind speed data from the National Renewable Energy Laboratory (NREL), for a site in Wyoming.

As shown in Figure 3, there are four operating regimes for a wind turbine, separated by critical wind speed values. At wind speeds below a minimum cut-in velocity, there is insufficient kinetic energy in the wind to cause any rotation, and thus no electrical power is produced. At wind speeds above a cut-out velocity, a braking system is activated for safety reasons,

Figure 4: Turbine power vs wind speed.

and again no power is produced. Between the rated and the cut-out velocity values, the turbine provides a steady maximum power level, also known as the rated power. Finally, for the range between the cut-in and rated speeds, the power is calculated by the following equation:

$$P = \eta \frac{1}{2} \rho U^3 \frac{\pi d^2}{4} \quad (4)$$

where  $\eta$  is the conversion efficiency of the wind turbine,  $\rho$  is the density of the air at the site,  $U$  is the wind velocity, and  $d$  is the diameter of the turbine blades. In essence, this equation relates the power delivered by the turbine to the amount of kinetic energy available in the wind, via an overall lumped efficiency number. At a typical site, the majority of the turbine operation occurs in this regime.

Like the Brayton plant, the battery is modeled using a first-order transfer function:

$$H_{battery}(s) = \frac{1}{\tau_{battery}s + 1} \quad (5)$$

We assume the maximum power delivered by the battery is equal to the renewable power, so a unity gain is used. It is important to not confuse the time constant  $\tau_{battery}$  with the charge or discharge rate of the battery. Instead, the time constant is used to characterize the smoothing effect that the battery would have on the electricity delivered by a renewable and battery arrangement.

Electrical power from the Brayton plant  $P_{brayton}^e$  and the renewable and battery arrangement  $P_{battery}^e$  are combined in the electricity distribution center. The electrical distribution center contains a logic block that dynamically calculates the distribution of electricity to the grid and HTSE. When the combined electrical power  $P_{avail}^e$  is less than the grid demand, all available power is directed to the grid. When excess power is

available, it is directed to the HTSE. This is modeled using the following equations:

$$P_{avail}^e = P_{brayton}^e + P_{battery}^e \quad (6)$$

$$P_{grid}^e = \begin{cases} P_{demand}^e & \text{if } P_{avail}^e > P_{demand}^e \\ P_{avail}^e & \text{otherwise} \end{cases} \quad (7)$$

$$P_{htse}^e = \begin{cases} P_{avail}^e - P_{demand}^e & \text{if } P_{avail}^e > P_{demand}^e \\ 0 & \text{otherwise} \end{cases} \quad (8)$$

Finally, electricity and helium energy flows are combined in the HTSE system, whose corresponding model is shown in Figure 5.

Figure 5: High temperature steam electrolysis model.

As illustrated by the dotted line in Figure 5, the mass flow rate of helium  $\dot{m}_{htse}^{He}$  enters the HTSE but is not used in any calculations. This is because the helium distribution center ensures that the appropriate flow of helium is directed to the HTSE in accordance with the amount of electricity being consumed there. Therefore, only one of the two parameters is needed in the HTSE model.

Values of all simulation parameters, including gains in the blocks shown in Figures 3 and 5, can be found in Table 1 in section 3.

## 2.2 Optimization methodology

A general optimization problem can be written as a function minimization problem, as follows:

$$\text{minimize } f(x), \quad f: \mathfrak{R}^n \rightarrow \mathfrak{R} \quad (9)$$

In general, the values of the design variables  $x$  are selected within a bounded range, while satisfying inequality constraints  $c_k$  and equality constraints  $\hat{c}_j$ :

$$\text{subject to } \begin{cases} x_{lower} \leq x \leq x_{upper} \\ c_k(x) \leq 0, \quad k = 1, \dots, m \\ \hat{c}_j(x) = 0, \quad j = 1, \dots, \hat{m} \end{cases} \quad (10)$$

Solving this general optimization problem requires an algorithm that iteratively adjusts the values of the design variables until some termination criterion regarding the values of the objective and constraint functions is met, most commonly when the Karush-Kuhn-Tucker (KKT) conditions are satisfied [5]. Many different types of optimizers have been developed and applied to a wide variety of engineering problems. These

include gradient-based and gradient-free methods, as well as hybrid approaches for mixed-integer problems [6, 7] and surrogate-based methods [8, 9]. As shown in Figure 1, in this case we adopt a black-box optimization approach, in which the optimization algorithm uses the HES model output to update each iteration of the optimization loop, but does not access any state variables within the HES model. In selecting an appropriate optimization algorithm, it is important to consider the nature of the objective function and associated design variables, and match the optimizer according to the mathematical properties of the problem. In general, gradient-based methods converge more efficiently than gradient-free methods, and are thus preferred for smooth problems [10]. However, the objective function in this study, defined in section 3 as the total variability in the electrical power delivered to the HTSE, is very noisy with a large number of local minima that are problematic for gradient-based methods. Since the optimization routine is conducted in MATLAB, we select the *fminsearch* function as the optimizer. This is an implementation of the Nelder-Mead simplex method [11] included in the MATLAB Optimization Toolbox.

The Nelder-Mead method creates a simplex with  $n + 1$  vertices in an  $n$ -dimensional design space, and iteratively manipulates the size and shape of the simplex using operations such as reflection, expansion, contraction and reduction based on the relative objective function values at the vertices. The method is gradient-free because only the values of the objective functions at the vertices are used, and thus it is suitable for noisy or discontinuous functions. The general Nelder-Mead method is valid for unconstrained optimization problems; to handle constraints, we modify the objective function  $f(x)$  by introducing a penalty function:

$$\hat{f}(x) = f(x) + p(x) \quad (11)$$

The penalty function  $p(x)$  is equal to zero in the feasible space, and gives a positive value when a constraint is violated. We then apply the optimizer to minimize the modified objective function  $\hat{f}(x)$  instead of the original function  $f(x)$ . We use a quadratic form of the penalty function that can be easily computed:

$$p(x) = \rho \sum_{i=1}^{m+\hat{m}} \max(0, c_i)^2 \quad (12)$$

where  $m$  and  $\hat{m}$  are the number of inequality and equality constraints, respectively. This penalty function is valid for both inequality and equality constraints [12]. The coefficient  $\rho$  must be large enough to force the

optimizer into the feasible space when a constraint is violated; a value of  $\rho = 10$  is found to be sufficient in this study.

The time constants of the HTGR, Brayton plant, and battery are designated as the design variables. Although the Nelder-Mead simplex method has been shown to suffer from poor convergence rate for problems involving a large number of design variables, it is suitable for the three variables considered here [13].

### 3 Problem formulation

Available wind velocity data are sampled at time intervals of 600 seconds; we conduct our simulations with the same time step size in order to avoid numerical errors that would arise from interpolating between data points. All simulations are conducted for a time period of one week ( $6.048 \times 10^5$  seconds), for a total of 1009 time steps per simulation. This time period is selected to balance the need to capture the effects of variability in the renewable energy input, with the need to conduct simulations at a feasible computational cost. As shown in Figure 6, the wind turbine experiences very fast dynamics, with numerous transient peaks and valleys observed in the velocity and power profiles within a single week. This high degree of variability confirms that the time period selected provides a representative sample of the overall long-term variability in renewable energy input experienced by the HES.

Figure 6: Wind velocity and turbine power profiles for one week sample time period.

Since the properties of the wind turbine are assumed to be constant throughout the simulations, we lump all of these values from Equation 4 together, such that each individual turbine provides maximum of 2 MW rated power. This is equivalent to an overall conversion efficiency of 55%, air density of  $1.2 \text{ kg/m}^3$  and

	Parameter	Symbol	Value	Units
HTGR	Power output	$K_{htgr}^{e,b}$	135	MWe
	He reactor gain	$K_{htgr}^{He,n}$	0.464	kg/MJ
	Power to mass flow	$K_{htgr}^{He,b}$	1.06	kg/MJ
	Electrical gain	$K_{htgr}^e$	0.0838	-
Brayton	Mass flow to power	$K_{brayton}^e$	0.9429	MJ/kg
HTSE	H <sub>2</sub> gain	$K_{htse}^{H_2}$	0.00724	kg/MJ
	O <sub>2</sub> gain	$K_{htse}^{O_2}$	7.94	-
	Time constant	$\tau_{htse}$	1	s
Wind	No. of turbines	$n_T$	15	-
	Cut-in speed	$U_{cut-in}$	3	m/s
	Rated power speed	$U_{rated}$	14	m/s
	Cut-out speed	$U_{cut-out}$	25	m/s
Grid	Target load	$P_{demand}$	100	MWe

Table 1: Fixed system properties and simulation parameters.

turbine diameter of 53 m, for an overall gain value of  $k_{wind} = 7.28 \times 10^{-4} \text{ MW}\cdot\text{s}^3/\text{m}^3$  between the cut-in and rated power wind speeds:

$$P = k_{wind} U^3 \quad (13)$$

We also simplify the scaling problem by assuming that the individual turbines, which constitute the renewable component of the HES, are separated sufficiently far apart so as to not experience mutual interference. A simple linear scaling in renewable power with the number of turbines is thus used.

The fixed simulation parameter values are listed in Table 1. The thermal and electrical outputs from all system components are initialized to be zero in order to analyze the impact of the initial start-up phase on the overall system performance, and a constant electricity profile of 100 MWe delivered from the HES to the grid is assumed. For simplicity, we select a fixed HTGR power output (135 MWe) that exceeds this output level to ensure that the HTSE unit can be operated continuously even when no renewable power is provided to the system. This is necessary because frequently shutting down the HTSE process entails a high cost while also making the system susceptible to damage.

Given these considerations, it is logical to design HES in which energy flow variability is minimized. For this purpose, we define the objective function to be minimized in our optimization problem as the total amount of variability in the electrical power input to the HTSE:

$$P_{var}^e(t) = |P_{htse}^e(t) - \bar{P}_{htse}^e| \quad (14)$$

$$f(x) = \int_0^{t_f} P_{var}^e(t) dt \quad (15)$$

where the quantity  $\bar{P}_{htse}^e$  is the time-averaged value of electrical power input to the HTSE.

For optimization, this integral can be approximated by first computing  $\bar{P}_{htse}^e$  and then applying a numerical integration scheme to the HES simulation data. Using the trapezoidal method, we obtain the following form of the objective function used by the optimizer:

$$f(x) = \sum_{i=1}^n (t_i - t_{i-1}) \frac{P_{var,i}^e + P_{var,i-1}^e}{2} \quad (16)$$

where  $n = 1009$  is the number of time steps.

We consider two optimization problems, one unconstrained and one constrained. Three design variables are considered in both cases: the time constants for the battery ( $\tau_{battery}$ ), HTGR ( $\tau_{htgr}$ ), and Brayton cycle ( $\tau_{brayton}$ ). In the unconstrained case, the design variables are bounded but allowed to vary independently. An arbitrary baseline case ( $\tau_{battery} = 3600$  s,  $\tau_{htgr} = 1200$  s,  $\tau_{brayton} = 600$  s) is used as the starting point for the optimization routine, and the following upper and lower bounds shown in Table 2 are specified.

Variable	Minimum	Maximum
$\tau_{battery}$ (s)	1800	18000
$\tau_{htgr}$ (s)	240	3600
$\tau_{brayton}$ (s)	180	3600

Table 2: Upper and lower bounds on design variables.

From an understanding of the physics governing the performance of the system, we can expect the optimizer to converge towards these bounds in the absence of constraints. This is because a larger time constant for the battery allows greater smoothing of the variability in the wind power profile, thus reducing the variability of electricity distributed to the HTSE. Conversely, a smaller time constant for the HTGR and power cycle allows them to track the electrical power demanded by the grid more closely, which again would reduce variability in electricity directed to the HTSE. Due to this understanding of the expected solution, the unconstrained optimization problem serves as a good benchmark case to verify whether the optimizer performs as expected.

Of course, the unconstrained case provides limited insight into the design of HES, because there are important constraints that need to be considered. As the time constant of the battery increases, so does the minimum battery size required to accommodate the necessary charging and discharging. This is illustrated in Figure 7, where the renewable power profiles, with and without the operation of the battery, are plotted together for three different battery time constants. To

Figure 7: Effect of time constant on required battery size and delivered electrical power.

facilitate a comparison between the three cases, the difference between the two profiles is shaded (blue for when the battery is being charged, red for when it is being discharged). The required battery size (in terms of energy storage capacity) is represented by the largest shaded area, and is observed to increase with the battery time constant. Since the capital and operating costs of the battery are directly related to its size, it is clear that a constraint is needed to assess a penalty to increasing its time constant. Similarly, the time constant for the HTGR and Brayton plant cannot be arbitrarily decreased, as faster dynamics put a greater strain on the system components and lead to damage and reduced reliability - ultimately leading to increased total cost.

To address these cost issues, we consider a second optimization problem in which the following linear constraint is applied to the design variables:

$$c_1(x) = k_1 \tau_{battery} - k_2 \tau_{htgr} - k_3 \tau_{brayton} - k_4 \leq 0 \quad (17)$$

where the weighting coefficients ( $k_1=1$ ,  $k_2=3.5$ ,  $k_3=1$ ) reflect the relative cost associated with each component. The nuclear reactor is the most capital-intensive of the three, and thus has the highest weight applied to

it in the constraint function. Note that the signs of the coefficients manipulate the optimizer into decreasing  $\tau_{battery}$  while increasing  $\tau_{htgr}$  and  $\tau_{brayton}$ . The coefficients are selected such that the constant term vanishes ( $k_4 = 0$ ).

In addition to the linear constraint in Equation 17, we also apply two nonlinear constraints governing the relative speeds of the HTGR and Brayton cycle:

$$c_2(x) = \frac{\tau_{htgr}}{\tau_{brayton}} - 2 \leq 0 \quad (18)$$

$$c_3(x) = \frac{\tau_{brayton}}{\tau_{htgr}} - 2 \leq 0 \quad (19)$$

These two constraints are included to ensure that neither component becomes a significant bottleneck to the other. Note that all constraints in this case are inequality constraints; our optimization problem does not consider equality constraints (i.e.,  $\hat{c}_j(x)$  in Equation 10).

## 4 Results and discussion

Figure 8: Progression of design variables (top) and objective function (bottom) for unconstrained optimization problem.

Optimization results for the unconstrained problem are shown in Figure 8. For illustration purposes, non-dimensional time constants are plotted by normalizing

using the upper and lower bounds reported in Table 2:

$$\tau_i^* = \frac{\tau_i - \tau_{i,\min}}{\tau_{i,\max} - \tau_{i,\min}} \quad (20)$$

As expected, the optimizer converges the battery time constant to the upper bound, and the others to their lower bounds. The value of the objective function at the optimum is  $f(x) = 1181.1$  MW-hr, which represents a reduction of 17.7% in the HTSE electrical power variability. Although this may not seem like an especially large improvement, the impact can in fact be quite substantial due to the highly capital-intensive nature of HES. A substitution of the unconstrained optimum into Equation 17 shows that the linear cost constraint is not satisfied, and thus the unconstrained optimum is not a feasible solution for the constrained problem.

As shown in Figure 9, the constrained optimum is located at  $\tau_{battery} = 15311$  s,  $\tau_{htgr} = 3600$  s,  $\tau_{brayton} = 2712$  s, with HTSE variability of  $f(x) = 1275.5$  MW-hr - a 11.2% improvement over the baseline case. The HTGR time constant experiences the most significant change compared to the unconstrained case, increasing from its minimum to its maximum bound. This is due to the high weighting assigned to the cost constraint  $c_1$ . Although the HTSE variability is increased by 6.5% compared to the unconstrained case, this loss is outweighed by the benefits in operational costs due to fast reactor dynamics. Note that in the final solution, the linear constraint  $c_1$  is active since the constraint function value is equal to numerical zero, while the nonlinear constraints  $c_2$  and  $c_3$  are inactive. This can be verified by inspection using Equations 17-19. A comparison of the optimization solutions with respect to the baseline case is summarized in Table 3.

	Baseline	Unconstrained	Constrained
$\tau_{battery}$ (s)	3600	18000	15311
$\tau_{htgr}$ (s)	1200	240	3600
$\tau_{brayton}$ (s)	600	180	2712
$f(x)$ (MW-hr)	1435.4	1181.1	1275.1

Table 3: Design variables and objective function results for baseline, unconstrained, and constrained cases.

In addition to considering the values of the design variables, constraints and objective function at the optima, it is also important to examine the HES simulations themselves to gain a better understanding of the physics occurring within the system. Figure 10 plots the electrical power profiles in the HTSE for the three cases, as well as the mean power level in each case.

Figure 9: Progression of design variables (top), objective function (middle), and constraints (bottom) for constrained optimization problem.

The shaded area between the two is the numerically integrated area used to compute the value of the objective function. We note that in both optimization cases, not only is the total shaded area reduced, but the power profile is also generally smoother, with fluctuations of lesser amplitude and frequency. The main difference between the unconstrained and constrained solutions occurs in the initial ramping of the HTSE, where the constrained case incurs a substantial penalty due to slower reactor and power cycle dynamics. This is a direct consequence of the initial conditions in the problem formulation. For example, a long-term analysis that ignores the start-up phase of the system would likely exhibit a smaller difference between the two solutions.

Figure 10: HTSE power profile for baseline, unconstrained, and constrained cases.

## 5 Conclusions and future work

In this paper, we have successfully established a computational framework for simulating and optimizing the performance of HES by interfacing the Modelica system model with analysis and optimization tools via the FMI for model exchange. Results from two optimization problems, one unconstrained and one constrained, illustrate the complex interplay between HES system components in the presence of high variability in the renewable power source. These preliminary results also highlight the difficulty of designing resilient and robust systems, again due to the high degree of variability and uncertainty over the lifespan of the system. The results obtained in this study represents an important step towards our goal of developing a flexible, efficient, and expandable framework for optimizing HES and achieving a level of understanding of the system dynamics and performance that would enable the deployment of HES in real world applications.

An important focus of future research efforts will be the models of the HES components. Since the main objective of the present study is to demonstrate the framework and to gain a better understanding of

the performance of HES through simulations, the simplistic but computationally efficient signal-based HES model is considered adequate in this case. However, to properly utilize the available analysis and optimization tools, a system that more closely models the relevant physical phenomena is needed. This would entail replacing the signal block component models with, for example, process models for the HTSE [14] and equivalent-circuit models for the battery [15]. To retain reasonable computational cost, reduced-order models constructed using surrogate-based techniques may also be applied [16, 17, 18]. Furthermore, a comprehensive design process for such systems must take into account a large number of variables and constraints, which cannot be investigated to a sufficient level of detail using the present model. Therefore, current efforts are aimed at creating higher fidelity, physics-based models to incorporate into the computational framework established in this study.

Another topic that warrants future investigation is the comparison of different HES configurations and assessment of new technologies. A valuable benefit of conducting the simulations in Modelica is the flexibility of the resulting framework, allowing for certain model components to be readily replaced with those representing different technologies - and for the performance of the different systems to be directly compared. For instance, we may be interested in examining the relative performance of nuclear and natural gas power plants, or the relative cost of electrical versus thermal storage in grid-scale applications.

Finally, our present efforts have focused on design optimization - i.e., optimizing certain properties of the system components. Another equally important consideration, however, is the operation of the HES after it has been properly designed. In the present study, parameters related to the system operation (such as those located in the helium and electricity distribution centers) are assigned fixed empirical values; the proper operation of the system will require incorporation of additional factors such as economics and energy efficiency into optimization problems of much greater scale.

## 6 Acknowledgment

The present research efforts have been supported by the Energy Security Initiative (ESI) at Idaho National Laboratory (INL) under the United States Department of Energy contract DE-AC07-05ID14517.

## Abstract

This paper shows how different kinds of optimization related task such as offline optimization or optimal control are solved using a combination of Modelica, Optimica, JModelica.org and Python. The application examples presented in this paper are all real industrial applications in the field of Combined Cycle Power Plants. Therefore different workflows have to be combined to solve the underlying task. This paper shows that these workflows can be conveniently connected using Python.

*Keywords: Dynamic optimization, Nonlinear Model Predictive Control, Extended Kalman Filter*

## 1 Introduction

Using simulation models to study plant behavior is state of the art today. So more and more attention is paid to applications related to optimization tasks. This includes e.g. offline optimization of plants, optimal plant control or parameter estimation using measurement data. These tasks often need different parts as initialization, simulation and optimization.

This paper shows a methodology which combines the optimization platform JModelica.org [1], the modeling language Modelica, an optimization extension to Modelica (Optimica) and a scripting environment (Python [2][1]) in order to solve the different optimization tasks mentioned above.

Each optimization task is illustrated by an industrial application.

The paper is structured as follows: Section 2 gives some background information about Optimica and Python, while section 3 explains the different industrial applications with focus on scripting. Section 4 summarizes the results of the paper.

## 2 Background

JModelica.org is an extensible Modelica-based open source platform for optimization, simulation and analysis of complex dynamic systems. A unique feature of JModelica.org is the support for the extension Optimica. Optimica enables users to conveniently formulate optimization problems based on Modelica models using simple but powerful constructs for encoding of optimization interval, cost function and constraints. For user interaction JModelica.org relies on the Python language. Python offers an interactive environment suitable. The following subsections give an introduction to Optimica and show the advantages of the scripting language Python.

### 2.1 Optimica

The Optimica extension mainly consists of an additional class, *optimization*, which includes the attributes such as *startTime*, *stopTime* and *objective*, which specify the objective function of the optimization problem. Another supplement is the *constraint* section, which can handle different kinds of linear and non-linear equality- and inequality constraints.

A wide range of optimization problems may be solved formulated with Optimica, for example: parameter estimation, tracking, optimal control and so on. Here is a simple example, an optimization problem, based on the double integrator:

$$\min_{u(t)} \int_0^{t_f} 1 dt$$

Subject to:

$$\begin{aligned} \dot{x}(t) &= v(t) & x(0) &= 0 \\ \dot{v}(t) &= u(t) & v(0) &= 0 \\ x(t_f) &= 1 & v(t_f) &= 0 \\ v(t) &\leq 0.5 & -1 &\leq u(t) \leq 1 \end{aligned}$$

For this problem,  $t_f$  is considered to be free and the objective is to minimize the time it takes to transfer the states from (0, 0) to (0, 1) without violating the constraints. The corresponding problem formulated in Modelica and Optimica looks like this:

```

model DoubleIntegrator
  Real x(start=0);
  Real v(start=0);
  input Real u;
equation
  der(x)=v;
  der(v)=u;
end DoubleIntegrator;

optimization DIMinTime (
  objective= finalTime,
  startTime=0,
  finalTime(free=true, initialGuess=1))

  extends DoubleIntegrator(
    u(free=true, initialGuess = 0.0));
constraint
  x(finalTime)=1;
  v(finalTime)=0;
  v<=0.5;
  u>=-1;
  u<=1;
end DIMinTime;

```

The attribute *free* = true indicates that the variable is an optimization variable and the attribute *initialGuess* provides the numerical solver with an initial guess.

The optimization problem is solved numerically and there is hence an aspect of discretization to consider, but this is considered outside of Optimica. Optimica only represents the mathematical formulation of the problem and several different solver algorithms can be used for solving the different problems at hand. For details on Optimica, see [9].

## 2.2 Python

Python is open source and a very powerful dynamic programming language that is used in a wide range of application domains. Especially interesting features of Python related to the applications covered in this paper are how well it works with other tools and its scripting possibilities. There are for example interfaces for Gnuplot [10] and Matplotlib [11], which are both suitable for plotting purpose.

Python is compatible with Optimica and it is possible to interact with Modelica and Optimica models through Python scripting (the Python interface of the Jmodelica.org platform is great for this). For example, it enables the possibility to do parameter manipulations and to perform simulation and optimization for a variety of setups. The discretization and solver options (e.g. tolerances) for simulation and optimization can easily be set through the Python script.

The Modelica and Optimica models consists of a set of states, algebraic variables and input variables and they are represented by two model object types; FMU (Functional Mock-up Unit) and JMU (JModelica Model Unit), respectively. FMUs are mainly used for simulation and they follow the FMI-standard (Functional Mock-up Interface), which specifies how the models should be represented and stored [16]. JMUs are mainly used for optimization and follow the JModelica.org standard, similar to the FMI standard for FMUs. For more details see [14]. Both model object types can be imported in to Python. Besides JModelica.org the open source simulation and optimization tool OpenModelica [8] supports Python with its interface called OMPython enabling the user to use the modeling and simulation capabilities of OpenModelica within the Python environment.

The Python packages SciPy [12] and NumPy [13] support linear algebra and matrix operations and are useful when scripting, both for pre- and post-processing, in plotting and in the implementation of algorithms.

Below is a simple example that demonstrates what scripting in Python may look like, using JModelica.org. The script solves the optimization problem described in section 2.1. DoubleIntegrator.mo contains the model and DIMinTime.mop contains the optimization model. A JMU object is created based on these.

```

# Importing necessary packages and functions
import numpy as N
from pymodelica import compile_jmu
from pyjmi import JMUModel
import matplotlib.pyplot as plt

# Compiling a JMU- object for optimization
# based on the double integrator
jmu_name= compile_jmu("DIMinTime",
    ["DoubleIntegrator.mo", "DIMinTime.mop"])

# Loading the JMU-object
model_opt = JMUModel(jmu_name)

# Calling the optimization function with
# default settings
res = model_opt.optimize();

# Plotting the results
x= res['x']
v =res['v']

# u is the optimal trajectory
u =res['u']
time = res['time']

plt.plot(time, x, ':k', time, v, '--k',
    time, u, '-k')
plt.grid(True)

# Increasing the plot window to show results
plt.ylim([-1.5,2])
plt.legend(('x','v','u'))
plt.title('Simple example')
plt.show()
    
```

Figure 1: The optimization results

### 3 Case studies

The JModelica.org platform can be used to perform offline optimization. Python scripting is used for pre- and post-processing.

#### 3.1 Offline optimization: Start-up of a combined cycle power plant

The aim of this offline optimization is to maximize power output of gas and steam turbines without violating given constraints on temperature differences in

several components. The optimizer shall find optimized control inputs for gas turbine power and four different control valves (see Figure 2).

This model is an extension of the model presented in [6]: the model scope has been enlarged to also include high pressure (HP) and intermediate pressure (IP) turbine and the corresponding valves.

Figure 2: Model for startup optimization

##### 3.1.1. Python Scripting

Figure 3 illustrates the steps written in Python to perform offline optimization.

Since the gas turbine power is fixed until synchronization of the gas turbine, the optimization can not start at  $t = 0s$ , but only after synchronization, at  $t = t_{opt\_start}$ . Therefore a first simulation determines the initial conditions for the optimization. Additionally to the state initialization at optimization starting point, the optimization algorithm also needs a guess trajectory for all variables. If no explicit guess trajectory is supplied it can be obtained using a second simulation. After the optimized control input has been obtained, several post-processing steps are taken (see Figure 3). In this specific application, the optimization result and the result of the first simulation (until synchronization of the gas turbine) are concatenated to obtain the complete time-dependent behavior of the plant. Also it proved to be useful to run a check, whether all variables are well scaled and whether the constraints are also kept between the collocation points. It has to be stated, that the Python scripting environment offers a very convenient and flexible way to include different pre- and post-optimization tasks.

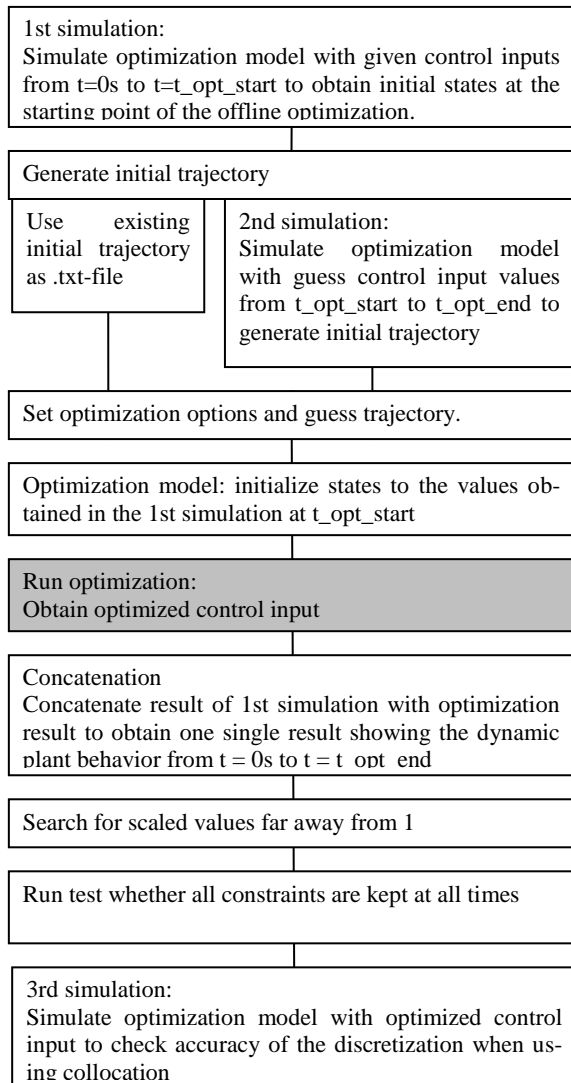

Figure 3: Steps written in Python when performing offline optimization

### 3.1.2. Results of the offline startup optimization

An offline startup optimization of the system shown in Figure 2 has been performed where the characteristics are given below:

Constraints:

- Model equations
- Maximum pressure of 170 bar
- Pressure dependent maximum wall temperature difference for several components (i.e. HP and IP turbine casing, heat exchanger manifolds etc.)
- Minimum mass flow rate change for a certain mass flow range
- Maximum negative GT power derivative

Control inputs:

- Gas turbine power
- HP and IP turbine bypass valve
- HP and IP turbine control valve

Optimization objective:

- Maximization of total power output (gas turbine power + power of HP and IP turbine)

Some optimization results are presented in the following figures.

Figure 4: Normalized gas turbine (GT) load (actual divided by maximum gas turbine load).

Figure 5: Normalized steam turbine power (solid line: HP turbine, dashed line: IP turbine)

**Figure 6: Normalized temperature differences (actual temperature difference divided by maximum allowable temperature difference) in critical components**

It can be seen that the optimizer first strongly increases the gas turbine power to maximize the power output (Figure 4). Then the gas turbine power is decreased again to keep the temperature difference in the critical components below their maximum value (Figure 6).

### 3.2 Nonlinear Model Predictive Control with State Estimation: Extended Kalman Filter

The basic concept of Nonlinear Model Predictive Control (NMPC) is to use a dynamic model to forecast system behavior and optimize the forecast to produce the best decision. In practice an optimal control problem is solved over a finite future horizon, but only the first optimal control signal is applied to the system. Then the optimization horizon is shifted and the calculations are repeated.

The solution of the optimal control problem depends on the initial state of the model which is the current state of the plant. In general, measurements are disturbed by noise or are missing, so that a state estimation algorithm is needed to determine the initial states under consideration of the past record of measurements.

#### 3.2.1 Python Scripting

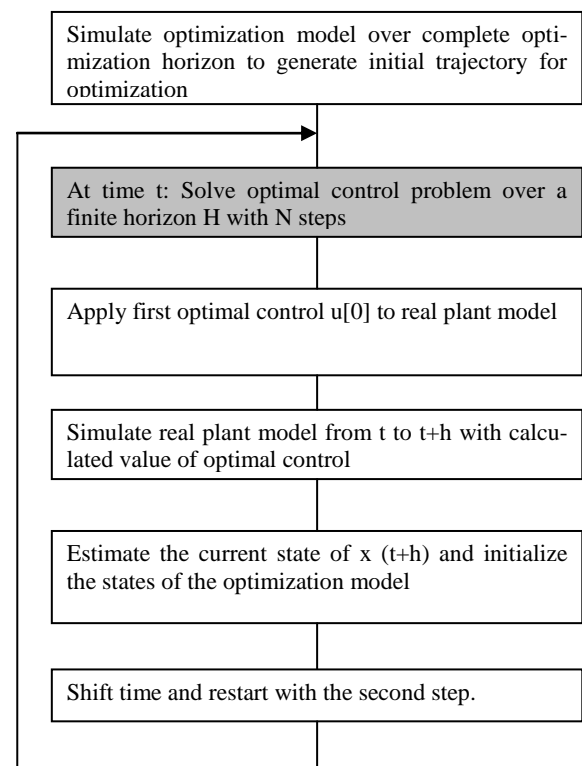

The python script for optimization with JModelica.org looks as in Figure 7.

This scheme describes the NMPC loop with two dynamic models – one model called optimization model, the other real plant model. The real plant model illustrates the real plant behavior and is more detailed than the optimization model. In future the

real plant model will be replaced by measurements of the real plant.

The NMPC loop starts with the generation of an initial trajectory for the optimization. As an alternative the optimization can be initialized with an optimization result too. The initial trajectory is generated by simulating a FMU of the optimization model.

The second step is to solve the optimization problem from  $t$  to  $t+H$ , where  $t$  is the actual time and  $H$  the length of the finite optimization horizon (see Figure 8). The optimization horizon is divided into  $N$  steps, but only the first control signal is applied to real plant model and the model is simulated to get the new state of the plant. The following step is the state estimation which is explained in more detail below. After the initial state of the model is updated the optimization horizon is moved and the optimization is solved again from  $t = t+h$  ( $h = H/N$ ) to  $t+2 \cdot h$ . All steps will be repeated until the final time of the optimization  $t_{opt\_end}$  is reached.

**Figure 7: Steps written in Python performing NMPC with state estimation**

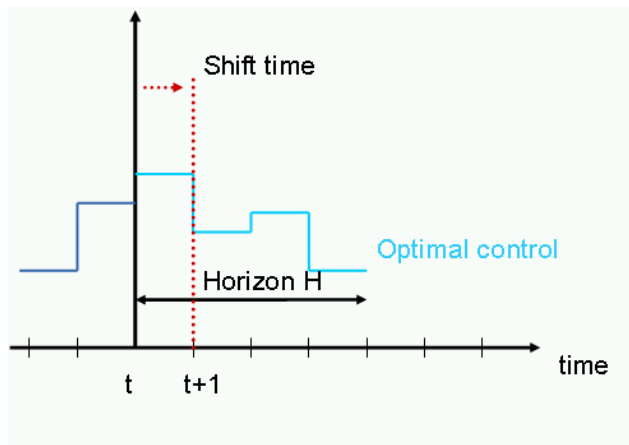

Figure 8: NMPC scheme

The strategy of Extended Kalman Filter (EKF) is used for state estimation. The Kalman filter originates from probability theory and it is well established that the Kalman filter is the optimal state estimator for a linear system affected by white noise. The Kalman filter minimizes the estimation error by considering past data of the system. This can be described in a recursive way which is convenient for implementation purposes [15]. Concerning the notation,  $\hat{x}_{t+1|t}$  corresponds to the estimation of  $x$  at  $time = t+1$  given the information at  $time = t$ .

The setup of EKF is according to Figure 9. The estimation consists of two main steps; the prediction and the correction. In the prediction step, the state values at time  $t+1$  are estimated from the system representation ( $\hat{x}_{t+1|t}$ ). The covariance matrix of the estimation error at the prediction step ( $P_{t+1|t}$ ) is also updated in this step.

In the correction step, the Kalman gain ( $K_{t+1}$ ) is updated. It is then used to derive the corrected state estimation ( $\hat{x}_{t+1|t+1}$ ) by combining the result of prediction step and the latest plant measurements ( $y_{t+1}$ ). The covariance matrix for the estimation error at the correction step ( $P_{t+1|t+1}$ ) is also updated here. The steps are described in more detail below.

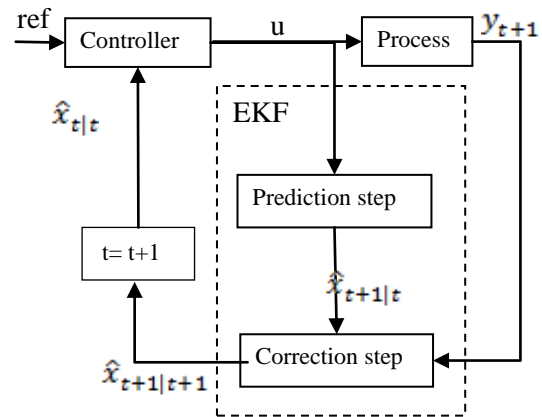

Figure 9: Structure of EKF, where  $ref$  corresponds to the control reference,  $u$  to the control signal, and  $x$  to the state estimation at different stages and  $y$  to the real plant measurements.

The EKF is an extension of the Kalman filter for nonlinear process models and the approach is basically the same as in the linear case, with an additional linearization to get approximations of  $A_{t|t}$  and  $C_{t+1|t}$  matrices (using standard notation for linear systems), which are used by the filter. The linearization step was realized with the JModelica.org library `pyjmi.linearization`.

Prediction:

- $\hat{x}_{t+1|t}$  By simulating a FMU of the optimization model.
- $A_{t|t}$  By linearizing a JMU of the optimization model (at  $\hat{x}_{t|t}$ ).
- $P_{t+1|t} = A_{t|t}P_{t|t}A_{t|t}^T + Q_t$

Correction:

- $C_{t+1|t}$  By linearizing a JMU of the optimization model (at  $\hat{x}_{t+1|t}$ )
- $K_{t+1} = P_{t+1|t}C_{t+1|t}^T(C_{t+1|t}P_{t+1|t}C_{t+1|t}^T + R_t)^{-1}$
- $y_{t+1}$  By simulating a FMU of the real plant model.
- $\hat{x}_{t+1|t+1} = \hat{x}_{t+1|t} + K_{t+1}(y_{t+1} + \hat{x}_{t+1|t})$
- $P_{t+1|t+1} = P_{t+1|t} + K_{t+1}C_{t+1|t}P_{t+1|t}$

$Q$  and  $R$  represent the covariance matrices for process and measurement noise.

For this example, we assumed that both noises are uncorrelated and conform to a normal distribution.  $Q$  and  $R$  are diagonal matrices. The entries on the diagonal of the covariance matrices  $Q$  and  $R$  are the vari-

ances of each process variable and measurement and are set to 1 in most cases. Q and R were approximated to be uncorrelated in time and the diagonal elements were set to: one over the square root of the standard deviation of the corresponding state/measurement, in most cases to 1.

The EKF does not consider constraints, and this has to be compensated for in an additional step (the feasibility correction). This is important to note since the optimization strategy is interior point optimization, and no solution will be found if the starting point is outside of the feasible region.

The strategy to considering this fact was simply to use the prediction as state estimation, without the correction step, since the prediction always will be feasible.

### 3.2.2 Results of NMPC with State Estimation: Extended Kalman Filter

In reality, there will be large differences between the controller model and the real plant, this is natural. However, for the evaluation of the implementation, the models were kept basically the same, with the same state representation. The optimization model was augmented in order to compensate for the differences between the plant models. The differences were approximated as constant disturbances, by introducing the additional states  $d$ , here on referred to as *the disturbance states*. These are unmeasurable states of the real plant and their values can be estimated by the EKF.

See a simple example of the augmentation below, where  $x$  represent the original states,  $f(x, u)$  represents the process with input  $u$  and  $d$  represent the disturbance states.

$$\begin{bmatrix} x_{k+1} \\ d_{k+1} \end{bmatrix} = \begin{bmatrix} f(x_k, u_k) \\ d_k \end{bmatrix}$$

The NMPC loop combined with state estimation was evaluated using the example of an enthalpy controller of the heat recovery steam generator (HRSG) (consisting of economizer, evaporator and superheater, see Figure 10) of a combined cycle power plant.

**Figure 10: Rough sketch of the system to be controlled.**

Two disturbance states were added to the optimization model (one to the flue gas mass flow rate and one to the water pressure) in order to consider differences. Additionally a parameter related to the heat transfer was modified to represent a typical modeling error in addition to initial offsets for each state.

There were three objectives for the controller and they were considered in the formulation of the optimization problem:

1. Keep the steam temperature at the superheater outlet at desired set point.
2. Guarantee subcooling at the evaporator inlet by keeping the temperature below a specified maximum value.
3. Have an adequate degree of superheating at the outlet of the evaporator section.

Figure 11 and Figure 12 display the results for this setup.

**Figure 11: The progress of the state estimation, scaled according to nominal value and time. The red line represents the real plant behavior. The top plot represents one of the process states, the enthalpy at the inlet of first evaporator. The bottom plot represents the introduced disturbance state, with an initial error**

**Figure 12: The control objective, scaled according to nominal value and time. The *top plot* displays the temperature set point control; the red line represents the set point. The *middle plot* displays the sub cooling control; the red line represents the maximum value for the temperature at the economizer outlet (pressure dependent). The *bottom plot* displays the superheating control, the red lines represents the minimum/maximum degree of superheating.**

The jumping in Figure 11 is related to the correction step of the EKF. Also worth noting is that the disturbance state does not estimate the constant disturbance to 0, and this is probably due to the introduced modeling error. The disturbance state tries to compensate for this as well.

The controller performance is quite satisfying, but there are some offsets that should be considered in the future work with optimization problem formulation. The reason for the offset can for example be related to the fact that the plant did not reach steady state within the time frame for the experiment. It is not clear from Figure 11, but it is however the case. Evaluating the performance for a longer time might get rid of the offset, but this was not possible to realize at the time of the application evaluation because of some memory leaks. Modifications to the objective function could be increasing the weight on the elements in the objective function related to set point deviations.

### 3.3 Parameter estimation

Parameters are typically estimated by some form of least squares. This method minimizes the sum of the squared discrepancies between measurement and expected value.  $M$  is the number of measurements and  $N$  the number of discrete time steps.

$$\min \sum_{i=1}^N \sum_{j=1}^M \left( x_{i,j} - x_{i,j}^{meas}(t[i]) \right)^2$$

The default algorithm for solving optimal control problems and parameter estimation problems in JModelica.org is the collocation algorithm. For our application we used the Nelder-Mead method, a heuristic search method using the concept of a  $(N+1)$ -dimensional simplex, where  $N$  is the number of estimated parameters. These kinds of derivative free algorithms are implemented in JModelica.org ([2]).

The Nelder-Mead algorithm was the preferred choice, although this method is quite slow, but has the best convergence behavior especially for many measurements and a lot of parameters.

#### 3.3.1 Python Scripting

As the Nelder-Mead method is already implemented in JModelica.org as described in [9], the python script is quite simple. In a first step all measurements are imported from .mat file. Then the Nelder-Mead function `nelme` is called which solves the optimization problem and uses the defined objective function as input.

#### 3.3.2 Results of Parameter estimation

A parameter estimation of the Modelica model for optimizing the start up process of a combined cycle power plant in 3.1 has been implemented.

The real plant measurements were given for a period of 1h. The data were loaded in python as .mat file. The gas turbine power, the gas turbine mass flow, the injection mass flow and the back pressure measurement were set directly as boundaries of the model, the other measurements (wall temperatures, fluid temperatures and pressure) are used to minimize the error between the measurements and their simulated values.

The algorithm was tested for two measurement sets to verify the result, one for a hot start and one for a warm start of the power plant. As expected the estimated parameters have smaller differences, but have equal dimensions.

Figure 13 shows the simulation result with original and optimized parameters compared to measurements. As can be seen, the simulation result with the optimized parameter fits better to the measurements. Nevertheless there are still differences between the model and the real plant behavior. Uncertainty of measurements, not modeled effects and components are some reasons for the deviations.

**Figure 13: Simulation result with original parameters (green) optimized parameters (blue) and measurements (red). The top plot displays the wall temperature of the separator; the middle plot displays the reheat mass flow and the bottom plot the outlet temperature of the first superheater.**

## 4 Summary

This paper shows how different industrial optimization applications can be solved combining Modelica and Optimica with the scripting language Python.

Three different optimization tasks have been considered to improve the dynamic processes in a combined cycle power plant: offline optimization of the start-up process, online enthalpy control of the HRSG and parameter estimation for the start-up optimization.

All optimization tasks have been formulated with Optimica based on Modelica models. For pre- and post processing issues and interaction of JModelica.org and the Modelica models, the scripting tool Python was used.

As shown in section 3 ‘Case studies’, for complex optimization techniques like NMPC with combinations of several optimization and simulation steps, Python is ideally suited. For industrial applications of power plant sector the definition of such controllers inside the Modelica model is not desired and unnecessary since other interfaces (e.g. connection to database) have to be realized additionally.

The work presented in this paper is one step towards a complete online-optimization tool chain for NMPC.

## Abstract

Concepts such as smart grids, distributed generation and micro-generation of energy, market-driven as well as demand-side energy management, are becoming increasingly important and relevant as emerging trends in the design, management and control of energy systems. Appropriate modeling and design, efficient management and control strategies of such systems are currently being studied. In this line of research a very important enabling component is efficient and reliable simulation. However those energy models are typically large, stiff and exhibiting heavy discontinuities, and at the same time consist of interconnected multi-domain subsystems encompassing electrical, thermal, and thermo-fluid models. Object-Oriented (O-O) languages such as Modelica are obviously well-suited for the modeling of such systems; however, traditional state-of-the-art hybrid differential algebraic equation solvers cannot efficiently simulate these systems especially when their size grows to the order of hundreds, thousands, or even more interconnected units.

The goal of this paper is to show, through a couple of exemplary case studies, that Quantized State System (QSS) integration methods are ideally suited to solve models of such systems, as they scale up better than traditional methods with the system size, and provide time savings of several orders of magnitude, while achieving comparable numerical precision.

## 1 Introduction

The growing interest in new paradigms for energy systems such as Smart Grids (SG) is posing new challenges in the control of procurement, conversion, distribution and use of energy to meet environmental and economic objectives.

Computer simulation of SG systems is a fundamental tool for production planning and control, price regulation, logistics, etc. To carry out the simulation one must deal with two problems. First, modeling complex SG systems involves taking into account components from various domains such as thermal, electrical, ventilation, etc. Each component could be developed by different specialists, possibly using different languages or formalisms that must then be coupled to produce the complete model. SG models are commonly composed of energy production facilities, energy transmission networks and usually hundreds or thousands of energy consumption units. Thus the modeling of these types of systems is a difficult task. Second, once the problem is modeled, the actual simulation of a large hybrid model (with continuous and discrete subcomponents) can turn out to be prohibitively expensive in terms of CPU time, as the scale of the system grows.

Modelica [13] is an Object-Oriented (O-O) language for modeling and simulation of complex multi-domain physical systems, described by hybrid differential-algebraic equations. In the literature several research efforts show the use of Modelica as a language for modeling SG problems [6, 7, 8, 19, 20, 21]. State-of-the-art Modelica simulation tools generate simulation code that solves the differential equations using classical numerical integration methods, such as Euler, Runge-Kutta, or DASSL, which are based on time discretization.

Another approach is the use of Quantized State System (QSS) methods [4, 14, 15] which replace time discretization by state quantization. The QSS methods have certain features (sparsity exploitation, efficient discontinuity handling, explicit stiffness treatment) that make them particularly effective for large, sparse, hybrid, dynamical systems like the SG models.

In this work we investigate the suitability of the QSS methods for simulating SG models described in Modelica and compare their efficiency, as well as simulation quality, against classical integration methods.

We shall focus on two models, first a District Cooling System taken from [5] and then an Energy Market with houses as energy consumption units adapted from [6].

The paper is organized as follows: Section 2 introduces the main concepts used along the article, then Section 3 describes the two smart-grid applications, and in Section 4 we compare different numerical integration methods. Finally, Section 5 concludes the article and outlines future work.

## 2 Background

This Section introduces the main concepts used along the remainder of the article.

### 2.1 Classical Numerical Integration Methods

The mathematical models describing Energy Management problems such as the SG are usually time dependent dynamical systems. These can be expressed in the form of a set of Differential Algebraic Equation (DAEs) or directly in a set of Ordinary Differential Equations (ODEs) as:

$$\dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}(t), t) \quad (1)$$

where  $\mathbf{x}(t)$  is the state vector.

Classical numerical integration methods discretize the time variable computing the states variables for certain time points.

We shall focus on two well-known numerical integration methods [4]:

**Runge-Kutta** An explicit variable step algorithm of fourth order.

**DASSL** An implicit variable step algorithm based on a series of Backward Difference Formulae

(BDF) of different orders of approximation accuracy.

As both methods are based on time discretization, discontinuity detection is an expensive mechanism. Also, only implicit algorithms are able to efficiently simulate stiff systems, i.e. systems that exhibit simultaneous fast and slow dynamics, without resorting to unnecessarily short time steps.

### 2.2 QSS Integration Methods

Quantized State System (QSS) methods replace the time discretization of classic numerical integration algorithms by the quantization of the state variables.

Given the ODE of Eq.(1), the first order Quantized State System method (QSS1) [16] approximates it by

$$\dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{q}(t), t) \quad (2)$$

Here,  $\mathbf{q}$  is the *quantized state vector*. Its entries are component-wise related with those of the state vector  $\mathbf{x}$  by the following *quantization function*:

$$q_j(t) = \begin{cases} x_j(t) & \text{if } |x_j(t) - q_j(t^-)| \geq \Delta Q_j \\ q_j(t^-) & \text{otherwise} \end{cases} \quad (3)$$

where  $\Delta Q_j$  is called *quantum* and  $q_j(t^-)$  denotes the left-sided limit of  $q_j$  at time  $t$ . The quantization function  $\mathbf{q}(t)$  in QSS methods also contains a *hysteretic* term (not shown here for simplicity) that is necessary in order to avoid illegitimate models [16].

It can be easily seen that  $q_j(t)$  follows a piecewise constant trajectory that only changes when the difference between  $q_j(t)$  and  $x_j(t)$  becomes equal to the quantum. After each change in the quantized variable, it results that  $q_j(t) = x_j(t)$ .

The QSS1 method has the following features:

- In the solution, the quantized states  $q_j(t)$  follow piecewise constant trajectories.
- The state variables  $x_j(t)$  follow piecewise linear trajectories.
- The state and quantized variables never differ by more than the quantum  $\Delta Q_j$ . This fact ensures stability and global error bound properties [4, 16].
- The fact that the state variables follow piecewise linear trajectories makes the detection of discontinuities a trivial task. Moreover, after a discontinuity is detected, its effects are no different

from those of a normal step (because changes in  $q_j$  are discontinuous). Thus, QSS1 is very efficient in simulating discontinuous systems [14].

- Each step is local to a state variable  $x_j$  (the one that reaches the quantum change), and it only provokes evaluations of the state derivatives that explicitly depend on it. This fact implies that QSS1 performs intrinsic sparsity exploitation.
- If some state variables do not change significantly, they will not provoke any step or evaluation at all. This feature reinforces the efficient sparsity exploitation.

The last two points show that QSS methods integrate each state variable at its own pace i.e. a fast changing variable would provoke more local integration steps than a slow one.

As QSS1 only performs a first order approximation, good accuracy cannot be obtained without a significant increment in the number of steps. Also as QSS1 is an explicit solver, the algorithm is not suitable for simulating stiff systems. The former limitation was solved with the introduction of higher order QSS methods like QSS2 and QSS3 [15]

For the simulation of stiff systems, a family of linearly implicit QSS methods (LIQSS) of orders 1 to 3 was also proposed in [17]. LIQSS methods are semi-implicit methods that can handle certain types of stiff systems.

In the context of this work, the efficient sparsity exploitation, the semi-implicit treatment of stiff systems and the native handling of frequent discontinuities compose the main advantages of the QSS methods.

### 2.3 Stand-Alone QSS Solver

It was shown that the behavior of the QSS approximation of Eq.(2) can be described as a Discrete Event System (DEVS)[22]. Thus, a straightforward implementation of these algorithms is through their equivalents in a DEVS simulation engine.

DEVS-based implementations of QSS methods are simple but they are not efficient. The problem is that the DEVS simulation engines waste a large amount of the computational load attending the DEVS simulation mechanism. This fact motivated the development of a stand-alone QSS solver.

Recently, the complete family of QSS methods was implemented in a *stand-alone QSS solver* coded in plain C language [9]. This solver simulates models

described in a subset of the Modelica language, called  $\mu$ -Modelica [3].

In this work all simulations are performed using the stand-alone QSS solver.

### 2.4 OpenModelica

OpenModelica [12] is an open-source Modelica-based modeling and simulation environment. OpenModelica offers different numerical integration methods for simulation, amongst them, the before mentioned DASSL and Runge-Kutta. In this article we shall use this tool as a reference to compare the performance of different integration methods.

### 2.5 Related Work

The goal of this article is to study the application of QSS methods to Smart Grid problems described in the Modelica language. To the best of the authors' knowledge, this problem has not previously been studied.

The application of QSS methods to Modelica models was studied in [3, 10, 11], showing the benefits of QSS methods for problems with frequent discontinuities. Also the use of QSS methods (not using Modelica) for a large hybrid sparse load management problem was studied in [18].

The use of the Modelica language for Energy Management problems was studied in [6, 7, 8, 19, 20, 21] showing the powerful advantages that the language offers to this set of models.

An advanced control system for the optimal energy management of a building cooling system is studied in [5]. In this system, a centralized facility produces chilled water that is then distributed among a certain number of thermal zones (e.g. small houses or apartments). The optimal control algorithm requires multiple simulations of the whole system model for different parameter settings. A simplified, equation-based version of that model is presented in this paper. Although the original system was designed for a reasonably low number of users (5 to 20, i.e., a micro-grid), this simplified model is representative of a larger class of systems with a centralized heat or cooling source, and many end users with their independent control systems. Such systems can easily scale up to contain hundreds, thousands, or even more individual units. The controllers have also been simplified in this work, as the achieved speed-up factor is not depending on the specific control laws, but rather on the efficient way the QSS algorithm exploits

the sparsity and weak coupling of the system model, combined with the efficient event handling.

### 3 Case Studies

In this section we present two case studies. First a District Cooling System and second an Energy Market model. As stated before, the Modelica language is suitable for describing multi-physics and multi-energy problems like SG models. In fact there are Modelica libraries for modeling energy problems that help the development process.

The QSS stand-alone solver accepts models described in a subset of the Modelica language, therefore all models used in the article are coded in this simplified language called  $\mu$ -Modelica. Being a subset of the complete language,  $\mu$ -Modelica is accepted by all Modelica simulation tools enabling us to simulate the same model both in OpenModelica and in the QSS stand-alone solver. For more information regarding the transformation of Modelica to  $\mu$ -Modelica models, we refer the reader to [3].

#### 3.1 Case Study I: A District Cooling System

As mentioned above, the District Cooling System is adapted from [5] and consists of the following elements:

- The *Cooling Plant* that generates cooling power used to control the temperature of a cooling load.
- The *Chilled Water Circuit* that connects the cooling plant to the cooling load allowing heat transfer between the two.
- The *Cooling Load* that transfers heat to the chilled water circuit. The load is composed by a group of zones affected by heat exchange with the outside ambient and by internal heat gains such as occupants and office equipment. The chilled water circuit exchanges heat with the zones by means of fan coils.
- The *Chilled Water Temperature Controller* that keeps circuit temperature at a specified set-point. The control variable is the cooling plant cooling power set-point.
- The *Zone Temperature Controller* that keeps each zone at the desired temperature. The control variable is the fan coil valve opening.

In the following paragraphs, the model adopted for each element is described.

**Cooling Plant** The cooling plant is simplified in this article to deliver exactly the energy needed for the Chilled Water Circuit set-point  $Q_{CSP}$ .

**Chilled Water circuit** Chilled water circuit dynamics are described using a lumped RC model. The following power balance equation can be written:

$$C_{CW} \frac{dT_{CW}}{dt} = \sum_i^N (Q_{ZAi}(t) - Q_C(t))$$

where  $T_{CW}$  is the circuit temperature and  $C_{CW}$  its thermal capacity.  $Q_{ZAi}$  is the heat exchanged with the  $i$ -th zone and  $Q_C(t)$  is the cooling power contribution provided by the Cooling Plant. Heat losses in the circuit are neglected.

**Cooling Load** Zones are modeled as lumped RCs as well. Their power balance equation is:

$$C_{ZA} \frac{dT_{ZAi}}{dt} = -Q_{ZAi} + k_{out}(T_{OA}(t) - T_{ZAi}(t)) + Q_{INTi}(t)$$

where  $T_{ZAi}$  is the zone temperature and  $C_{ZA}$  its thermal capacity,  $Q_{ZAi}$  is the heat exchanged with the chilled water circuit,  $X_{C,Zi}$  is the heat exchanger valve opening, and  $Q_{INTi}$  is the heat produced by zone occupants.  $Q_{ZAi}$  evolves according to the following expression:

$$\tau_{ex} \dot{Q}_{ZAi}(t) + Q_{ZAi}(t) = X_{C,Zi}(t) k_{cw}(T_{ZAi}(t) - T_{CW}(t))$$

where  $\tau_{ex}$  is the heat exchanger time constant. It is worth noticing that the introduction of the exchanger dynamics has the twofold purpose of a more accurate modeling and of obtaining a stiff model in order to test the QSS solver's performance in such conditions.  $Q_{INTi}$  is modeled according to the following polynomial function of the zone temperature:

$$Q_{INTi}(t) = (p_1 T_{ZAi}^2(t) + p_2 T_{ZAi}(t) + p_3) n_{peoplei}(t),$$

where  $n_{peoplei}$  is the number of zone occupants. Such a model is proposed in [2] where suitable coefficient values  $p_1$ ,  $p_2$  and  $p_3$  can be found.

The number of occupants is generated by a simple stochastic model: the next arrival/departure time of a person is given by a fixed time (1000 seconds) plus a uniform random variate between 0 and 1000 seconds. At each event, a person either comes in or leaves with

Figure 1: District Cooling System model graphical representation (a) and, in more detail, the submodel used for each zone (b). In (c) the simulated trajectory of the temperature state variable in zone 10 is plotted against the ambient temperature, while in (d) the number of the people being present in zone 10 is depicted over time.

a 50% probability. Although this model does not represent any specific realistic pattern for the coming and going of occupants, it serves the purpose of generating a number of *uncorrelated* time events, whose density in time grows with the number of zones. Any realistic system will exhibit this kind of behavior, as events happening in different buildings will usually be uncorrelated, no matter what their actual probability distribution is.

**Chilled Water Temperature Controller** A PI controller is adopted to control chilled water circuit temperature. The control variable is the power set-point for the cooling plant  $Q_{CSP}$ . Since no dynamics are considered for the chillers, the power set-point coincides with the actual power generated. The controller

is modeled as follows:

$$\begin{aligned} \dot{z}_{C,CW}(t) &= -\frac{k_{I,CW}}{k_{P,CW}} \cdot z_{C,CW}(t) + \frac{k_{I,CW}}{k_{P,CW}} \cdot Q_{CSP}(t) \\ Q_{CSP}(t) &= \Phi_{[0, Q_{C,max}]}(k_{P,CW} \cdot e_{C,CW}(t) + z_{C,CW}(t)) \\ e_{C,CW}(t) &= T_{CW}(t) - T_{CWSP}(t) \end{aligned}$$

where  $z_{C,CW}(t)$  is the integral state,  $k_{P,CW}$  and  $k_{I,CW}$  are the PI gains, and  $\Phi_{[a,b]}(\cdot)$  is the saturation function:

$$\Phi_{[a,b]}(x) = \begin{cases} a, & x < a \\ x, & x \in [a, b] \\ b, & x > b. \end{cases}$$

**Zone Temperature Controller** Each zone temperature is controlled by a PI controller as well. The control variable is the heat exchanger valve opening

$X_{C,Z}$ , spanning the range  $[0, 1]$ .

$$\begin{aligned}\dot{z}_{C,Z}(t) &= -\frac{k_{I,Z}}{k_{P,Z}} \cdot z_{C,Z}(t) + \frac{k_{I,Z}}{k_{P,Z}} \cdot X_{C,Z}(t) \\ X_{C,Z}(t) &= \Phi_{[0,1]}(k_{P,Z} \cdot e_{C,Z}(t) + z_{C,Z}(t)) \\ e_{C,Z}(t) &= T_{ZA}(t) - T_{ZASP}(t),\end{aligned}$$

**Model scaling** The presented model is designed to scale with the number of zones  $N$ , while providing a reasonable behavior for all controlled variables. For this purpose, certain model parameters are proportional to the number of zones  $N$ . In particular, the cooling plant maximum power  $Q_{C,max}$  and the cooling plant controller (chilled water temperature controller) gains  $k_{I,CW}$  and  $k_{P,CW}$  are proportional to  $N$ . The chilled water circuit thermal capacity  $C_{CW}$  is also linearly scaled with the number of zones  $N$ .

### 3.2 Case Study II: An Energy Market

The Energy Market model was introduced in [6] as a typical toy model written in Modelica and capturing many of the aspects typically found in realistic smart grid applications. The interactions between the different components in the Energy Market model are graphically sketched in Fig. 2. The model consists of the following components:

**Environment** We assume that the temperature of the environment is given by a sinusoidal function:

$$T_{amb} = \overline{T_{amb}} + \Delta T \sin(\omega t + \phi)$$

where the mean temperature  $T_{amb}$  is set to  $10^\circ\text{C}$ , while the frequency and offset are selected such that the minimum temperature is reached every midnight.

**Heaters** Each house has a heater that is controlled by an agent that switches it on and off, according to:

$$\dot{Q}_i^{heater} = \begin{cases} 0 & \text{if } T_i > T_i^{max} \\ P_{heat} & \text{if } T_i < T_{min} \end{cases} \quad (4)$$

**Walls** Each house has one wall that acts as a thermal resistor with the heat flow given by:

$$\dot{Q}_i^{wall} = \frac{1}{R_{th}}(T_i - T_{amb}), \quad (5)$$

where  $R_{th}$  is the thermal resistance of the wall.

**Windows** We assume that each house has one window that exhibits a stochastic behavior. More specifically, we assume that the opening time of each window is drawn randomly from a uniform distribution. It is closed again a random amount of time later.

$$\begin{aligned}openNextT[i] &\sim \mathcal{U}(pre(openNextT[i]) + 1000, 50) \\ closeNextT[i] &\sim \mathcal{U}(openNextT[i] + 100, 200),\end{aligned}$$

Each time a window is open, heat is exchanged between the environment and the house according to:

$$\dot{Q}_i^{window} = G(T_i - T_{amb}), \quad (6)$$

where  $G$  is a large heat conductance constant.

**Agents** Each house has a simple controller that controls the heater settings optimizing the power consumption. The agent turns the heater on at a lower goal temperature  $T_{min}$  and turns it off at an upper temperature  $T_{max}$ . If the energy price calculated in the energy market exceeds a threshold  $p_{max}$ , the agent decreased the upper level  $T_{max}$  to  $T_{max}^{alt}$ .

$$T_i^{max} = \begin{cases} T_{max} & \text{if } p < p_{max} \\ T_{max}^{alt} & \text{if } p \geq p_{max} \end{cases} \quad (7)$$

Figure 3: Simulated trajectories of the average temperature in the houses against the ambient temperature.

**Houses** Houses act as energy consumption units. The temperature inside each house is related to the heat flows described in the previous paragraphs with the following formula:

$$\dot{T}_i = \frac{1}{\rho V C_{th}}(\dot{Q}_i^{heater} - \dot{Q}_i^{window} - \dot{Q}_i^{wall}) \quad (8)$$

Figure 2: Energy Market model graphical representation (a) and, in more detail, the submodel used for each house(b)

The energy consumed per unit of time for a specific house is the power of its heater integrated over a time unit, as given by:

$$E_i = \dot{Q}_i^{heater} \cdot t_{unit} \quad (9)$$

**Energy Market** The energy market component simulates the behavior of an energy price regulator for the whole network. According to the estimated energy price the house agents decide if they should reduce the energy consumption or not. Various energy price models could be employed, but for simplicity we choose to linearly relate the energy price to the mean energy consumed in the houses:

$$p = \bar{p} + p_1 \times \frac{1}{N} \sum_{i=1}^N E_i$$

## 4 Results

In this Section we show the simulation results for the two models presented before. Both  $\mu$ -Modelica models can be downloaded from [1]. We compare the runtime efficiency and quality of the solutions obtained by different integration methods for different system sizes and tolerance values.

### Simulation Benchmark

The simulation benchmark is as follows:

- Runge-Kutta and DASSL results were computed using OpenModelica 1.9.1 (r18381) (RML version).
- LIQSS2,3 and QSS3 results were computed using the QSS Stand Alone Solver from [9] r645.

- The simulation platform is a Dell 32bit desktop with a quad core processor @ 2.66 GHz and 4 GB of RAM.
- The Jacobian matrices of the presented models are quite sparse and banded. This information could be exploited by all algorithms to make the simulation more efficient, however this has not been investigated for DASSL and Runge-Kutta methods. The QSS methods exploit this fact natively without having to get any information on the structure of the Jacobian matrix.

Calculating the accuracy of the simulations can only be performed approximately, since the state trajectories of the models cannot be computed analytically. To estimate the accuracy of the simulation algorithms for a given setting, reference trajectories ( $\mathbf{t}^{\text{ref}}, \mathbf{y}^{\text{ref}}$ ) were obtained using LIQSS3 with a tight tolerance of  $1 \cdot 10^{-9}$  on an equidistant grid consisting of 5000 points. To calculate the simulation error, all methods were forced to output points on the same equidistant grid, without changing the integration step, thus obtaining simulated trajectories ( $\mathbf{t}^{\text{ref}}, \mathbf{y}^{\text{sim}}$ ). Then, the mean absolute error is calculated as:

$$error = \text{mean}(|\mathbf{y}^{\text{sim}} - \mathbf{y}^{\text{ref}}|). \quad (10)$$

Regarding the error calculation we have to note that special care had to be taken in order to achieve comparable solutions from two independent runs of each model, since both models are based on the generation of random event sequences. To this end, we implemented a special random generator that, at every call, outputs the seed for its next call. Therefore, starting from the same seed, two independent model simulations generate the exact same sequence of random events.

The measured CPU time (simulation time) should not be considered as an absolute ground-truth since it will vary from one computer system to another, but the scaling of the algorithms as well as their relative ordering is expected to remain the same. Another important aspect is that, in order to objectively compare the simulation time needed by different algorithms we did not compare the time measurements of the algorithms for the same requested tolerance, but for the same achieved error.

#### 4.1 Case Study I

Figure 4: Simulation time for varying size of the District Cooling System model. All algorithms achieve a mean error on the order of  $10^{-4}$ .

The District Cooling System model is a comparatively stiff model and this becomes apparent when comparing the measured CPU time of the QSS3 and LIQSS methods in Fig. 4. This is confirmed by estimating the different time constants. The time constants of the temperature controlled zone ( $\sim 3,8 \times 10^3$  sec) and of the temperature controlled chilled water circuit ( $\sim 7,5 \times 10^3$  sec) proved to be greater by three orders of magnitude than the time constant of the heat exchanger ( $\sim 1$  sec).

Regarding the scaling of the algorithms, Fig. 4 suggests that DASSL scales quadratically ( $\sim 6N^2$ ), while QSS methods scale linearly with the number of variables ( $\sim 3N$ ). Due to the time constraints for the present study we had to stop the DASSL experiments at  $N=300$ , but the linear scaling of the QSS methods allowed us to test their performance up to  $N=3000$ , thus for a 10 times larger model.

Besides time, another factor that prohibited us from performing further experiments with DASSL on larger models, was that the OpenModelica compiler failed to compile larger models. For the largest model, that all methods could simulate ( $N=300$ ), the LIQSS methods are more than two orders faster than DASSL ( $10^2$  sec compared to  $600 \times 10^2$  sec).

Finally, a very interesting and useful aspect of the QSS methods is that they exhibit a strong correlation between the requested tolerance and the achieved error. This correspondence is depicted in Fig. 5a for the LIQSS2 method (the other QSS methods exhibit similar behavior). In contrast, the performance of DASSL was only slightly affected by changing the requested tolerance. This is a very important feature of the QSS methods as it allows the user to exploit the trade-off between computational speed and achieved error. Indeed in Fig. 5b, we see that a user who is willing to sacrifice one order of simulation accuracy will be rewarded by a simulation that executes roughly ten times faster when using LIQSS2.

#### 4.2 Case Study II

As the Energy Market model is not stiff we simulated it in OpenModelica using both DASSL and the fourth-order explicit Runge-Kutta algorithm. The measured simulation timings are shown in Fig. 6 where all methods achieve a mean error of order  $10^{-5}$ . The scaling of the algorithms, as well as their relative performance, agrees with the one obtained for the District Cooling System model. However, all methods perform better on this benchmark, because it is a simpler model in general.

More precisely, DASSL scales quadratically with the number  $N$  of variables ( $\sim 2N^2$ ) while Runge-Kutta scales linearly ( $\sim 5N$ ) since it is an explicit algorithm and does not have to perform any matrix inversion calculations. All three QSS methods exhibit a linear scaling ( $\sim N$ ) with the explicit QSS3 being marginally faster than the LIQSS3 algorithm (QSS3 needed 250 sec for  $N=10000$ , while LIQSS3 270 sec). For  $N=300$ , the LIQSS methods are over three orders more efficient than DASSL and over two orders more efficient than Runge-Kutta (10 sec compared to  $5000 \times 10$  sec and  $180 \times 10$  sec respectively).

Besides the linear scaling of the QSS methods becomes prominent their advantage over classical methods when simulating large sparse hybrid models with discontinuities. Each variable is being updated locally at its own speed, with no need of making global computations on the whole system matrix. Further-

Figure 5: District Cooling System model - Mean Simulation Error (a) and Simulation Efficiency (b) for LIQSS2 and varying requested tolerances.

more, discontinuities are being handled as native simulation steps without the need of backtracking to detect the zero-crossings. Therefore, we observe that even though Runge-Kutta methods scale linearly with the system order just like the QSS methods, the latter are much more efficient than the former. QSS methods can simulate a system with  $N=10000$  states within the same execution time as a Runge-Kutta algorithm needs to simulate a much smaller system with  $N=300$  states.

## 5 Conclusion and Future Work

In this article we study the use of Quantized State System (QSS) integration methods for Smart-Grid (SG) simulation problems. The QSS methods have certain features (intrinsic sparsity exploitation, semi-implicit stiffness treatment and efficient discontinuity handling) that make them suitable for simulating SG models.

After analyzing two large hybrid SG models and comparing the efficiency and the quality of the solution obtained by the QSS methods against standard numerical integration methods we can conclude that:

- In both cases QSS methods outperform DASSL (and Runge-Kutta) by more than two orders of magnitude in terms of simulation speed, while at the same time, achieving a comparable simulation error.
- The QSS methods scale linearly with system size, while DASSL scales quadratically. The Runge-Kutta solvers also scale linearly, but they are far less efficient than their QSS competitors nevertheless.
- In both examples the QSS stand-alone simulator is able to handle larger model without running out of memory.
- We were able to simulate with the QSS methods up to 1000 times larger models than with DASSL, while still needing much less time to perform the simulations.

Figure 6: Simulation time for varying size of the Energy Market model. All algorithms achieve a mean error on the order of  $10^{-5}$ .

However, there still remain open problems to be addressed in the future. First of all, we need to perform experiments with a larger set of models typically used in the SG community, while at the same time testing more numerical integration methods against the QSS family. We note here that other implicit methods included in the OpenModelica environment, such as Radau and Lobatto, have been tested but failed to simulate the models. A necessary step that has to be performed in the future is including the family of QSS methods as integration methods in OpenModelica.

Finally, an interesting line of research could be the utilization of QSS methods in energy optimization algorithms, such as the one proposed in [5].

## 6 Acknowledgments

This work was in part funded by CTI grant Nr.12101.1;3 PFES-ES and supported by the OPENPROD-ITEA2 project. The authors would like to thank the developer of the stand-alone QSS solver, Joaquín Fernández, for fixing several bugs that enabled us to correctly and efficiently simulate the analyzed models.

## Abstract

Offshore oil facilities are complex systems that involve elaborate physics combined with stochastic aspects related, for instance, to failure risk or price variation. Although there exist many dedicated software tools to simulate flows typically encountered in oil exploitations, there is still no tool that combines physical (mostly engineering fluid mechanics) and risk simulation. Such a tool could be useful to engineers or decision makers for specification, design and study of offshore oil facilities. We present a first step towards the creation of such a tool. Our current simulator is based on new Modelica components to simulate fluid flows and on stochastic simulation at a higher level, for modeling risk and costs. Modelica components implement physical models for single and two-phase flows in some typical devices of an offshore field. The risk simulation uses Markov chains and statistical indicators to assess performance and resilience of the system over several months or years of operation.

*Keywords: fluid flow; two-phase flow; risk estimation; Monte Carlo simulation*

## 1 Introduction

With the increasing rarity of readily accessible reservoirs, as oil has to be extracted from deeper undersea, capital investments and risks associated to offshore oil facilities become higher and higher. In this context, a careful evaluation of cost and risk represents a crucial step in the conception of a new offshore facility. This evaluation must be performed at the system level because it involves phenomena of very different na-

tures and scales, that can interact together. We identify three main types of phenomena to be taken into account in the simulation: *Physical*, *failure-related* (risk) and *economic* (cost). The *physical phenomena* obviously include fluid flow through common components (pipes, tanks, valves, etc.) but can also include various other aspects like e.g. strength of materials, heat transfer or chemistry of wax or hydrate formation. The *failure phenomena* are the discrete-time events due to specific (extreme) conditions (e.g. break due to component fatigue) or to accidental situations. Simulating failures is useful to evaluate the potential risks of a particular architecture/design. The *economic phenomena* encompass all that is related to cost or price but does not directly depends on physics (unlike e.g. the oil production). For instance the oil barrel price, the price of pipe wall material (typically steel) or the transportation cost. All these variables directly impact the profitability of an exploitation.

This paper presents our first effort in the conception of a system-level offshore facility simulation. Before starting the work, it was necessary to point out simulation requirements and expected difficulties. Requirements are more related to the user point-of-view while difficulties are more related to the physics of an offshore oil facility:

- Reasonable computation times are preferable since we want the simulator to be usable as a design tool,
- Complexity: An offshore exploitation can involve dozens or hundreds of elementary components,
- Modularity: A model is meant to be built by as-

sembling elementary components of typical parts of an offshore field,

- Accurate prediction of highly-turbulent fluid flow is not possible (typical Reynolds number in oil & gas industry flows is  $> 10000$ ),
- Many physical parameters are known only in certain ranges or even uncertain,
- Experimental validation is difficult or limited to existing literature.

Henceforth it was decided to build first physical models with moderate complexity in order to follow the large-scale behavior of the real components within reasonable computation time. Another choice was to decompose the simulation into two different layers: One for the physics and one for the cost/risk estimation. The physics layer models deterministic phenomena only, while the cost/risk layer is based on probabilities to model risk and uncertainty. The physical simulation takes advantage of the flexibility and modularity that are possible with Modelica features (object-oriented, acausality). Other authors have used a similar approach of employing a stochastic simulation layer on top of a Modelica-based simulation. For instance in the context of Building Performance Simulation [14] to model weather and room occupancy as stochastic processes. Propositions were recently submitted by Bouskela *et al.* [3] to enrich the Modelica language with the possibility to define uncertain variables with user-configurable probability law. The authors exposed some applications in power plant or combustion engine field to perform data reconciliation or uncertainty propagation. With the current Modelica version, the authors had to rely on the external program OpenTURNS [7] to compute uncertainty propagation on a fluid pipe system example. It seems presently unavoidable to work with this kind of architecture (Modelica + external program with an interface layer) since stochastic modeling is clearly out of the scope and objectives of the current Modelica specifications.

The paper is divided as follows. Section 2 focuses on fluid flow simulation. It describes the hypotheses and equations used to build the Modelica components of the offshore facility. Section 3 deals with the estimation of cost and risk. It details the different variables of interest and their stochastic model (Markov chain representation and Monte Carlo simulation). Section 4 presents some first results obtained on a simplified architecture used as a proof of concept.

## 2 Simulation of flows in an offshore oil facility

The first choice when conceiving the fluid flow simulation was to decide the accuracy level that would give the appropriate balance between fast computation time and physical coherence. To ensure the computational tractability of the models we have chosen 1D or 0D models depending on the component. This for permanent-regime study. The latter choice comes from the considered time scale that is rather large in order to estimate typical daily production (hours extrapolated to a full day). In the current development stage, we are not yet concerned with heat transfer so isothermal transformations are assumed. The fluid that flows from an oil reservoir is usually a mixture of oil and gas (in particular because gas might be injected inside the reservoir to increase the flow rate of production). The basic connector used in our simulation is then defined by three parameters ( $p, q, \varphi$ ):

```
connector TPPort "Two-phase port"
  SIunits.Pressure pressure "Pressure";

  //Volumetric flow:
  flow SIunits.VolumeFlowRate q;

  //Volume ratio of liquid in the mixture:
  stream SIunits.VolumeFraction phi;
end TPPort;
```

In addition to the permanent-regime assumption, we assume that fluids are incompressible with exceptions for a few components (e.g. the oil-gas separator in Section 2.4). The aforementioned assumptions are more restrictive than the ones of the *Fluid* library [4] in the Modelica Standard Library that is more generic, at the price of a higher computation time.

### 2.1 Single-phase flow in a pipe

The model of single-phase flow in a pipe is encountered only in limited areas of the offshore field, e.g. after an oil-gas separator. It is however useful in order to compute the virtual single-phase pressure drop used in the two-phase pipe model (Section 2.2). It requires a variant of the TPPort connector where  $\varphi$  (phi) is removed. The fluid velocity  $v$  is computed from the volume flow rate  $q$  and the pipe cross-sectional area  $A$ :

$$v = \frac{q}{A}. \quad (1)$$

Since we have volume flow conservation,  $q = q_a = q_b$  where  $q_a$  and  $q_b$  are the values of  $q$  in the two connectors at the ends of the pipe.

Reynolds number is

$$Re = \frac{\rho D_h |v|}{\mu}, \quad (2)$$

where  $\rho$  is the fluid density,  $D_h$  the pipe hydraulic diameter and  $\mu$  denotes dynamic viscosity of the fluid.

The frictional pressure loss is computed as

$$\Delta p = \pm f_d \frac{L}{D_h} \rho \frac{v^2}{2}, \quad (3)$$

where  $f_d$  is the Darcy friction factor and  $L$  the pipe length. The sign of  $\Delta p$  must be chosen so that the pressure decreases in the direction of the flow.

The Darcy friction factor  $f_d$  depends on the flow regime. As only turbulent flows are encountered in the considered oil and gas applications, only the turbulent regime is of interest. For this regime, among the many existing correlations, we chose Haaland's formula [9]:

$$f_{d_{turbulent}} = \left( -1.8 \log_{10} \left( \frac{6.9}{Re} + \left( \frac{k_s}{3.7 D_h} \right)^{1.11} \right) \right)^{-2}, \quad (4)$$

where  $k_s$  is the roughness height that characterizes the rugosity of the pipe inner wall. It is typically between  $1 \mu\text{m}$  and  $1 \text{mm}$ .

## 2.2 Two-phase flow in a pipe

Several Modelica models have been proposed to deal with two-phase flow modeling [1, 6, 10, 2], with applications to steam generators or refrigerators. These models are centered on accurate simulation (1D, boundary model) of a few components. To simulate an offshore field architecture, since we are for now only concerned with the related evolution of pressure loss and flow rate, we chose a much simpler model with very low computational requirements, based on the work by Lockhart and Martinelli [12]. Lockhart and Martinelli proposed a correlation to compute the pressure drop of a two-phase mixture in a pipe, from the pressure drops computed for the two (virtual) single-phase flows. Chisholm [5] gave some theoretical basis for the correlation and recommended a simplified version of the formula, for engineering calculations:

$$\Delta p_{TP} = \pm \left( \Delta p_L + C \sqrt{\|\Delta p_L \Delta p_G\|} + \Delta p_G \right), \quad (5)$$

where:

- $\Delta p_{TP}$  is the pressure drop for the two-phase mixture,
- $d\Delta p_L$  is the pressure drop as if the liquid flowed alone,
- $d\Delta p_G$  is the pressure drop as if the gas flowed alone,
- $C$  is a correction coefficient which depends on the flow type of each phase (see Table 1). In practice, only the turbulent-turbulent case is of interest.

The sign of  $\Delta p$  must be chosen so that the pressure decreases in the direction of the flow.

Flow regime		
Liquid	Gas	Coefficient $C$
turbulent	turbulent	20
laminar	turbulent	12
turbulent	laminar	10
laminar	laminar	5

Table 1: Coefficient  $C$  for two-phase pressure drop computation (from [5]).

Note that the library *FluidDissipation*[16] also refers to the work of Chisholm, in a more complete implementation<sup>1</sup>.

## 2.3 Junctions

They are components used to direct the flows in two pipes into a single one. The junctions can be for instance used to inject gas in a liquid flow in order to increase its flow rate. When the two mixing fluids are in the same phase, a simple model can be used that just averages their characteristics. When the two phases are different a finer model is necessary. We consider here the cases of horizontal and vertical junctions.

### 2.3.1 Horizontal junction

The configuration of Figure 1 is considered.  $(p_1, v_1, \rho_1)$ ,  $(p_2, v_2, \rho_2)$  and  $(p_3, v_3, \rho_3)$  are the pressure, velocity and density at the liquid inlet, gas inlet and mixture outlet respectively,

Fluid velocities are  $v_1 = \frac{q_1}{A}$ ,  $v_2 = \frac{q_2}{A_g}$  and  $v_3 = \frac{q_3}{A}$  where  $A$  is the cross-section area of the liquid inlet and mixture outlet and  $A_g$  is the cross-section area of the gas

<sup>1</sup><http://xrg-simulation.de/en/products/xrg-library/xrg-fluiddissipation-library>

Figure 1: Schematic of the horizontal two-phase junction.

inlet. Conservation of both mass and volume flows gives:

$$\varphi = \frac{v_1 A}{v_1 A + v_2 A_g}, \quad (6)$$

$$\rho_3 = \varphi \rho_1 + (1 - \varphi) \rho_2, \quad (7)$$

$$v_3 = -(v_1 A + v_2 A_g) / A. \quad (8)$$

From Ji *et al.* [11] we took the empirical equation for the momentum correction coefficient  $K$  that is computed from the momentum flux ratio  $M$ . The equations are:

$$M = \frac{\rho_1 v_1^2}{\rho_2 v_2^2}, \quad (9)$$

$$K = 1 + 0.256 M^{0.223}, \quad (10)$$

$$p_1 - p_3 = K (\rho_3 v_3^2 - \rho_1 v_1^2). \quad (11)$$

Note that we use here the most generic formula in [11], because the roles of gas (side inlet) and liquid (front inlet) are swapped compared to what is in the paper. At this point, the system is under-determined since  $p_2$  does not appear in any of the above equations (it would if the junction angle was  $\neq 90^\circ$ ) so we need an extra equation. We choose the assumption that both inlet 1 and inlet 2 are close enough to the mixing point in order to have

$$p_1 = p_2. \quad (12)$$

### 2.3.2 Vertical junction

A vertical junction is a horizontal junction rotated with a  $90^\circ$  angle (Figure 2). Compared to the horizontal junction, a correction term is added to take into account the weight of the fluid:

$$p_1 - p_3 = K (\rho_3 v_3^2 - \rho_1 v_1^2 + 0.5 L g (\rho_1 + \rho_3)), \quad (13)$$

where  $g$  is the gravitational acceleration and  $L$  the junction length.

Figure 2: Schematic of the vertical two-phase junction.

Figure 3: Schematic of the oil-gas separator.

## 2.4 Separator

The purpose of an oil-gas separator is to output two single-phase flows (one of liquid and one of gas) from one two-phase inflow (liquid+gas) (Figure 3). The studied separator dissociates the two phases by gravity, inside a tank or vessel. The physical input to the separator is the volume flow of oil-gas mixture that goes into the tank, while the outputs are the volume flows out of the tank. The device contains control loops to maintain the liquid level and the inside gas pressure at desired reference values. The oil-gas separator is consequently modeled as a controlled system. The two controlled values are the height of oil in the tank (denoted by  $h$ ) and the gas pressure inside the tank (denoted by  $p_{in}^{gas}$ ). Internal sensors (supposedly perfect) measure both  $h$  and  $p_{in}^{gas}$  so that they can be compared to their respective reference values  $h_{set}$  and  $p_{set}$ . There is one control loop for each of  $h$  and  $p_{in}^{gas}$  and some variables are involved in the two control loops [8] (Figure 4).

The controllers are simple PIDs (Proportional-Integral-Derivative). Transmission lines conduct the

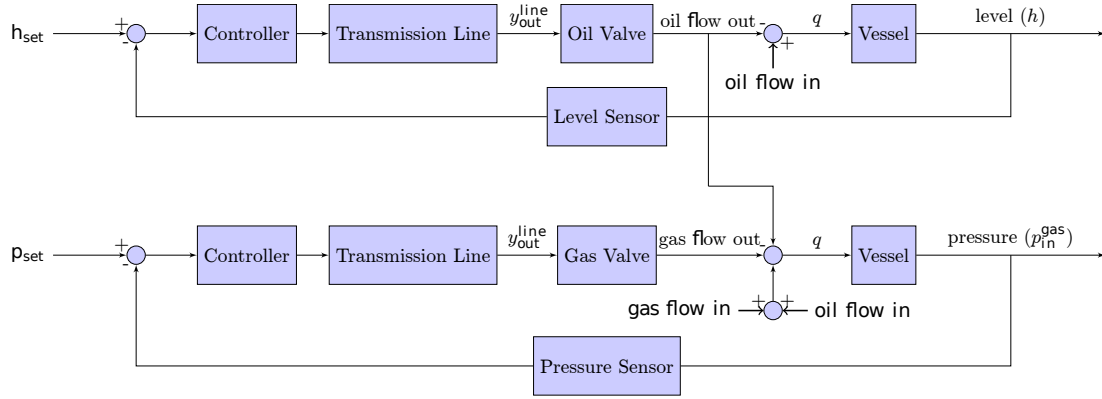

Figure 4: Liquid level and gas pressure control loops.

controller outputs to the control valves. They are modeled as first-order low-pass filters [8]. The valve aperture control parameter  $\sigma_{valve}$  is the line signal  $y_{out}^{line}$  after a  $[0; 1]$  saturation is applied:

$$\sigma_{valve} \in [0; 1] = \max(0, \min(y_{out}^{line}, 1)). \quad (14)$$

We give more details on each control loop in next sections.

#### 2.4.1 Level loop

The vessel is a horizontal cylinder with diameter  $d_{\varnothing}$ , radius  $r$  and length  $L$ . Let us introduce the distance  $\tilde{h}$  from the liquid height  $h$  to the vessel middle (i.e.,  $h=r$ ):

$$\tilde{h} = \begin{cases} h & \text{if } h \leq r, \\ d_{\varnothing} - h & \text{if } h > r. \end{cases}$$

The liquid level  $h$  is then related to liquid volume flows according to

$$q_{in}^{liq} - q_{out}^{liq} = 2\sqrt{d_{\varnothing}\tilde{h} - \tilde{h}^2} L \frac{dh}{dt}, \quad (15)$$

where

$$q_{in}^{liq} = \varphi q_{in}^{liq+gas}. \quad (16)$$

Finally  $q_{out}^{liq}$  is related to  $p_{in}^{liq} - p_{out}^{liq}$  with a friction law like in Section 2.1, which is denoted  $f_{fric}(\cdot)$ . The factor  $\sigma_{valve}$  is added because we assume the valve aperture to act linearly on the flow:

$$q_{out}^{liq} = \sigma_{valve} f_{fric}(p_{in}^{liq} - p_{out}^{liq}). \quad (17)$$

#### 2.4.2 Pressure loop

The gas volume flows are:

$$q_{in}^{gas} = (1 - \varphi) q_{in}^{liq+gas}, \quad (18)$$

$$q_{out}^{gas} = \sigma'_{valve} f'_{fric}(p_{in}^{gas} - p_{out}^{gas}), \quad (19)$$

where  $\sigma'_{valve}$  is the gas valve aperture and  $f'_{fric}(\cdot)$  a friction function like in Section 2.1. The ideal gas law in the vessel gives:

$$p_{in}^{gas} V^{gas} = n^{gas} RT, \quad (20)$$

where  $V^{gas}$  is the volume of gas inside the tank (above the liquid),  $n^{gas}$  is the gas mass quantity (moles) inside the vessel,  $R$  the ideal gas constant, and  $T$  the temperature inside the tank.

Differentiating Eq.(20), while replacing  $V^{gas}$  with  $(V^{total} - V^{liq})$ , leads to:

$$\underbrace{(V^{total} - V^{liq})}_{V^{gas}} \frac{dp_{in}^{gas}}{dt} - p_{in}^{gas} \frac{dV^{liq}}{dt} = RT(q_{in,mass}^{gas} - q_{out,mass}^{gas}), \quad (21)$$

where  $V^{total}$  is the tank volume,  $V^{liq}$  the volume occupied by the liquid,  $q_{in,mass}^{gas}$  and  $q_{out,mass}^{gas}$  are the gas mass inflow and outflow respectively. The tank volume is

$$V^{total} = \pi r^2 L. \quad (22)$$

Volume  $V^{liq}$  is computed from the liquid height by introducing

$$V_{tmp} = L \left( r^2 \arccos\left(1 - \frac{\tilde{h}}{r}\right) - (r - \tilde{h}) \sqrt{2r\tilde{h} - \tilde{h}^2} \right), \quad (23)$$

$$V^{liq} = \begin{cases} V_{tmp} & \text{if } h \leq r, \\ V^{total} - V_{tmp} & \text{otherwise.} \end{cases}$$

The mass flows are computed from the ideal gas law (also assuming  $p_{in}^{liq+gas} = p_{in}^{gas}$ ):

$$q_{in,mass}^{gas} = q_{in}^{gas} \frac{p_{in}^{liq+gas}}{RT}, \quad (24)$$

$$q_{out,mass}^{gas} = q_{out}^{gas} \frac{p_{in}^{gas}}{RT}. \quad (25)$$

Figure 5 shows the system response when the separator receives a sequence of inflow steps.

Figure 5: Responses to a square-wave input flow. The system shows a second-order behavior (overshooting and pseudo-oscillations).

## 2.5 Other models

Other models are necessary to simulate an offshore field. For instance, valves, pumps or tanks. The models are not described in detail here due to lack of space. They are chosen as simple as possible at this stage of the work. Hence ideal behavior is assumed:

- Valve: Two ports: port\_a, port\_b, one parameter: open=aperture signal:
 

```
equation
if noEvent(open >= 0 ) then
port_b.q = -port_a.q;
port_b.p = port_a.p;
port_b.phi = inStream(port_a.phi);
port_a.phi = inStream(port_b.phi);
```

```
else
port_a.q = 0;
port_b.q = 0;
end if;
```

- Pump: Two ports: port\_a, port\_b, one parameter: q0=imposed flow rate:
 

```
equation
port_a.q = q0;
port_b.q = -q0;
port_b.phi = inStream(port_a.phi);
port_a.phi = inStream(port_b.phi);
```
- Tank: One port: port\_in, one parameter: A=horizontal area, one variable: h=liquid level:
 

```
equation
//hydrostatic pressure:
port_in.p = rho * g * h;
der(h) = port_in.q/A;
```

## 3 Estimation of costs and risks

Estimating costs and risks requires a different modeling level than fluid flow simulation since it depends on exogenous factors, possibly stochastic (oil market, steel market, weather), or endogenous stochastic factors (failures). Dividing the simulation in two layers does not mean however that the layers are uncoupled. There is instead a strong dependency between them. For instance, the production income depends both on the extracted oil volume, computed in the physical simulation with an additional random perturbation term, and on the oil market and system state, the latter being modified by possible failures. Next sections describe the stochastic modeling of the facility. As further explained in Section 4, this part is not performed with Modelica but interacts with the Modelica simulation used for fluid flow modeling.

### 3.1 Stochastic model of the offshore oil facility

#### 3.1.1 Markov chain model

The system is assumed to be a Markovian process (i.e., memoryless) with discrete time. The time step is long (e.g. day or week) compared to the physical simulation time. The Markovian process is modeled as a Markov chain i.e., a finite state machine with transitions described as conditional probabilities. Each state of the chain corresponds to a particular operation state

Figure 6: Markov chain representation of the offshore field with four possible operation states. The operating costs are given as percentages of the cost when in optimal state (state 1).

of the oil facility. Production volume of each state is computed with the physical simulation. It means that as many physical simulations will be conducted as the number of defined system states. The Markov chain requires the definitions of the possible transitions between states and their respective probability. These definitions are typically obtained from experimental data or expert knowledge. Figure 6 shows an example of Markov chain for four defined states with their associate operating cost and production volume. The Markov chain is used to simulate virtual life-cycles of the field under the randomness hypotheses on the events (price change, failure) that may occur over time. One such virtual cycle corresponds to one realization of randomness. Repeating many simulations allows to build empirical distributions of the output of interest (production, cost, resilience performance, etc.). This is the principle of Monte Carlo simulation.

### 3.1.2 Monte Carlo simulation

The goal of Monte Carlo simulation is to derive statistics from repeated simulations. With the Markov chain model, it means computing the evolution of the system state by random selection of the transition at each time step. The transition selection depends on the previously-defined transition probabilities. We now present some of the statistical quantities that are interesting in the context of offshore field simulation.

## 3.2 Assessment indicators

Various indicators can be calculated to obtain information about the system performance. Some indicators concern for instance how the production is affected by the failure events. We will present the resilience indicator that aims at quantifying the impact of failures on the production. Other indicators are related to the

gain and the risk of loss. Both types of indicator (production and gain) can be applied to one or many simulations. In the latter case, new indicators might be derived to estimate the uncertainty of the performance indicator, from its estimated variance for instance.

### 3.2.1 Production resilience

Resilience is the ability of a complex system to respond and recover from damages. The definition comes from ecology but can be found in various fields. For oil facility study, we will refer to the concept as defined in the study of urban resilience [13]. For a given simulation, resilience is used to quantify the effect of sub-optimal (i.e., disturbed) states on the level of performance. Resilience  $R$  is expressed in % and, for a discrete-time system, is computed as

$$R = 100 \left( 1 - \frac{(V_{opt} - V)}{V_{opt}} \right), \quad (26)$$

where  $V$  is the production volume for the considered time period and  $V_{opt}$  is a reference production volume that corresponds to optimal production state. Resilience will vary from 0% (no production) to 100% (optimal production). Repeated experiments give statistical values of duration and occurrences of disturbance situations.

### 3.2.2 Gain and risk of loss

The gain represents the difference between the value of recovered oil and the operation and capital costs:

$$\text{gain} = \text{recovered\_oil} \times \text{barrel\_price} \times \Phi_0 - \text{OPEX} \times \Phi_1 - \text{CAPEX} \times \Phi_2 - \text{risk\_losses}, \quad (27)$$

where OPEX stands for *operating expenditure* (i.e., ongoing cost to run the field), CAPEX stands for *capital expenditure* (i.e., cost to acquire or upgrade the equipments) and  $\Phi_0, \Phi_1, \Phi_2$  are factors due to income/cost sharing with consortium partners ( $\Phi_0, \Phi_1, \Phi_2$ ) or extra bank/insurance costs ( $\Phi_1, \Phi_2$ ).

The cumulative distribution function (cdf) of gain is denoted  $F_{\text{gain}}(x)$  and defined as

$$F_{\text{gain}}(x) = P(X_{\text{gain}} \leq x), \quad (28)$$

where  $P(X_{\text{gain}} \leq x)$  is the probability that the gain random variable  $X_{\text{gain}}$  is smaller than  $x$ . The considered gain is the gain over a given time period (e.g. a week or a year if several years are simulated). Risk indicators can be computed directly from the cdf. For instance, the probability of loss can be simply estimated

Figure 7: Estimation of the cumulative distribution function of the gain (green curve), from a one-year simulation. Intersection of the curve with the vertical line (Gain=0) gives an estimation of the probability of loss (blue dashed line). Intersection of the curve with the horizontal line at 10% gives an estimation of the first 10%-quantile (red dashed line). The gain is normalized so that the maximum weekly gain is 1.

as  $F_{gain}(0)$  and the  $k$ -th q-quantile ( $k \in [1..q]$ ) is the solution of  $F_{gain}(x) = \frac{k}{q}$ . Figure 7 shows the example of an estimated cdf with the estimated probability of loss and the estimated first 10%-quantile.

### 3.2.3 Uncertainty and performance

All the aforementioned indicators are estimations of the real quantities that could be obtained only from an infinite number of random paths. Therefore, all decisions made on behalf of the performance indicators must include some consideration about indicator uncertainties. A tradeoff between estimated performance and reliability of the estimation should be found; for instance by representing the indicator in the space (*performance, uncertainty*). Monte Carlo simulation already provides insights on the variability of indicators based on the gain cdf. Indeed, confidence intervals on risk indicators can be derived as shown in Figure 8. The uncertainty can be estimated in various manners, e.g. as a function of the variance of the performance estimator. The variance can be approximated with the results of several experiments. The number  $N$  of experiments can also quantify the reliability of an estimation since the latter increases with  $N$ .

## 4 Results on a simplified design

A simplified design has been chosen to illustrate the methodology (Figure 9). Oil is extracted from three wells whose flows are combined and sent to one among two vertical pipes (*risers*). The specific model for the riser is not detailed here. The two-phase flow is

Figure 8: The cumulative distribution of gain averaged on 1000 one-year simulations (blue curve) and the confidence interval (magenta dashed curve) for a 30% and a 60% threshold. How far are the magenta curves from the blue curve tells how uncertain is the blue curve at a given time. The gain is normalized so that the maximum weekly gain –over the 1000 simulations– is 1.

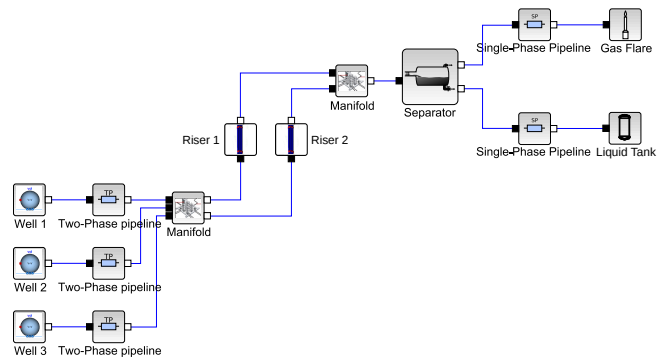

Figure 9: The studied simplified design of the offshore facility.

then received in an oil-gas separator and the two output single-phase flows are sent to a gas flare and an oil tank. The corresponding Markov chain is shown in Figure 6. States 1 and 2 are normal states with one of the two risers selected. States 3 and 4 are failure states (well 3 is blocked) with one or the other riser selected. Note that even though the characteristics (i.e., cost and production) of state 3 and 4 are identical, the states themselves are not as they do not have the same connections nor transition probabilities.

### 4.1 Fluid flow simulation

Some outputs of the fluid flow simulation are shown in Figure 10. In the presented results, initial oil level in the separator is far below the reference value, therefore all the input flow is used to fill the separator and the level in the tank does not increase until  $t \approx 2000$ s. Then, because of overshoot in the controlled system, level exceeds the reference value before eventually reaching the reference. A step is added to well flow

at  $t=5000$ s that explains the little peak in oil level.

Figure 10: Some results of the fluid flow simulation with Modelica. From top to bottom: Pressure drops in a pipe with two-phase flow and at gas-oil separator outlet; oil level in final tank; oil level in separator.

## 4.2 Cost and risk simulation

Whereas all the fluid flow simulation is performed with Modelica, the cost and risk simulation uses Scilab [15]. Scilab has a built-in block diagram modeler/simulator called Scicos that can use blocks based on Modelica code. The block diagram of Figure 9 is from Scicos interface. The simulation can then be ran from a Scilab script using the `scicos_simulate(...)` command. Results are returned in Scilab workspace and can consequently be directly post-processed for statistical estimation. Figure 11 shows the post-processed resilience of a one-year simulation with several computed indicators. Figure 7 is also an output of statistics processing in Scilab.

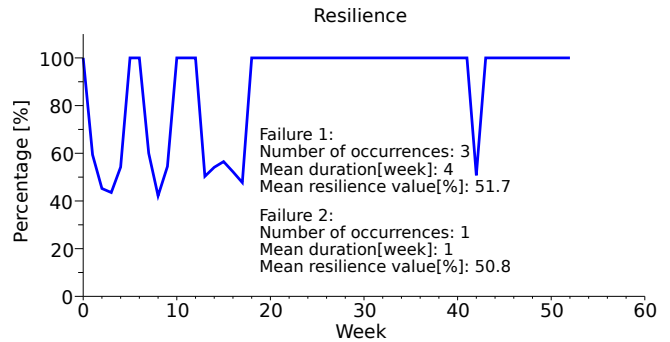

Figure 11: Resilience computed for a one-year simulation. For each type of failure, several indicators are computed like the number of occurrences or the mean duration.

## 4.3 Discussion

The presented simulation framework can be used to compare different designs of an offshore oil facility, in order to choose the most productive and/or robust, depending on the choice of a performance evaluator like those of Section 3.2.3. At the current stage of the project, the operating states and their occurring probabilities were defined arbitrarily. In further steps, they have to be set from technical data and part of the complexity of failure dependencies has to be handled automatically.

## 5 Conclusion and perspectives

We have presented our first results on the simulation of an offshore oil facility at the system level i.e., simulating all the plant components while considering also risk and failure estimations. Modelica is used to describe the physics of the flow through the various components of the offshore field. All the stochastic processes that can affect an offshore oil exploitation (failure, price variations, etc.) can be integrated in the stochastic layer of the simulation. Statistical indicators are obtained using simulation. Ongoing research is focused on up-scaling the approach and addressing industrial scale-one designs.

## Acknowledgments

The authors would like to thank Arnaud Antkowiak, associate professor at Université Pierre et Marie Curie for his help on two-phase flow modeling, Jean-Louis Grange, former senior expert at EDF and Gérard Le Coq, former head of department at EDF for their support on junction models. The authors are also

grateful to Jean-Philippe Chancelier, senior researcher at CERMICS lab of École des Ponts ParisTech, for his precious advice concerning Scilab/Scicos and its interface with Modelica. Finally, special thanks go to Lei Zhang for his several contributions to the work [17].

## Abstract

A combined cycle power plant are modeled and considered for calibration. The dynamic model, aimed for start-up optimization, contains 64 candidate parameters for calibration. The number of parameter sets that can be created are huge and an algorithm called subset selection algorithm is used to reduce the number of parameter sets. The algorithm investigates the numerical properties of a calibration from a parameter Jacobean estimated from a simulation of the model with reasonably chosen parameter values. The calibrations were performed with a Levenberg-Marquardt algorithm considering the least squares of eight output signals. The parameter value with the best objective function value resulted in simulations in good compliance to the process dynamics. The subset selection algorithm effectively shows which parameters that are important and which parameters that can be left out.

## 1 Introduction

Increasing environmental awareness has resulted in more demanding requirements. Energy supply is getting more attention and more and more wind turbines and solar power stations are built to adapt to a more environmentally friendly world. The challenge however is that the sun doesn't always shine and the wind doesn't always blow. Combined cycle power plants (CCPP) work as a good complement, because of its fast startup and shutdown time. Furthermore, the CCPPs have high thermal efficiency and are relatively environmentally friendly [1].

The market energy price fluctuates every day, which

affects the profitability of the CCPPs. Because of this it is of importance to adapt to the market and be able to quickly start up and shut down the process. A quick start-up is important because energy is not produced until the gas turbine reaches full speed and is synchronized to the grid. However, this cannot be done too quickly because a rapid temperature change wears out sensible parts. The startup follows three phases: the first to accelerate the gas turbine to full speed, the second to increase the load of the gas turbine and the third to drive the steam to the steam turbine. The model of this work focuses on the second part which is the most critical during a startup. Sensible parts as the drum after the evaporator and the header of the superheater are important to model for a successful startup optimization. A model was therefore set up aimed for optimization of the startup, considering the temperature gradient in the sensible parts to estimate the tensions. The model has previously been used in optimizations [2, 3]. The startup of combined cycle power plants has been optimized in several studies before [4, 5, 6, 7, 8].

Accurate modelling of the CCPP is a difficult task, which if successful can cut expenses. This requires a good calibration of the model to make the discrepancy to the real process dynamics as small as possible. The main purpose of the calibration is to enable a valid model for optimization of startups. The parameter estimation is performed using a Levenberg-Marquardt algorithm, which effectively uses the parameter Jacobean to find the optimum.

A model usually contains many parameter candidates for calibrations. Estimating many parameter simultaneously leads to ill-conditioned calibration problem due to dependency between the parameters, that make convergence bad and with wide confidence intervals as a result. A parameter-selection algorithm,

called subset selection algorithm (SSA) is proposed that ranks the parameter by two properties,  $\alpha$  and  $\kappa$  [9]. The parameter  $\alpha$  is correlated to the size of the confidence regions for a parameter set and  $\kappa$  is a measure of how well-conditioned the parameter Jacobean for a parameter set is. The algorithm that significantly reduces the number of parameter sets to study, has recently been proven to work good for a model of a polyethylene plant [10].

## 2 Theory

### 2.1 Differential algebraic equation systems

The general non-linear index-1 differential algebraic equation (DAE) form is defined by

$$\mathbf{0} = \mathbf{F}(\dot{\mathbf{x}}, \mathbf{x}, \mathbf{w}, \mathbf{u}, \mathbf{p}) \quad (1)$$

$$\mathbf{y} = \mathbf{g}(\dot{\mathbf{x}}, \mathbf{x}, \mathbf{w}, \mathbf{u}, \mathbf{p}) \quad (2)$$

$$\mathbf{x}(t_0) = \mathbf{x}_0 \quad (3)$$

where  $\mathbf{x}$ ,  $\mathbf{w}$ ,  $\mathbf{u}$  and  $\mathbf{p}$  are vectors denoting state and algebraic variables that describe the inputs and parameters of the model. In Eq 2, the output variables of the system that is subject to calibration are denoted  $\mathbf{y}$ . The initial state is defined by  $\mathbf{x}_0$  and is expressed in Eq 3. To solve the steady-state problem the state derivatives  $\dot{\mathbf{x}}$  are set to 0 and  $\mathbf{x}$  and  $\mathbf{w}$  are solved to fulfill Eq 1.

### 2.2 Non-linear regression methods for differential algebraic models

Regression methods are roughly classified into two broad categories: *gradient methods* and *direct-search methods* [11]. The former depends on accurate parameter gradients, while the latter does not. Gradient methods include the Gauss-Newton Method, the steepest descent method and the Levenberg-Marquardt method, while direct-search include the simplex method, differential evolution algorithms and pattern search [12, 13]. The Gauss-Newton method gives the best results when gradients are available [14].

The Levenberg-Marquardt method is a more stable variant of the Gauss-Newton method [12] and can be used to solve the problems of estimating dynamic parameters, where the Newton step  $\Delta \mathbf{p}$  is calculated from

$$(\mathbf{J}^T \mathbf{W} \mathbf{J} + \delta \text{diag}(\mathbf{J}^T \mathbf{W} \mathbf{J})) \Delta \mathbf{p} = \mathbf{J}^T \mathbf{W} (\hat{\mathbf{y}} - \mathbf{y}) \quad (4)$$

where  $\hat{\mathbf{y}}$  is the measurements for the output and  $\delta$  is a Levenberg-Marquardt parameter, which controls the allowed step length and is updated in each iteration,

based on the quality of the Newton step. The sensitivity matrix is defined as the parameter Jacobean matrix

$$\mathbf{J} = \frac{d\mathbf{y}}{d\mathbf{p}} \quad (5)$$

and was estimated with finite differences using the central approximation.

A single shooting approach is common to solve problems of estimating dynamic parameters [15]. It starts with a guess of the parameters. The dynamic model is then simulated, and the parameters are updated iteratively by a regression method, such as Levenberg-Marquardt method.

### 2.3 Statistics

Confidence regions are calculated to assess the quality of the parameter estimates. A confidence interval of  $1 - \beta$ , with  $n_y$  number of measurements and  $n_p$  number of parameters, is estimated from

$$\mathbf{p}^* \pm s_p T_{inv}(\beta/2, n_y - n_p) \quad (6)$$

and means that there is a probability of  $1 - \beta$  that the true parameter lies within the estimated interval. Here,  $\mathbf{p}^*$  is the calibrated parameters,  $T_{inv}$  is the inverse of the Student's T test and  $s_p$  is the estimated standard error of the parameters defined as

$$s_{p_k} = \sqrt{(\chi)_{kk}}, \quad \text{for } k = 1, \dots, n_p \quad (7)$$

where  $\chi$  is the covariance matrix calculated as

$$\chi = \sigma^2 (\mathbf{J}^T \mathbf{W} \mathbf{J})^{-1}. \quad (8)$$

where  $\sigma^2$  is the error variance and can be estimated by

$$\sigma^2 = \frac{1}{n_y - n_p} |\hat{\mathbf{y}} - \mathbf{y}|^2 \quad (9)$$

and the diagonal weighting matrix,  $\mathbf{W}$ , used to scale the outputs, is defined as

$$\mathbf{W} = \begin{pmatrix} \hat{y}_1^{-2} & 0 & \dots & 0 \\ 0 & \hat{y}_2^{-2} & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & \hat{y}_{n_y}^{-2} \end{pmatrix} \quad (10)$$

### 2.4 Subset selection algorithm

The numerical properties of a parameter estimation can be estimated from the sensitivity matrix,  $\mathbf{J}$ . An algorithm is suggested [9] that investigates parameter

sets from a nominal operating point, and ranks the parameter sets according to two quantities: the condition number,  $\kappa$ , and the parameter selection score,  $\alpha$ . Here,  $\kappa$  is defined as the ratio between the largest and smallest singular value of  $\mathbf{J}$ , and  $\alpha$  is defined by  $\alpha(\mathbf{p}) = |\mathbf{v}|$ , where  $\mathbf{v}$  is the scaled standard error for the parameters

$$v_i = s_{pi}/p_i \quad \text{for } i = 1, \dots, n_p \quad (11)$$

The quantities  $\kappa$  and  $\alpha$  are used to estimate the parameter dependencies and the uncertainties in the parameters. A low value of  $\alpha$  shows that the estimated parameters have been accurately determined, while a low value of  $\kappa$  shows that the calibration problem are well conditioned. Both  $\alpha$  and the confidence interval are calculated from the standard error of the parameters and the quantities are closely related. A low value of  $\alpha$  indicates narrow confidence intervals. The parameter  $\kappa$  is a measure of how well the calibration problem is conditioned. Low values are preferable because it indicates that the parameters are independent of each other, while high values indicates a difficult calibration, where an inverse of the sensitivity matrix does not exist or can only be calculated with low accuracy.

Both  $\alpha$  and  $\kappa$  can be calculated without any calibration of the model, by setting some reasonable parameter values, referred to as nominal values, and determine the sensitivity matrix from a simulation. From the full sensitivity matrix,  $\alpha$  and  $\kappa$  can be calculated for every parameter subset. The sensitivity matrix for a parameter subset is created by taking the corresponding columns from the full sensitivity matrix.

## 3 Methods

### 3.1 Modelling Languages and Tools

The mathematical model has been implemented in Modelica [16], which is a high-level language for describing complex physical systems, supporting object-oriented concepts such as classes, components and inheritance. It can also encode textbook-style declarative equations. This modelling paradigm has significant advantages over the block-based paradigm that is often used in the context of physical modelling. In particular, acausal modelling systems do not require the user to solve the derivatives of a mathematical model. Instead, differential and algebraic equations may be mixed, which then typically results in a differential algebraic equation.

The calibrations in this paper have been performed using JModelica.org, which is a Modelica-based open-source platform targeted at dynamic optimization

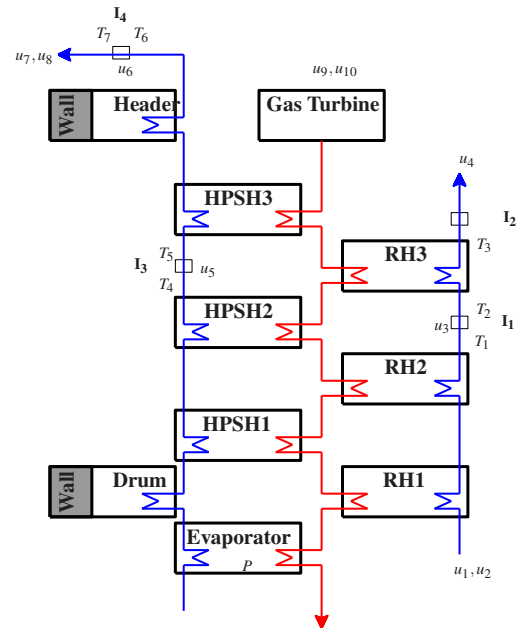

Figure 1: A schematic figure of the process.

[17]. The optimization is enabled by an extension to Modelica, Optimica, which strengthens its optimization capabilities by adding a small number of constructs. JModelica.org uses an interior point algorithm, IPOPT, to solve for feasible solutions, that fulfil the equation system[18]. Further, JModelica.org uses the Assimulo package [19], which interfaces the IDA solver from the Sundials suite [20].

To handle the high number of calibrations in this work in a reasonable time, a simple parallelization was performed. A simulation can only utilize one processor core, while it takes several simulations in every iteration of a calibration. By distributing the simulations with the python package subprocess, all eight processor cores could be utilized.

### 3.2 Mathematical plant model

A simple model scheme is found in Figure 1. The model has previously been used in startup optimization where it is described in more detail[2, 3]. The model, consisting of both differential and algebraic equations, has been derived from a combination of first principles and semi-empirical relations. It is focused on the heat recovery steam generator (HRSG) where the water side, indicated with blue arrows, are modeled by dynamic balance equations. The heat from the gas turbine (GT), shown with a red arrow, is statically modeled from the temperature ( $u_9$ ) and the mass flow ( $u_{10}$ ) of the GT. The water side is modeled as two different streams, one through the high pressure super-

Notation	Description
$u_1$	RH inlet enthalpy
$u_2$	IP mass flow
$u_3$	water injection flow $I_1$
$u_4$	IP back pressure
$u_5$	water injection $I_3$
$u_6$	water injection $I_4$
$u_7$	HP back pressure
$u_8$	HP mass flow
$u_9$	temperature GT
$u_{10}$	mass flow GT

Table 1: A list of the inputs used.

heaters (HPSHs) and the other through the reheaters (RHs). The water is evaporated in the evaporator and going through the drum before it is superheated in three steps, HPSH1, HPSH2 and HPSH3. Finally the steam is led through the header and continues to the high pressure steam turbine. The drum and the header are similarly modeled as a volume, where the wall are subject to high stress during transients that needs to be constrained. The wall is spatially discretized so that the temperature gradient can be modeled, which is an indicator of the stress. The right blue line is going through the three reheaters RH1, RH2 and RH3 and continues to the intermediate pressure steam turbine. There are also four water injections modeled, shown in boxes in the Figure, where the first  $I_1$  is located between RH2 and RH3 and  $I_{2-4}$  are located after RH3, between HPSH2 and HPSH3 and after the header, respectively. In the model there are also several valves to control the flow rates. The temperature sensors are also modeled to account for sensor lags.

The model is simulated with ten inputs following measurement data and are shown in Table 1. Three of the inputs are mass flows of the water injections, two describe the temperature and mass flow of the exhaust gas from the GT and five describe the state of the water on the HPSH and RH side. The mass flow of the exhaust gas from the GT are not measured directly, but calculated from balance equations. Eight objective signals are considered in the calibration and are shown in Table 2. The input and objective signals are also shown in Figure 1.

There are 64 potential parameters to calibrate in the model. The parameters are roughly divided in eight categories, see Table 3. Heat transfer coefficients are denoted as  $k_{in}$ , describing the transfer between the exhaust gas and metal wall,  $k_{out}$ , describing the heat transfer between the metal wall and the cold water, and  $k$ , describing either the heat transfer in the sensors or the heat transfer in the metal walls of the header

Notation	Description
$T_1$	temperature before $I_1$
$T_2$	temperature after $I_1$
$T_3$	temperature before $I_2$
$T_4$	temperature before $I_3$

Table 3: The parameter used in the SSA analysis. Merged parameters are indicated in bold.

and drum. There are two categories of masses, denoted as  $m_{H_2O}$  for water volumes and  $m_{Fe}$  for iron walls. The last categories are the fluid volume  $V$  for the header and drum and the heat capacity of the sensors,  $cap$ . Last category is  $k_v$  that affects the dynamics of the valves, that is modeled with a constant pressure drop. There are seven sensors measuring the outputs  $T_{1-7}$ , each with two parameters and paired as  $\{42, 49\}$ ,  $\{44, 51\}$ ,  $\{43, 50\}$ ,  $\{45, 52\}$ ,  $\{47, 54\}$ ,  $\{48, 55\}$  and  $\{46, 53\}$ .

Some parameters describe the same kind of parameter in different places of the model. For example, in the superheaters SH1, SH2 and SH3, the  $k_{out}$  parameter is described with the parameters 22, 23, 24 that has the same nominal values. A merged parameter is introduced that enables a reduction of parameters, which is important in calibration problems. For  $k_{out}$  in the superheaters, the parameter 5 is a merged parameter. Setting this parameter means that the children parameters 22, 23 and 24 gets the set value. There are 11 merged parameters in the analysis, where  $k_{in}$ ,  $k_{out}$ ,  $m_{H_2O}$  and  $m_{Fe}$  are set by the parameters 9, 5, 18, 21 for the superheaters and the parameters 12, 6, 19, 11 for the reheaters, the parameter 13 sets all the other  $k_v$  parameters and  $k$  and  $cap$  for the temperature sensors are set with the parameters 14 and 16. A merged parameter can not be in the same parameter set as its children.

Naturally, many of the parameters are highly correlated, such as  $k_{in}$  and  $k_{out}$ . For convenience the parameter set  $\{p_1, p_2, p_3\}$  is denoted as  $p_{1,2,3}$

## 4 Calibration methodology for large-scale systems

### 4.1 Calibration procedure

The calibration is made by minimising the objective function described by a least square formulation of the error between the plant data and the model response. If all parameters are included in the calibrations, it leads to badly conditioned problems. The number of parameter sets that can be combined grows rapidly with the number of parameters. To reduce the number of parameters to estimate in the model a parameter selection algorithm called subset selection algorithm was used. Information from the sensitivity matrix is used to avoid ill-conditioned parameter estimations and to find parameter sets that can be determined with low parameter uncertainty.

The calibration procedure is solved by a single shooting procedure, where the model is simulated for every iteration of parameters. An attempt is made in each iteration to find the initial states for the updated parameters. The system simulation then proceeds during the whole start-up. The initial states are found by solving a steady-state problem, defined in Eqs. (1)-(3) and with  $\dot{\mathbf{x}} = 0$ . The system is subsequently simulated, with the inputs  $\mathbf{u}$  following the measurement data. The parameters can be updated by minimising the objective value defined as the weighted sum of squares of the residuals

$$Q(\mathbf{p}) = \sum_{i=1}^{n_t} (\hat{\mathbf{y}}_i - \mathbf{y}(t_i, \mathbf{p}))^T \mathbf{W} (\hat{\mathbf{y}}_i - \mathbf{y}(t_i, \mathbf{p})), \quad (12)$$

where  $n_t$  is the number of time points and  $\mathbf{y}_z(t_i, \mathbf{p})$  is the model outputs from the simulation at time  $t_i$ . The calibration problem is solved iteratively by updating the parameters using the Levenberg-Marquardt algorithm, described in Section 2.2. The dynamic calibration is formulated as an optimization problem

$$\begin{aligned} \min_{\mathbf{p}} Q(\mathbf{p}) \\ \text{subject to Eqs. (1) - (3)} \\ \mathbf{x}_{min} \leq \mathbf{x} \leq \mathbf{x}_{max} \\ \mathbf{w}_{min} \leq \mathbf{w} \leq \mathbf{w}_{max} \\ \mathbf{p}_{min} \leq \mathbf{p} \leq \mathbf{p}_{max} \end{aligned} \quad (13)$$

In this work, only one data set was used for calibration and no validation was performed. In a previous work, several calibration and validation data sets were used with a similar approach on another model, which showed good compliance [10].

### 4.2 Reduction of parameter sets

Models often have many potential parameters to calibrate, where many of the parameters are dependent of each other. If all parameters are included in the calibration it results in parameter Jacobians that are highly ill-conditioned and a calibration that is impossible to solve. It is desirable to choose a subset of the parameters that are independent of each other, minimizes the objective function and with parameters that can be determined with good accuracy. The number of parameter combinations increase rapidly with the number of parameters and the exploration of all parameter sets is heavy computationally. An approach to reduce the parameter sets is suggested, where the  $\kappa$  and  $\alpha$  numbers of the SSA algorithm are used to rank the parameters. The selection method consists of two loops, the SSA loop and the calibration loop, each one consisting of three base parts: combination, evaluation and filter blocks, Figure 2. The blocks are defined as follows:

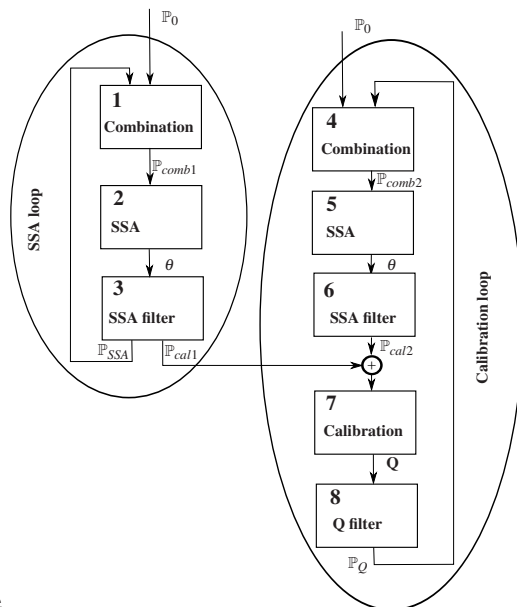

**Combination** is the process of taking an input population  $\mathbb{P}_{in}$  that contains the  $n_{pin}$  parameter sets  $\{\mathbf{p}_{in}^1, \dots, \mathbf{p}_{in}^{n_{pin}}\}$  and mixing it with all  $n_{p0}$  parameters  $\mathbb{P}_0 = \{p_1, \dots, p_{n_{p0}}\}$  to create a new parameter set population  $\mathbb{P}_{out}$  that contains parameter sets with one more parameter than the parameter sets of the input population. The input population is empty before the first iteration, and thus the output population will contain one parameter set for every parameter in  $\mathbb{P}_0$ .  $\mathbb{P}_{in}$  is not empty before the next iteration, and thus the  $\mathbf{p}_{in}^1$  will enter the output population as  $n_{p0}$  parameter sets defined by  $\{\{\mathbf{p}_{in}^1, p_1\}, \dots, \{\mathbf{p}_{in}^1, p_{n_{p0}}\}\}$ , and the parameter sets  $\mathbf{p}_{in}^2, \dots, \mathbf{p}_{in}^{n_{pin}}$  will be combined in the same way. The same parameter set can be created from two different parameter sets in the input population, and thus an operation is carried out to remove all duplicates. The maximum number of parameter sets in the output population is  $n_{p0}n_{pin}$ , but this may be reduced when duplicates are removed. There are two combination blocks, Block 1 (SSA loop), where  $\mathbb{P}_{comb1}$  is created and Block 4 (calibration loop), where  $\mathbb{P}_{comb2}$  is created.

**SSA Evaluation** evaluates  $\alpha$  and  $\kappa$  values for each

parameter set of the input population as defined in Section 2.4, and calculates a SSA score  $\theta$ , given by  $\theta = \lg \alpha + \lg \kappa$ , that is later used in the filter block to determine the best parameter sets in the SSA loop.

**Calibration** is the step where calibrations are made for all parameter sets in the input population, that consists of both  $\mathbb{P}_{cal1}$  and  $\mathbb{P}_{cal2}$ . All parameter sets are calibrated and the objective value that measures the deviation between model and measurements is returned. The calibration step is the most computationally expensive step.

**Filters** are used to reduce the number of parameter sets, which otherwise would increase rapidly. There are three filter blocks, one in the SSA loop and two in the calibration loop. The filter block takes a population of parameter sets, a score that has been calculated to rank the parameter sets, and a cutoff that defines how many parameter sets should pass. In Block 2 and 5,  $\theta$  is used as score and  $n_{SSA1}$  is used as cutoff for  $\mathbb{P}_{SSA}$ ,  $n_{cal1}$  for  $\mathbb{P}_{cal1}$  and  $n_{cal2}$  for  $\mathbb{P}_{cal2}$ . In Block 8,  $Q$  is used as score and  $n_Q$  is used as cutoff. The choice of the cutoffs are arbitrarily, but should not be chosen too small for a good analysis.

The

Figure 2: The SSA selection procedure used.

SSA evaluation is relatively cheap, but the number of parameter sets increase rapidly as  $n_p$  increases. The number of parameter sets increases as the binomial coefficients  $\binom{n_{P0}}{n_p}$ , which for  $n_{P0} = 64$  are

$\{64, 2016, 41664, 635376, 7624512, \dots\}$ . Setting a filter cutoff limits the population that must be examined to  $n_{SSA}n_{P0}$  per iteration instead. The number of calibrations are dependent of  $n_{P0}$  and the filters  $n_{cal1}$  and  $n_{cal2}$ . In the first iteration,  $n_{cal1}$  calibrations were performed and in the following rounds,  $n_{cal1} + n_{cal2}$  calibrations are performed.

In this work, the cutoffs have been chosen to  $n_{SSA} = 300$ ,  $n_{cal1} = 5$  (10 in the first iteration),  $n_{cal2} = 4$  and  $n_Q = 1$  in the work presented here. In this work the loops were iterated for parameter sets ranging from one parameter to seven parameters. The total number of calibrations performed is around five in the first iteration and nine in the rest, totally 59 calibrations.

## 5 Calibration results

### 5.1 Calibration

The calibration of the model was done for many parameter sets in the calibration loop of the SSA method. The parameter set with the best objective value with seven parameters,  $p_{6,13,16,17,22,24,47}$ , is called  $C_3$  and is shown in Figure 3. The parameters in the set consist of four  $k_{out}$  parameters for SH1, SH3 and all RHs, one valve parameter and two sensor parameters. No parameters for masses, volumes and heat transfer in walls and gas side are represented. The calibration reduces the objective function value from 1.85 with nominal parameter values to 0.585 and improves all eight objective signals. The largest improvements are for  $T_1$ ,  $T_4, T_6$  and  $P$ , with 72%, 70%, 87% and 74% reduction.

In Table 4 the calibrated parameters with confidence interval for the three calibrations  $C_{1-3}$  are compared. The confidence intervals are narrow for all parameters, except for  $p_{24}$  that is  $k_{out}$  in SH3. This parameter affects mainly the objective  $T_6$ , which transient for the nominal parameter value are far below the measurements. To increase the temperature, the obtained parameter value is therefore very high, with the values 64.9, 79.3 and 79.5. The confidence intervals are almost as big as the parameter which is a very inaccurate parameter. The  $\alpha$  and  $\kappa$  values are also notably worse at the optimum.

### 5.2 Parameter selection

The SSA analysis was performed for the parameters and is shown in Figure 4. The evaluated parameter sets results in dot clouds that move upwards and to the right, the more parameters that are added. The dot

$p_{22}$		$0.38 \pm 0.014$	$0.375 \pm 0.014$
$p_{23}$	$0.54 \pm 0.021$		
$p_{24}$	$64.9 \pm 46.2$	$79.3 \pm 78.7$	$79.5 \pm 79.5$
$p_{47}$	$9.6 \pm 0.078$		$1.26 \pm 0.069$

Table 4: Calibrated parameter values with a 95% confidence interval for calibrations  $C_1$  and  $C_2$ . All parameters are scaled with the nominal parameter value.

Figure 4: The SSA analysis for  $n_p$  from 1 to 8. The dot clouds move to the right and up when parameters are added. Parameter sets with best  $\theta$  is marked as (•) and parameters from the best objective loop (×)

clouds are created from the SSA loop of the SSA analysis, with 64 parameter sets for  $n_p = 1$  and  $64 \cdot 300$  parameter sets for  $n_p$  from two to eight. The parameter sets with the lowest values of  $\theta$  ( $\mathbb{P}_{cal1}$ ) are shown with black dots and are located in the lower left corner in each figure. Those parameter sets were calibrated and the objective values are shown in Table 5. The objective value improves when parameters are added for  $n_p$  from one to five. After that the calibration gets worse for  $n_p$  equal to six and seven.

In the calibration loop of the SSA analysis, the best parameter sets were combined with new parameters to create  $\mathbb{P}_{cal2}$  that were calibrated and is presented in Table 6. Those parameter sets, marked with crosses are also located in the lower left corner for  $n_p$  from two to seven. The objective values of this loop gets better for every iteration as new parameters are added to the best parameter set of the previous iteration until eight parameters are reached where the calibrations do not converge. Also the  $\alpha$  and  $\kappa$  values for those parameter sets are very bad.

In Table 5 there is 20 unique parameters  $\{5, 6, 12, 13, 14, 16, 17, 22, 23, 24, 26, 43, 45, 46, 47, 48, 52, 53, 54, 55\}$  where  $\{5, 6, 12, 13, 14, 16\}$  are merged parameters. Seven of the parameters,  $\{5, 6, 17, 22, 23, 24, 26\}$  are  $k_{out}$  parameters, while only one parameter,  $\{12\}$  is a  $k_{in}$  parameter, indicating that the parameters for heat transfer between the metal wall to the cold water have greater impact than the heat transfer between the exhaust gas and the metal wall. No drum or header parameter are visible in the best parameter

sets of the analysis. For the valves, only the merged parameter {13} is visible in the tables. There are many sensor parameters visible in the result, namely {43,45,46,47,48,52,53,54,55}, corresponding to the sensors for  $T_{1,4,5,6,7}$ .

In Table 6 there is only 11 unique parameters 6, 13, 14, 16, 17, 22, 24, 47, 48, 54, 55. All of those are not surprisingly also visible in Table 5, because they are partly derived from the best parameter sets of that table.

The parameter set with the lowest objective value for parameter sets with one parameter is  $p_{24}$  with  $Q = 1.03$ . This parameter is also visible for all of the best parameter sets, even though the confidence intervals are wide. The  $\alpha$  and  $\kappa$  values at the optimum were much worse at the optimum than for the nominal parameter values.

The parameter sets with  $p_{47}$  and  $p_{54}$  are replaceable in several places, for instance in  $p_{6,22,24,47}$  and  $p_{6,22,24,54}$  that give the same objective value. Both of

those are sensor parameters for output  $T_5$ . Also the  $T_6$  parameters  $p_{48}$  and  $p_{55}$  seem replaceable, apart from some small difference in objective value.

## 6 Discussion and summary

The objective function values became better when adding more parameters, but reached a point where adding of parameters made the calibrations too hard to solve. The best parameter set ( $C_3$ ) chose parameters from different parts of the model to minimize as many outputs as possible in the objective function.

The trend in the calibrations is that the parameter sets get harder to solve when more parameters are added and take more iterations. For eight parameters and more the calibrations fail to converge more often. Apart from that the calibrations are more complex when parameters are added, it is also harder to find independent parameters for a larger parameter set. Ill-conditioned calibration problems leads to parameter steps that make the simulations infeasible.

The analysis shows that the  $k_{out}$  parameters occur more frequently than the  $k_{in}$  parameters and indicates that the cold water side has greater impact of the model than the exhaust gas side. This is probably because the exhaust gas is only statically modeled in contrast to the cold water side. The analysis also shows that some parameters are replaceable, such as  $p_{47}$  and  $p_{54}$ . Only

one of the parameters are therefore needed for further analysis.

The merged parameters performed well in the analysis where six of the 11 merged parameters appeared in the best parameter sets. Merged parameters are effective for parameters that is expected to behave similarly and keeps the number of parameters in the calibration problem less.

The information to the SSA analysis is estimated from uncalibrated parameters but give a good indication about the best parameter sets considering the  $\alpha$  and  $\kappa$  values. The values are dependent of the parameter values and will obviously change for the calibrated parameter values, but hopefully not much. For most parameter sets, the  $\alpha$  and  $\kappa$  values stayed roughly the same, but for parameter sets including  $p_{24}$  resulted in worse  $\alpha$  and  $\kappa$  values at the optimum. Still, the analysis highlights  $p_{24}$  as a crucial parameter, that can decrease the objective function value the most, but with very wide confidence intervals as a result. A further analysis is required to understand this behavior.

Both the SSA and calibration loop of the analysis is dependent of the cutoff numbers for good performance. The calibration numbers were consciously set to low numbers, because of long calibration times that were performed on a single computer. The numbers can be set higher for a more thorough analysis if time or a computer cluster is available. The result shown here proves that satisfactory calibration results can be reached even with low cutoff numbers.

The parameter estimation results are in good compliance to the process dynamics. The subset selection algorithm effectively shows which parameters that are important and which parameters that can be left out. Considering the few number of calibrations that were performed, the result is satisfactory.

# Restarting algorithms for simulation problems with discontinuities

Fatemeh Mohammadi Carmen Arévalo Claus Führer\*  
Numerical Analysis, Center of Mathematical Sciences, Lund University  
Sölvegatan 18, SE-22100 Lund, Sweden

## Abstract

Modelica's language support includes so-called events for describing discontinuities. Modern integrating environments, like Assimulo, provide elaborate event detection and event handling methods. In addition, the overall performance of a simulation of models with discontinuities (hybrid models) depends strongly on the methods for restarting the integration after an event detection. The present paper reviews two restarting methods for multistep methods, both based on Runge–Kutta starters, and presents preliminary first experiments with Assimulo and LSODAR as a proof of concept, which motivates to apply the technique to hybrid systems described in Modelica and simulated by JModelica.org/PyFMI and Assimulo [1, 3, 2].

*Keywords: events, discontinuities, hybrid systems, multistep method, Runge–Kutta method, simulation restart*

## 1 Introduction

When dealing with hybrid systems, i.e. dynamic systems with state or time discontinuities, much emphasis has been put on the modeling aspect. Attempts to standardize the formulation of events and algorithms for event detection were in the focus of development and research, e.g. [4]. On the other hand, the question of restarting complex integration methods like multistep methods, with their sophisticated internal error and order control algorithms and internal data representations, did not attract much attention. In this paper we want to take up and review two early ideas for restarting and to present some experiments using the JModelica.org - PyFMI - Assimulo toolchain.

A multistep method is classically started by stepwise increasing the order of the method, starting with a

first order method (implicit Euler method) and leading to a method having the operational order of the problem at hand. Simulations are often done for a set of parameterized models for which the operational order and also good guesses of initial step sizes are available from other simulation runs. Thus, a goal for improving the integration performance is to avoid costly starting phases and directly start the integrator with a method already having the operational order. To start such a higher order method several internal values are required. Here we consider two ideas for providing these values. In both cases the starting values are obtained from the stage values of a single Runge–Kutta step of a specially designed method. One of them uses state values, while the other is geared to Nordsieck based multistep methods like LSODAR.

## 2 Runge–Kutta starter with state values

We demonstrate the principle by constructing a Runge–Kutta starter for a third order multistep method, [8].

Furthermore, we construct two error estimates for determining the starting step of both the Runge–Kutta starter and a class of multistep methods, i.e. Adams methods.

Such a Runge–Kutta starter has to have an internal stage of order 3 as soon as possible and all subsequent stages need to be at least of order 3. In addition; the final result should be of order 4 for the purpose of error estimation. It is well-known that to get third-order accuracy at least three internal stages are necessary, and to conserve this accuracy for subsequent stages we need to aim for a Runge–Kutta method with at least six stages, [5]. We will thus consider a 6-stage Runge–Kutta method.

For the initial value problem

$$y' = f(t, y), \quad y(0) = y_0, \quad (1)$$

\*partly supported by LCCC - Lund Center for Control of Complex Engineering Systems

Figure 1: Runge–Kutta starter after a discontinuity

an  $s$ -stage explicit Runge–Kutta method can be written in the form,

$$\begin{aligned}
 k_i &:= f(t_0 + c_i H, g_{i-1}), \\
 g_i &:= y_0 + H \sum_{j=1}^i a_{ij} k_j, \quad i = 1, \dots, s, \\
 y_1 &:= y_0 + H \sum_{j=1}^s b_j k_j,
 \end{aligned} \tag{2}$$

where  $y_1$  is the numerical solution at  $t_1 = t_0 + H$ ,  $H$  is the Runge–Kutta step size and  $k_i$  are stage derivatives.

$f$  may be discontinuous but it is assumed to be piecewise smooth.

In the construction of an order 4, 6-stage explicit Runge–Kutta method, order conditions up to order four need to be satisfied. Let

$$\begin{aligned}
 b &:= (b_1, b_2, \dots, b_s)^T, \\
 a_i &:= (a_{i1}, a_{i2}, \dots, a_{ii}), \\
 C_i &:= \text{diag}(c_1, \dots, c_i), \\
 A_i &:= (a_{jk})_{j,k=1}^i, \\
 e_i &:= (1, 1, \dots, 1)^T.
 \end{aligned} \tag{3}$$

When deriving the stage order conditions, we make use of the fact that in Eq. (2), the stage values  $g_i$  and  $y_i$  have structurally the same form. Therefore, we can derive the order conditions for internal stages in the same way.

The order conditions for a fourth-order Runge–Kutta method are

- order 1

$$b^T e_s = 1.$$

- order 2

$$b^T C_s e_s = \frac{1}{2}.$$

- order 3

$$b^T C_s^2 e_s = \frac{1}{3},$$

$$b^T A_s C_s e_s = \frac{1}{6}.$$

- order 4

$$b^T C_s^3 e_s = \frac{1}{4},$$

$$b^T C_s A_s C_s e_s = \frac{1}{8},$$

$$b^T A_s C_s^2 e_s = \frac{1}{12},$$

$$b^T A_s^2 C_s e_s = \frac{1}{24}.$$

(4)

Additionally we require

$$\sum_{j=1}^s a_{ij} = c_i. \tag{5}$$

The remaining order conditions for internal stages  $i = 4, 5, 6$  are

- order 2

$$a_i^T C_i e_i = \frac{1}{2} c_i^2.$$

- order 3

$$a_i^T C_i^2 e_i = \frac{1}{3} c_i^3,$$

$$a_i^T A_i C_i e_i = \frac{1}{6} c_i^3.$$

(6)

We want to both obtain third-order accuracy and minimize the truncation error bound. Ralston [6] showed that the third-order Runge-Kutta method which has the minimal error bound among all third-order Runge–Kutta methods is

$$\begin{aligned}
 k_1 &= hf(t_n, y_n), \\
 k_2 &= hf(t_n + \frac{1}{2}h, y_n + \frac{1}{2}k_1), \\
 k_3 &= hf(t_n + \frac{3}{4}h, y_n + \frac{3}{4}k_2), \\
 y_{n+1} &= y_n + \frac{2}{9}k_1 + \frac{1}{3}k_2 + \frac{4}{9}k_3.
 \end{aligned} \tag{7}$$

This implies the Butcher tableau for the first four stages is

0	0		
$\frac{1}{2}c_4$	$\frac{1}{2}c_4$	0	
$\frac{3}{4}c_4$	0	$\frac{3}{4}c_4$	0
$c_4$	$\frac{2}{9}c_4$	$\frac{1}{3}c_4$	$\frac{4}{9}c_4$

From condition (5) we find

$$a_{21} = c_2, \quad a_{31} = (1 - \theta)c_3, \quad a_{32} = \theta c_3. \quad (8)$$

We now substitute (6) and (5) in (4) to calculate the values  $b_i$  for the six stage Runge–Kutta method.

$$\begin{aligned} b_2c_2^3 + b_3c_3^3 + b_4c_4^3 + b_5c_5^3 + b_6c_6^3 &= \frac{1}{4}, \\ b_3c_3\theta c_3c_2 + \frac{1}{2}b_4c_4^3 + \frac{1}{2}b_5c_5^3 + \frac{1}{2}b_6c_6^3 &= \frac{1}{8}, \\ b_3c_3\theta c_2^2 + \frac{1}{3}b_4c_4^3 + \frac{1}{3}b_5c_5^3 + \frac{1}{3}b_6c_6^3 &= \frac{1}{12}, \\ \frac{1}{6}b_4c_4^3 + \frac{1}{6}b_5c_5^3 + \frac{1}{6}b_6c_6^3 &= \frac{1}{24}. \end{aligned} \quad (9)$$

For the first three stages we require  $c_2 \neq 0, c_3 \neq 0$  and  $\theta \neq 0$ , otherwise a third-order Runge–Kutta method cannot be obtained. So  $b_2 = b_3 = 0$  and Equations (9) reduce to a single equation

$$b_4c_4^3 + b_5c_5^3 + b_6c_6^3 = \frac{1}{4}.$$

We repeat this process for order 2 and 3 conditions, getting

$$b_4c_4^2 + b_5c_5^2 + b_6c_6^2 = \frac{1}{3},$$

and

$$b_4c_4 + b_5c_5 + b_6c_6 = \frac{1}{2}.$$

respectively.

Here we have a system of equations for given  $c_4, c_5, c_6$ ,

$$\begin{pmatrix} c_4 & c_5 & c_6 \\ c_4^2 & c_5^2 & c_6^2 \\ c_4^3 & c_5^3 & c_6^3 \end{pmatrix} \begin{pmatrix} b_4 \\ b_5 \\ b_6 \end{pmatrix} = \begin{pmatrix} \frac{1}{4} \\ \frac{1}{3} \\ \frac{1}{2} \end{pmatrix}.$$

We obtain a Vandermonde type matrix, which has, for distinct  $c_4, c_5$  and  $c_6$ , a unique solution:

$$\begin{aligned} b_1 &= 1 - b_4 - b_5 - b_6, \\ b_4 &= \frac{3 - 4c_5 - 4c_6 + 6c_5c_6}{12c_4(c_4 - c_5)(c_4 - c_6)}, \\ b_5 &= \frac{3 - 4c_4 - 4c_6 + 6c_4c_6}{12c_5(c_4 - c_5)(c_5 - c_6)}, \\ b_6 &= \frac{3 - 4c_4 - 4c_5 + 6c_4c_5}{12c_6(c_4 - c_6)(c_5 - c_6)}. \end{aligned}$$

In order to obtain an equidistant grid for starting multistep methods, we can choose

$$c_4 = \frac{1}{4}, \quad c_5 = \frac{1}{2}, \quad c_6 = \frac{3}{4},$$

which gives

$$b_1 = b_2 = b_3 = 0, \quad b_4 = \frac{2}{3}, \quad b_5 = -\frac{1}{3}, \quad b_6 = \frac{2}{3}.$$

Finally, by solving the equations that guarantee the remaining order conditions, we obtain the Butcher tableau for the Runge–Kutta starter:

0	0					
$\frac{1}{8}$	$\frac{1}{8}$	0				
$\frac{3}{16}$	0	$\frac{3}{16}$	0			
$\frac{1}{4}$	$\frac{1}{18}$	$\frac{1}{12}$	$\frac{1}{9}$	0		
$\frac{1}{2}$	$\frac{5}{12}$	$-\frac{1}{3}$	$-\frac{4}{9}$	1	0	
$\frac{3}{4}$	$-\frac{1}{4}$	$\frac{3}{4}$	1	$-\frac{3}{2}$	$\frac{3}{4}$	0
	0	0	0	$\frac{2}{3}$	$-\frac{1}{3}$	$\frac{2}{3}$

We can apply the explicit Runge–Kutta starter to start  $k = 3$ -step Adams methods. We need  $k$  data points  $(t_i, f_i), i = n - k + 1, \dots, n$  to compute the respective polynomials for either the Adams–Moulton corrector or the Adams–Bashforth predictor.

### 3 Error estimation and step size control

The error of the numerical solution depends on the function  $f$  and on the step size  $H$ . The step size influences the size of the global error increment. Thus, for a given tolerance the step size is chosen in such a way that the global error increment meets a user-supplied tolerance bound.

We use an embedded formula to obtain an error estimate for the Runge–Kutta starter of the Adams method. The estimation can be done by reusing the available stages to produce a formula of different order. To do so, we apply stages  $k_4, k_5, k_6$  of the Runge–Kutta method in Section 2 and obtain  $\hat{y}_1$  by the third-order Adams–Bashforth method. We generate the difference table

$$\begin{aligned} c_4 = h & \quad k_4 \\ & \quad \quad \quad \nabla k_5 \\ c_5 = 2h & \quad k_5 \quad \quad \quad \nabla^2 k_6 \\ & \quad \quad \quad \nabla k_6 \\ c_6 = 3h & \quad k_6 \end{aligned}$$

where  $h = \frac{H}{4}$  and  $H$  is the Runge–Kutta step size. The third-order Adams–Bashforth method is

$$\hat{y}_1 = g_6 + h \sum_{i=1}^3 \gamma_{i-1} \nabla^{i-1} k_6 = g_6 + h \sum_{i=1}^3 \gamma_i^* k_{i+3}, \quad (10)$$

The latter is the Lagrange form of the Adams–Bashforth method and

$$\begin{aligned} \gamma_1^* &= \gamma_2 = \frac{5}{12}, \\ \gamma_2^* &= -\gamma_1 - 2\gamma_2 = -\frac{4}{3}, \\ \gamma_3^* &= \gamma_0 + \gamma_1 + \gamma_2 = \frac{23}{12}. \end{aligned}$$

As we have

$$g_6 = y_0 + H \sum_{j=1}^5 a_{6j} k_j, \quad (11)$$

we can rewrite equation (10) as

$$\hat{y}_1 = y_0 + H \sum_{j=1}^6 \hat{b}_j k_j$$

Thus, the error estimate is

$$\begin{aligned} y_1 - \hat{y}_1 &= \\ &= y_0 + H \sum_{j=1}^6 b_j k_j - \left( y_0 + H \sum_{j=1}^6 \hat{b}_j k_j \right) = \\ &= h \sum_{j=1}^6 \hat{e}_j k_j, \quad (12) \end{aligned}$$

giving the following coefficients

j	1	2	3	4	5	6
$\hat{b}_j$	$-\frac{1}{4}$	$\frac{3}{4}$	1	$-\frac{67}{48}$	$\frac{5}{12}$	$\frac{23}{48}$
$\hat{e}_j$	$\frac{1}{4}$	$-\frac{3}{4}$	-1	$\frac{99}{48}$	$-\frac{3}{4}$	$\frac{3}{16}$

This error estimation is the difference of a third-order predictor and the fourth-order result of the Runge–Kutta method that is applied to determine the step size for the Runge–Kutta starter.

We will now develop a second error estimate, to determine a step size for Adams method. We evaluate the right-hand side function  $f$  at the solution value  $y_1$  and call it  $k_7$ . Then we generate the third-order Adams–Moulton corrector using  $k_5, k_6, k_7$ ,

$$\begin{aligned} c_5 &= h & k_5 & & & & \\ & & & & \nabla k_6 & & \\ c_6 &= 2h & k_6 & & & \nabla^2 k_7 & \\ & & & & \nabla k_7 & & \\ c_7 &= 3h & k_7 & & & & \end{aligned}$$

The third-order approximation by the Adams–Moulton method is

$$\tilde{y}_1 = g_6 + h \sum_{i=1}^3 \beta_{i-1} \nabla^{i-1} k_7 = g_6 + h \sum_{i=1}^3 \beta_i^* k_{i+4}, \quad (13)$$

where the latter is the Lagrange form of the Adams–Moulton corrector and

$$\begin{aligned} \beta_1^* &= \beta_2 = -\frac{1}{12}, \\ \beta_2^* &= -\beta_1 - 2\beta_2 = \frac{2}{3}, \\ \beta_3^* &= \beta_0 + \beta_1 + \beta_2 = \frac{5}{12}. \end{aligned}$$

From Equation (11) we can rewrite the third-order corrector in Runge–Kutta form

$$\tilde{y}_1 = y_0 + H \sum_{j=1}^7 \tilde{b}_j k_j.$$

resulting in the following table:

j	1	2	3	4	5	6	7
$\tilde{b}_j$	$-\frac{1}{4}$	$\frac{3}{4}$	1	$-\frac{3}{2}$	$\frac{35}{48}$	$\frac{1}{6}$	$\frac{5}{48}$
$\tilde{e}_j$	$\frac{1}{4}$	$-\frac{3}{4}$	-1	$\frac{13}{6}$	$-\frac{51}{48}$	$\frac{1}{2}$	$-\frac{5}{48}$

The error estimate is used in determining the step size for starting the third-order Adams–Moulton method.

## 4 Runge–Kutta starter as an extrapolation method

The starting values of a multistep method can also be stored as a differentiation array, which constitutes the Nordsieck vector of scaled derivatives  $\frac{h^i y^{(i)}}{i!}$ ,  $i = 0, \dots, p$ . It is possible to convert a vector of state values at consecutive grid points into a Nordsieck array and vice versa without loss of accuracy. Classical multistep codes like LSODAR are based on Nordsieck formulations.

Based on such a Nordsieck formulation an alternative way of constructing a Runge–Kutta starter was developed by Gear, [5]. Here, the asymptotic expansion

of the global error of a base method is used to construct a Runge-Kutta method with higher order stage values.

We use the explicit Euler method as a base method to compute  $y_i^m$  (the super-script  $m$  refers to the corresponding step size,  $h_m = \frac{H}{m}$ ) for  $i = 1, \dots, m$ ,  $m = p, p-1, \dots, 1$ . From these values the terms in the asymptotic expansion, [7],

$$y_i^m = y(ih_m) + \sum_{q=1}^p e_q(ih_m)h^q + \mathcal{O}(H^{p+1}). \quad (14)$$

can successively be eliminated by an extrapolation technique until a method of a required order is obtained. The resulting method is known to be a Runge-Kutta method.

We exemplify the approach by aiming for third-order accurate Nordsieck values and restricting ourselves to autonomous differential equations for simplicity. The same process can be employed to obtain higher order accuracy.

Let  $h = \frac{H}{m}$ , and integrate the autonomous form of the differential equation (1) on the interval  $[y_0, y_0 + H]$  with Euler's method, using  $m$  steps of size  $\frac{H}{m}$  for  $m = 3, 2, 1$ .

For  $m = 3$

$$\begin{aligned} y_1^3 &= y_0 + hf(y_0) = y_0 + k_1, & k_1 &= hf(y_0), \\ y_2^3 &= y_1^3 + hf(y_1^3) = y_0 + k_1 + k_2, & k_2 &= hf(y_1^3), \\ y_3^3 &= y_2^3 + hf(y_2^3) = y_0 + k_1 + k_2 + k_3, & k_3 &= hf(y_2^3). \end{aligned} \quad (15)$$

For  $m = 2$

$$\begin{aligned} y_1^2 &= y_0 + \frac{3}{2}hf(y_0) = y_0 + \frac{3}{2}k_1, \\ y_2^2 &= y_1^2 + \frac{3}{2}hf(y_1^2) = y_0 + \frac{3}{2}k_1 + \frac{3}{2}k_4, & k_4 &= hf(y_1^2). \end{aligned} \quad (16)$$

For  $m = 1$

$$y_1^1 = y_0 + 3hf(y_0) = y_0 + 3k_1. \quad (17)$$

with  $h = \frac{H}{3}$ . We use approximation formulas for higher derivatives

$$\begin{aligned} h^k y^{(k)}\left(\frac{H}{2}\right) &= \sum_{i=0}^m d_{ik} y(ih_m) + \sum_{s=k+1}^p c_{sk} h_m^s y^s\left(\frac{H}{2}\right) \\ &\quad + \mathcal{O}(H^{p+1}), \quad m \geq k \end{aligned}$$

and (14) to obtain, after some algebraic manipulations,

$$\begin{aligned} D_3^3 &= y_3^3 - 3y_2^3 + 3y_1^3 - y_0 = h^3 y^{(3)}, \\ D_2^3 &= y_3^3 - y_2^3 - y_1^3 + y_0 = 2h^2 y^{(2)} + 2h^3 e_1^{(2)}, \\ D_2^2 &= y_2^2 - 2y_1^2 + y_0 = \left(\frac{3h}{2}\right)^2 y^{(2)} + \left(\frac{3h}{2}\right)^3 e_1^{(2)}, \\ D_1^3 &= y_3^3 - y_1^3 = hy^{(1)} + h^2 e_1^{(1)} + h^3 e_2^{(1)} + \frac{h^3}{24} y^{(3)}, \\ D_1^2 &= y_2^2 - y_0 = 3hy^{(1)} + \frac{9}{2}h^2 e_1^{(1)} + \frac{27}{4}h^3 e_2^{(1)} + \frac{9}{8}h^3 y^{(3)}, \\ D_1^1 &= y_1^1 - y_0 = 3hy^{(1)} + 9h^2 e_1^{(1)} + 27h^3 e_2^{(1)} + \frac{27}{24}h^3 y^{(3)}. \end{aligned} \quad (18)$$

All derivatives are evaluated at  $\frac{H}{2}$  and  $\mathcal{O}(h^4)$  terms are dropped. Estimates of the derivatives can be derived at any point within a constant multiple of the interval  $H$  with the same accuracy. We solve the system (18) to remove the error terms for  $h^k y^{(k)}\left(\frac{H}{2}\right)$ , for  $k = 1, \dots, m$ , to get

$$\begin{aligned} h^3 y^{(3)}\left(\frac{H}{2}\right) &= D_3^3 + \mathcal{O}(h^4), \\ h^2 y^{(2)}\left(\frac{H}{2}\right) &= \frac{3}{2}D_2^3 - \frac{8}{9}D_2^2 + \mathcal{O}(h^4), \\ hy^{(1)}\left(\frac{H}{2}\right) &= \frac{9}{2}D_1^3 - \frac{4}{3}D_1^2 + \frac{1}{6}D_1^1 + \frac{9}{8}D_3^3 + \mathcal{O}(h^4). \end{aligned} \quad (19)$$

The  $D_k^m$  can be expressed as combinations of stage values  $k_i$ . All  $\mathcal{O}(h^4)$  terms are neglected.

$$\begin{aligned} D_3^3 &= k_1 - 2k_2 + k_3, \\ D_2^3 &= -k_1 + k_3, \\ D_2^2 &= -\frac{3}{2}k_1 + \frac{3}{2}k_4, \\ D_1^3 &= k_2, \\ D_1^2 &= \frac{3}{2}k_1 + \frac{3}{2}k_4, \\ D_1^1 &= 3k_1. \end{aligned} \quad (20)$$

From (19) and (20),

$$\begin{aligned} h^3 y^{(3)}\left(\frac{H}{2}\right) &= k_1 - 2k_2 + k_3 + \mathcal{O}(h^4), \\ h^2 y^{(2)}\left(\frac{H}{2}\right) &= -\frac{1}{6}k_1 + \frac{3}{2}k_3 - \frac{4}{3}k_4 + \mathcal{O}(h^4), \\ hy^{(1)}\left(\frac{H}{2}\right) &= -\frac{3}{8}k_1 + \frac{9}{4}k_2 + \frac{9}{8}k_3 - 2k_4 + \mathcal{O}(h^4), \\ y\left(\frac{H}{2}\right) &= y_0 + \frac{3}{16}k_1 + \frac{18}{8}k_2 + \frac{9}{16}k_3 - \frac{12}{8}k_4 + \mathcal{O}(h^4). \end{aligned} \quad (21)$$

The first element of the Nordsieck vector,  $y\left(\frac{H}{2}\right)$ , is computed by Taylor expansion.

It follows that

$$\Gamma_{\frac{H}{2}} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ \frac{3}{16} & -\frac{3}{8} & -\frac{1}{6} & 1 \\ \frac{18}{8} & \frac{9}{4} & 0 & -2 \\ \frac{9}{16} & \frac{9}{8} & \frac{3}{2} & 1 \\ -\frac{12}{8} & -2 & -\frac{4}{3} & 0 \end{pmatrix}. \tag{22}$$

If the derivatives are instead computed at the origin, the matrix above becomes

$$\Gamma_0 = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & -\frac{5}{3} & 1 \\ 0 & 0 & 3 & -2 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & -\frac{4}{3} & 0 \end{pmatrix}. \tag{23}$$

The matrix  $A$  of coefficients  $\alpha_{i,j}$  in equation (2) is obtained from Equations (15) and (16)

$$A = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ \frac{3}{2} & 0 & 0 & 0 \end{pmatrix}. \tag{24}$$

For a fourth-order method we need at least six function evaluations, [5], and the relevant matrices  $\Gamma_0$  and  $A$  are

$$\Gamma_0 = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & -\frac{5}{6} & \frac{4}{9} & -\frac{1}{9} \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & \frac{1}{2} & -\frac{4}{9} & \frac{1}{9} \\ 0 & 0 & \frac{7}{3} & -\frac{19}{9} & \frac{7}{9} \\ 0 & 0 & -3 & \frac{10}{3} & -\frac{4}{3} \\ 0 & 0 & 1 & -\frac{11}{9} & \frac{5}{9} \end{pmatrix},$$

$$A = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 2 & 0 & 0 & 0 & 0 \\ \frac{3}{4} & 0 & \frac{9}{4} & 0 & 0 & 0 \\ \frac{1}{2} & 1 & \frac{1}{2} & 2 & 0 & 0 \\ \frac{1}{12} & 2 & \frac{1}{4} & \frac{2}{3} & 2 & 0 \end{pmatrix}.$$

The cost of this process in terms of function evaluations is  $1 + \frac{p(p-1)}{2}$ , since the interval  $H$  is integrated by Euler's method  $m$  times with step size  $\frac{H}{m}$  for

$m = p, p - 1, \dots, 1$ . For the first value of  $m$  we have  $p$  function evaluations because the initial value of  $y'$  has to be evaluated once, so for the next value of  $m$  we have  $p - 2$  function evaluations, and so on.

We constructed a Nordsieck vector with third-order accuracy. To do this we used four stages  $k_1, k_2, k_3, k_4$  as in (15) and (16) with lower order and an extrapolation technique. It can be shown that there exists no method of the same order with less stages and thus less function evaluations.

### 5 Order tests

To verify that the starter indeed achieves the expected order we consider the harmonic oscillator

$$y'' = -4y, \quad y_0 = 1, \quad y'_0 = 0.$$

Figure 2: Both Runge–Kutta starters achieved third-order accuracy when solving the harmonic oscillator problem with the 3-step Adams–Moulton method

### 6 The bouncing ball test example

In this section we demonstrate the method on the example of a bouncing ball with linear damping  $d = 0.1$ :

$$\begin{aligned} \dot{y}_1 &= y_2 \\ \dot{y}_2 &= -dy_1 + 9.81 \end{aligned}$$

The bounces are modeled using a coefficient of restitution was chosen to be  $c = 0.88$  to give the system sufficiently many impacts to be able to make a statement about the effect of restarting, see Fig. 3. The model includes two events, one to trigger bouncing and a second one which triggers the upper turning point. At the upper turning point the differential equation and its states remain unaltered, and only

Figure 3: A simulation of a bouncing ball (damping:  $d = 0.1$ , coefficient of restitution  $c = 0.88$ ).

the switch to control the bouncing event becomes activated. At the bouncing event the velocity  $\dot{y}(t^-)$  is altered to  $\dot{y}(t^+) = -c\dot{y}(t^-)$ .

In Fig. 4 the step size and order history of both restarting techniques is compared. The classical starting procedure clearly shows a drop in order and step size. The method recovers quite quickly from the reduced step size as LSODAR allows exceptionally big step size changes during the initialization phase.

Figure 4: Comparison of the step size and order history for the two restarting approaches. A logarithmic scale is used for the step size plot.

The run statistics, cf. Tab. 1 show the effect of the Runge–Kutta starter in Assimulo. The gain in the number of function evaluations for this example is about 58%.

## 7 Conclusions

The aim of this paper is to study the effect of Runge–Kutta restarting techniques on the performance of the

	Classic starter	Runge–Kutta starter
# steps	455	129
# function evals	1027	428
# event function evals	919	538
# events	38	37

Table 1: Run time statistics for the bouncing ball example with absolute and relative tolerance set to  $10^{-8}$ .

simulation of hybrid systems. Tests were made on a system with relatively small numbers of discontinuities. The tests give a clear indication that investigating a more sophisticated restarting procedure like the fourth-order Runge–Kutta starter presented here has a potential impact on the overall performance of a simulator.

The flexibility in selecting the order of the restarter as well as doing error control of the restarter is the topic of future research.

## Abstract

Often integrating ordinary differential equations or differential algebraic equations (DAE) do not constitute the problem alone. A common complement is finding the root of an algebraic function (an event function) that depends on the states of the problem. This formulation of a model enables the possibility of including discontinuities, an important part of the Functional Mock-up Interface standard which allows hybrid models of differential algebraic equations. The problem of root-finding during integration is however difficult. Both in a theoretical aspect and as a software problem.

An implementation of software for root-finding is done in Assimulo, a Python/Cython wrapper for integrators. The implementation takes the Functional Mock-up Interface standard into consideration. The implementation is made usable for a wide variety of integration algorithms and is also verified and benchmarked with advanced industrial models, showing good indications of being robust and scaling well for large systems.

## 1 Introduction

Models based on differential equations may contain discontinuities. One simple example is the bouncing ball. Gravity acting on the ball is modelled with a differential equation while the bouncing on the floor will

result in discontinuities in the velocity. A result from the velocity changing sign by impact. A reasonable way to model this would be to restart the integration of the differential equation with new initial values as the ball hits the floor. In this way, the discontinuity is modelled with what is called an event and the handling of that event (event handling).

Models with discontinuities are not only interesting theoretically but are also widely used in industry, something the Functional Mock-up Interface (FMI) standard <sup>1</sup> contributes to by making distribution and use of these models convenient. The explanation for why it is used by the industry can be found in [3], where the elements that give rise to discontinuities in models are listed. Some of them are:

- Friction
- Impact phenomena
- The degrees of freedom vary in time
- Time dependent input functions

Most advanced models in industry consist of many separate but interacting parts and, therefore, have at least one or some of the listed properties. With today's modelling tools and computational power, more and more advanced models become realistic to simulate. Which means new and increased demands on the integrators to support the solving of models with discontinuities robustly and with good scaling of the performance regarding the size of the models.

There are many difficulties with having discontinuities in differential equations. Missing a discontinuity or acting on the wrong discontinuity can be disastrous,

<sup>1</sup>See <https://www.fmi-standard.org/>.

The authors gratefully acknowledge the support from the Lund Center for Control of Complex Engineering Systems (LCCC).

leading to integrating the wrong equations or missing impacts. Furthermore the integration methods make assumptions on the smoothness of the solution and the incorrect handling of the discontinuities will most certainly violate these assumptions. The result will be an incorrect error estimate, leading to a significant decrease in the integration performance[6], or even leading to an incorrect solution.

To construct a state of the art event detection algorithm, undertaking these considerations of the need for correct event handling and performance, the demands will be that it should be robust and scale well, handling large systems originating from industry. It should also be clear what data is expected from the user, and in return the algorithm should guarantee correct event detection and event handling.

The contributions of this article is an implementation of an event algorithm with robust event handling and good performance. Using a safeguard and applying the domain formulation (used for event localization in the FMI specification, explained in Section 2.4) as opposed to the zero-crossing paradigm that uses a sign change to detect events. This algorithm converge and gains a robust performance and has an advantage for a special set of problems, this will be seen for the clutch example later. Given the additions to the event algorithm, a benchmark using advanced industry relevant models following the FMI standard was made to ensure that the performance is not compromised. In Assimulo<sup>2</sup> the algorithm can be utilized as a module that can be mounted onto solvers as needed. This result in an extension of Sundials and increases the number of solvers that can handle discontinuities and therefore the number of solvers that support the FMI standard.

Section 2 starts by giving background and motivation and moves on to highlighting the principles of event detection and event localization and the difficulties associated with it. In Section 3, the ideas for the event location algorithm are laid out. Leading up to the presentation of the algorithm in Section 4, where details of the implementation are discussed. Section 5 demonstrates and verifies the implementation on a number of test examples together with testing the performance. A summary and critical examination of the algorithm and the results are given in Section 6.

<sup>2</sup>See <http://www.jmodelica.org/assimulo>.

## 2 Background

Assimulo is a Cython/Python wrapper around various Ordinary Differential Equations (ODE) and Differential Algebraic Equations (DAE) solvers. An important aspect of Assimulo is to make it easy to access both state of the art solvers and more experimental solvers for both industry and the academic world. Assimulo is also the back-end simulation engine for JModelica.org.

On the other hand, for enabling the exchange of models in industry and the academic world there is the FMI standard, which is a standardized way of formulating models of ODEs. PyFMI can be used to wrap models that are instances of the FMI standard (FMUs) making them easy to simulate with Assimulo.

A powerful use of Assimulo and the FMI would be to give industry a larger variety of solvers from the academic world, while the academic world is given access to a large number of relevant models from industry, offering remedies for two weaknesses often present in the world of numerics.

The FMI allows advanced hybrid dynamic models by also allowing event functions. This standard therefore demands that the solver can handle discontinuities in the form of events. Currently, the only solvers in Assimulo that can do so are those of Sundials [12] and LSODAR and many solvers do not have the possibility of handling discontinuities on their own, leading to the need of a module in Assimulo that can handle the discontinuities for all solvers.

### 2.1 A motivating example

A motivational example for when the zero-crossing approach fail to detect the event correctly is:

```
model motivating_example
Real y;
Real x(start = 1.0);

equation
  y = noEvent(if 1-time > 0 then (1-time)^5
              else 0);
  der(x) = if y <= 0 then -x else x;
end motivating_example;
```

The model has a variable  $y$  that smoothly goes to zero at  $t = 1$  which should result in an event there. With the usual approach for detecting events, using an FMU from JModelica.org, the event is found significantly later than it occurred because the event is not

localized. This is especially a problem when the integrator take large steps. It is clear that the robustness of the event detection is questionable in for this case.

With an FMU from Dymola the event is not detected at all.

## 2.2 The theory of event location

Integration methods are dependent on that the problem has a continuous solution with continuous derivatives to a certain order [3]. Moreover, mathematically, continuity is needed to guarantee a unique solution. For example for the problem of an explicit ODE

$$\dot{y}(t) = f(t, y(t)), \quad y(t_0) = y_0,$$

$f$  should be continuous in  $t$  and Lipschitz continuous in  $y$  to guarantee a unique solution by the Picard-Lindelöf theorem. This is a big concern with multi-step methods, which will incorrectly use information before and after discontinuities if the problem is integrated straight forwardly without explicit event handling.

To avoid integrating over a discontinuity, the event formulation can be used. One way of looking at a problem formulated with events is to imagine that it has two states, each state representing a different continuous right hand side. The discontinuity then becomes switching between these two states (an event). More formally, the point in time of switching is decided by the sign change of an event function,  $g(t, y)$ , and at this time the integration is re-initialized with updated continuous variables and discrete variables, where the different states are represented by discrete variables that only change at events. For example, the discontinuous problem:

$$\dot{y} = f(t, y) = |y|,$$

is rewritten with the event formulation as:

$$\dot{y} = f(t, y, s) = \begin{cases} y & \text{if } s = s_1 \\ -y & \text{if } s = s_2, \end{cases}$$

$$g(t, y, s) = y,$$

where  $g$  and  $f$  are continuous for a fixed value of the discrete state  $s$  (that represent a state). The downside being that this add a root-finding problem for the event function  $g$  on the interval of the latest time steps,  $t_n$  and  $t_{n+1}$ , in case an event is detected.

What is described in this section is usually called discontinuity handling. It can intuitively be divided into three steps:

- Event detection
- Event localization (in  $[t_n, t_{n+1}]$ )
- Event handling

The detection is often done by checking the sign of  $g$  after every time step. Locating the event is done with a root-finding algorithm and the event handling is mainly a modelling question that is done by the user.

The integrating of ODEs with discontinuities has received a lot of attention over the years. Many of the differences between the approaches is how  $g$  will be represented on  $[t_n, t_{n+1}]$  and how the time of the event is localized.

Most of the methods for localizing the event require the ability to evaluate  $g(t, y)$  on  $[t_n, t_{n+1}]$ . In doing so effectively, a continuous extension of  $y(t)$  on  $[t_n, t_{n+1}]$  is desired. Not using a continuous representation when solving problems with discontinuities result in larger global error and more evaluations of  $f$ , see [4]. Also, the dependence between the global error and the tolerance was smoother for problems with discontinuities when using an interpolation polynomial for root-finding.

Further theoretical results strengthening the use of interpolation polynomials for problems with discontinuities are that if the interpolation polynomial is of the same order as the integration method the entire method has this order [16].

Besides the representation of  $y$  with an interpolation polynomial, there is the idea that additional states could be introduced through new state equations of the form  $\dot{y}_{n_y+1:n_y+n_g} = \dot{g}$ , where  $n_y$  is the dimension of  $y$  and  $n_g$  is the dimension of  $g$  [2] [17]. This will force the integrator to take steps such that the dynamics of  $g$  is captured, if this is not the case it is more likely that an event will be missed due to two changes in sign of  $g$  are canceled out or that not the first event of many on  $[t_n, t_{n+1}]$  is found.

### 2.2.1 The root-finding problem

The root-finding problem for localizing the event with the event function,  $g$ , have the properties that  $g \in C^0$  (on a bounded interval  $[a, b]$ ) and  $g(a)g(b) < 0$ . Through the intermediate value theorem, the existence of a zero in the interval  $[a, b]$  is guaranteed. Due to the nature of solving the problem numerically, the zero can often not be found exactly. Therefore the problem is said to be solved if an interval  $[a^*, b^*]$  is found, such that:

$$g(a^*)g(b^*) < 0 \text{ and } |a^* - b^*| < \delta.$$

This means that the zero of  $g$  is contained in a small interval of length  $\delta$ . Also, note how the condition  $g(a)g(b) < 0$  functions as an enclosing property; this will from here on be known as a regula falsi. The goal is to find an algorithm that always converge and doing so as quickly as possible for a wide range of functions. The goal can be considered delicate because of the large spectrum of functions that are allowed.

## 2.3 Integrators in Assimulo

Presented here are some of the ODE integrators wrapped by Assimulo that are suited to be used together with an event localization algorithm and therefore use to simulate FMUs. Their types, orders and interpolation are listed.

**Explicit and Implicit Euler:** Fixed step-size methods of order 1 with linear interpolation implemented.

**RungeKutta34:** Adaptive Runge-Kutta of order 4(3) with a Third-order Hermitian polynomial for interpolation.

**Radau5ODE:** Runge-Kutta method based on Radau IIA of order 5, with interpolation from its collocation solution. The interpolation polynomial is of order 3 [9] [10].

**Dopri5:** Runge-Kutta method, is of order 5(4) with an interpolation of order 4 [9] [10].

**RodasODE:** A Rosenbrock method of order 4(3). The order of the interpolation is not stated explicitly, but it is said to fulfil conditions such that the continuous solution is of the same order as the discrete points. Uses variable step-size [9] [10].

**CVode:** Uses BDF methods for stiff problems and Adams-Moulton methods for non-stiff problems. For both cases, the solver is of variable-order and has variable step-size. Contains an internal event localization algorithm [12].

## 2.4 FMI semantic and domain formulation

The condition that an event occurs when  $g$  changes sign (a change between  $g < 0$  and  $g > 0$ , zero-crossing formulation) means that the zero needs to be treated as an exception. An option is that one should instead look for an alternation between the domains  $g < 0$  and  $g \geq 0$  [14]. This leads to a formulation similar to the event formulation in the FMI standard, where the enclosing and detection properties (regula falsi) change

from  $g(a)g(b) < 0$  to  $(g(a) > 0) \oplus (g(b) > 0)$ <sup>3</sup>.

## 3 Event algorithm

### 3.1 Domain or zero-crossing formulation

The arguments for using the domain formulation, in addition to being consistent with the FMI standard, are that the zero is no longer a special case. [11].

The FMI formulation also has a major advantage when modeling systems that can take an unknown input. Let us suppose that  $g(t, y) = u(t)$ , where  $u$  is a signal that can become and stay at zero. A practical example would be if  $u$  is the power to a system. Imagine now that the system as a safety measure has a magnet-locking system or clutches that locks when the power disappears. An event is then expected when  $u > 0$  goes to  $u \leq 0$  or vice versa. This is an intuitive way to state the model and would, with the zero-crossing formulation, force the user to modify  $g$  or the inequality with a small  $\varepsilon$  to ensure zero-crossing. Moreover, the choice of  $\varepsilon$  is often not an easy task in this case because of scaling.

### 3.2 Event detection

One of the usual ways to detect an event is to check the regula falsi for  $g(t_n, y_n), g(t_{n+1}, y_{n+1})$  after having integrated from  $t_n$  to  $t_{n+1}$ . Other ways are, of course, possible - such as also checking  $g$  in the middle of  $[t_n, t_{n+1}]$  - but these are considerably slower. This is the case for many of the more sophisticated methods for detecting events and they furthermore demand access to the partial derivatives of  $g$ . This is also the case for the methods of adding extra states. Demanding the user to supply these or compute them numerically, giving the user a solver that scales badly (computing the derivatives numerically would also result in extra evaluations of  $g$ ) is not an option. It does not align with our demands of speed, it would also exclude models of the FMI standard.

Going with the simpler method of checking for a regula falsi, there is the possibility of having two events in  $[t_n, t_{n+1}]$  for a component of  $g$ . This is a problem, as pointed out in Section 2.2. The practical solution used here lies in letting the user supply a maximum stepping length,  $h_{\max}$ , such that all events are separated by at least  $h_{\max}$  in time.

<sup>3</sup>The logical symbol  $\oplus$  is XOR and in code the condition would be  $(g(a) > 0) \neq (g(b) > 0)$

### 3.3 Locating the event

A root-finding algorithm that is usually used in this context is the Illinois algorithm [5] [13] [12]<sup>4</sup>. Naturally, it gives fast convergence for most functions when doing event localization. There are of course other root-finding algorithms that would perform well for event localization, Illinois is however well tested. Furthermore, if  $g$  is multidimensional and the first root in time should be found for any of the components of  $g$  and this vectorization is best done for the Illinois algorithm.

The Illinois algorithm uses a linear interpolation that weights the function values to ensure convergence. The weight is applied so that the algorithm will not keep any bracket constant indefinitely. This gives major advantages when it comes to convergence compared to the false position algorithm. This is especially evident for all convex functions, a comparison can be seen in Figure 1.

An improvement can be done for when the function is zero for most of the interval as Illinois algorithm behaves badly in this case. This comes from the Illinois algorithm's inability to use its weights properly - zero times two is still zero. The intuitive remedy for this would be to use a bisection step if either  $g(t_n)$  or  $g(t_{n+1})$  are equal to zero. With this modification, the Illinois algorithm behaves better for this case.

#### 3.3.1 Safeguard

To ensure that the algorithm converges a safeguard method is used [7]. It consist of three points that, if followed, guarantee that the root-finding algorithm always converge. These are:

- The new bracket is inside the current interval
- The new bracket is closest to the best bracket<sup>5</sup>
- The new bracket is not too close to an existing bracket

Point one is incorporated in the Illinois algorithm. Point two is not always valid during the iterations, due to the weights. Point two is however only meant to ensure the speed of convergence, something that the weights do very well.

<sup>4</sup>The origin of the method is unknown - some believe it to come from the staff at the computer centre at the University of Illinois computer department.

<sup>5</sup>The best bracket is the one with the lowest function value, as it is expected to lie closer to the root.

Point three is often done by choosing a small number  $\delta$  and check if the new bracket is closer than  $\delta$  to a previous bracket, if it is the new bracket is moved by  $\delta$  towards the middle. It should be noted that Illinois algorithm dose not originally account for this. There is, however, no technical problem in implementing this (Sundials has this modification in its implementation).

## 4 Implementation

### 4.1 User interaction

The form of the event function  $g$  defined by the user should be a function returning an array of all the components of  $g$ . This is also how the event function is evaluated in the FMI standard, but results in that all components are evaluated, even if only one component has a change in sign when iterating with the Illinois algorithm. However, this gives the possibility of detecting roots that otherwise would have been missed due to being close to another root.

Also, the reporting of the found roots should be done with a separate array. The user cannot know for which component a root was detected in the case where the exact zero is not found due to scaling.

The tolerance for enclosing the event cannot be set and has a default value such that the error caused by it is small compared to that caused by the interpolation polynomial.

### 4.2 Algorithm details

The tolerance for which the domain change is locked into is somewhat weaker than machine precision. Specifically, the tolerance is set to:

$$TOL = \max(|t_n|, |t_{n+1}|) \cdot 10^{-13},$$

being roughly a factor 100 times larger than machine precision, it still does not introduce an error that is noticeable compared to that of the interpolation polynomial.

The small step  $\delta$  in the safeguard (see Section 3.1.1) is taken from Sundials as:

$$\delta = \frac{|a - b|}{2 \cdot \min(5, |a - b|/TOL)},$$

note that  $\delta$  is a minimum of a tenth of the current length of the interval and a maximum of half the interval, going from a tenth to a half as the interval goes toward TOL.

Figure 1: Comparison between the Illinois algorithm and the false position method, showing how the failing mode is escaped and fast convergence is achieved.

The domain formulation and the bisection step for the special case mentioned earlier are used by the algorithm. The algorithm is implemented in Assimulo using Python. It is called before the complete step function is called just after a successful step is taken.

### 5 Application example

For evaluating the implementation, benchmark models are selected to assert the correctness and scalability of the event location algorithm. A Furuta pendulum is chosen for having many event functions, a clutch model with inputs is chosen for causing events when the input reach zero for a finite time and a racing car is chosen for being a large advanced model with events.

The models are FMUs and PyFMI is used for simulating these models in Assimulo. Benchmarks are made for each model and each ODE solver that the event location is implemented for. The quantities included in the benchmark are: steps taken, function evaluations, Jacobian evaluations, event-function evaluations, number of events and simulation time in seconds.

The options for the solvers are tuned so that the solution at the final step is found with a relative error of roughly  $10^{-6}$  compared to a reference solution, with  $10^{-6}$  here roughly meaning that the relative error is in the interval  $[10^{-6}, 2 \cdot 10^{-6}]$ , preferably as close to the left bracket as possible. Formally, this means that the solution should satisfy the condition:

$$10^{-6} \leq \frac{\|y(t_{\text{final}}) - y_{\text{ref}}(t_{\text{final}})\|_2}{\|y_{\text{ref}}(t_{\text{final}})\|_2} \leq 2 \cdot 10^{-6}.$$

This error is foremost tuned by changing the relative- and absolute-tolerance. In case the integrator takes too

large steps and events therefore are missed, a maximum step length is also used to tune the accuracy of the solution. For RungeKutta34, the optional initial step length is also used - RungeKutta34 would otherwise have a problem reducing the tolerance sufficiently, as it has no possibility to reject its first step. The other steps are affected by the tolerance through the variable step-size (even though the step cannot be rejected).

For finding the reference solution, CVode with its internal event location is used. The options for relative and absolute tolerance is set to  $10^{-12}$ . At this tolerance, the relative error estimate does not change if the tolerance is increased or decreased by a factor 10, meaning that significantly more correct decimals are found for this solution compared to the solutions satisfying the condition on relative error.

An important reason for using CVode is that it is extensively tested and well established.

Following the numerical results there is a discussion of them. In the discussion, important differences between the solvers are pointed out, and extra emphasis is placed on the differences between CVode with internal event location and CVode with Assimulos event location, here after known as CVode(I) and CVode(A).

#### 5.1 Furuta pendulum

The Furuta pendulum (see Figure 2), generated by Dymola, is an extremely non-linear model and is often investigated in the field of control theory [18]. This model of the problem generates events from introduced friction, resulting in a problem with 32 event functions. When simulated for 5 seconds, 21 events occur for this problem, making it a good test model for the.

Solver options	CVode(I)	CVode(A)	Dopri5	Rodas	Radau5	RungeKutta 34
Relative tolerance	$2 \cdot 10^{-8}$	$3.1 \cdot 10^{-8}$	$1.81 \cdot 10^{-6}$	$1.42 \cdot 10^{-6}$	$1.8 \cdot 10^{-7}$	$5 \cdot 10^{-7}$
Absolute tolerance	$2 \cdot 10^{-8}$	$3.1 \cdot 10^{-8}$	$1.81 \cdot 10^{-6}$	$1.42 \cdot 10^{-6}$	$1.8 \cdot 10^{-7}$	$5 \cdot 10^{-7}$
Initial step length	-	-	-	-	-	$10^{-6}$

Table 1: The solver options to obtain the desired accuracy for the Furuta pendulum. CVode(I) is CVode with its internal event location, while CVode(A) is CVode with Assimulo's event location.

Run statistics	CVode(I)	CVode(A)	Dopri5	Rodas	Radau5	RungeKutta 34
Steps taken	1107	1050	113	329	231	589
f evaluations	1468	1430	776	2109	1680	2945
J evaluations	34	30	-	329	156	-
g evaluations	1332	1266	372	615	504	787
Execution time	2.760	2.888	0.6183	3.165	0.9516	6.157
Relative error	$1.05 \cdot 10^{-6}$	$1.08 \cdot 10^{-6}$	$1.13 \cdot 10^{-6}$	$1.03 \cdot 10^{-6}$	$1.18 \cdot 10^{-6}$	$1.13 \cdot 10^{-6}$

Table 2: Run-time statistics for the solvers used on the Furuta pendulum. CVode(I) is CVode with its internal event location, while CVode(A) is CVode with Assimulo's event location. All other solvers relies on Assimulos event handling algorithm.

Figure 2: A Furuta pendulum. The red cylinders being joints with given frictions and the blue cylinders being bars with given weights.

The first thing to note is that CVode(A) achieves the same error as CVode(I) with higher tolerances, somewhat adding robustness to the solving process. Nonetheless, the execution time is longer despite using fewer function evaluations.

Dopri5 is the solver that performs best.

## 5.2 Clutches with input

This system is of practical industrial interest, where an input signal causes events when reaching zero for

Figure 3: Plot of the input and where the first event is found for the different solvers. The event found by the reference solution and CVode(A) can not be distinguished in the figure.

a finite time, very much as described in Section 3.1. The number of events that occur for the 5 seconds that the system is simulated varies, as some of them are handled internally by the FMI's event iteration. However, all the events are detected and handled in one way or another, as indicated by the small relative errors the problem is solved for. The FMU is generated by JModelica.org.

The events caused by the input signals are located with close to machine precision for CVode(A) and only with the current step length when detecting  $g(t_{n+1}) = 0$  for CVode(I). Despite this, the same choices for tolerances give the same relative error. This is however still considered an

Solver options	CVode(I)	CVode(A)	Dopri5	Rodas	Radau5	RungeKutta 34
Relative tolerance	$6 \cdot 10^{-7}$	$6 \cdot 10^{-7}$	$1.7 \cdot 10^{-6}$	$7 \cdot 10^{-5}$	$4.39 \cdot 10^{-5}$	$5.033 \cdot 10^{-9}$
Absolute tolerance	$6 \cdot 10^{-7}$	$6 \cdot 10^{-7}$	$1.7 \cdot 10^{-6}$	$7 \cdot 10^{-5}$	$4.39 \cdot 10^{-5}$	$5.033 \cdot 10^{-9}$
Max step length	-	-	-	0.1	0.1	-
Initial step length	-	-	-	-	-	$10^{-10}$

Table 3: The solver options to obtain the desired accuracy for the Clutch system with the input signal. CVode(I) is CVode with its internal event location, while CVode(A) is CVode with Assimulo's event location.

Run statistics	CVode(I)	CVode(A)	Dopri5	Rodas	Radau5	RungeKutta 34
Steps taken	1594	1594	656	305	233	5312
f evaluations	2568	2552	4498	2370	1275	26545
J evaluations	71	71	-	305	93	-
g evaluations	2480	2733	1876	1739	1746	6223
Execution time	8.476	8.425	17.56	7.709	6.756	55.42
Relative error	$1.11 \cdot 10^{-6}$	$1.07 \cdot 10^{-6}$	$1.16 \cdot 10^{-6}$	$1.08 \cdot 10^{-6}$	$1.24 \cdot 10^{-6}$	$1.09 \cdot 10^{-6}$

Table 4: Run-time statistics for the solvers used on the Clutch system with the input signal. CVode(I) is CVode with its internal event location, while CVode(A) is CVode with Assimulo's event location. All other solvers relies on Assimulos event handling algorithm.

important result, finding the events with good accuracy is desired and is expected to pay off for other models. The first event from the input signal at 0.0375 is found to be 0.375000000000015, 0.378400333934374, 0.375000000000025 for the reference solution, the CVode(I) and the CVode(A) respectively, a significant improvement as can be seen in Figure 3. Radau5 performs best for this model.

### 5.3 Racing car

A large and advanced model from industry is the racing car. Here, the model not only contains the racing car but also a virtual driver. It consists of a regulator that tries to drive the car on an eight-shaped course. One reason for simulating this might, for example, be to investigate the dynamic response of the car.

Consisting of 47 states, 44 event functions and simulated for 30 seconds, this is the largest model used for testing. During simulation, the model caused 11 events. The model is developed and generated from Dymola originating from the Vehicle Dynamics Library, see Figure 4.

Here, CVode(A) performs better than CVode(I), in the sense that it needs less tolerance for achieving the same error. This is a good sign of robustness and scalability.

For the racing car model, evaluations of f are more

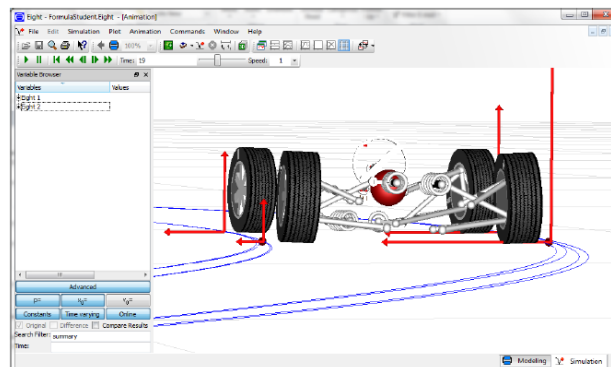

Figure 4: A picture of the car in Dymola.

costly compared to those in the Furuta model. This makes CVode the most effective integrator. Also note that Radau5 need the setting  $h_{\max} = 0.1$  for its maximum step length to capture all the events.

### 5.4 Summary

The event localization of Assimulo, using the domain formulation, finds the events caused by the inputs in the clutch model significantly better than Sundials, using the zero-crossing formulation.

If the event localization of Assimulo is compared by looking at the results for CVode(A) and CVode(I), it is clear that Assimulos event algorithm do not perform significantly worse than that of Sundials. For all

Solver options	CVode(I)	CVode(A)	Dopri5	Rodas	Radau5	RungeKutta 34
Relative tolerance	$5.5 \cdot 10^{-6}$	$10^{-5}$	$3 \cdot 10^{-3}$	$8 \cdot 10^{-5}$	$3.5 \cdot 10^{-5}$	$7.3 \cdot 10^{-3}$
Absolute tolerance	$5.5 \cdot 10^{-6}$	$10^{-5}$	$3 \cdot 10^{-3}$	$8 \cdot 10^{-5}$	$3.5 \cdot 10^{-5}$	$7.3 \cdot 10^{-3}$

Relative error	$1.31 \cdot 10^{-6}$	$1.54 \cdot 10^{-6}$	$1.39 \cdot 10^{-6}$	$1.57 \cdot 10^{-6}$	$1.17 \cdot 10^{-6}$	$1.31 \cdot 10^{-6}$

Table 6: Run-time statistics for the solvers used on the racing car model. CVode(I) is CVode with its internal event location, while CVode(A) is CVode with Assimulo's event location. All other solvers relies on Assimulos event handling algorithm.

models except the racing car CVode(A) uses more  $g$  evaluations than CVode(I). Sometimes, this results in better accuracy for the selected tolerances. This is the case for the Furuta pendulum and the racing car model. For the clutch model with an input signal, there is, on the other hand, nothing to be gained and all that is achieved is extra  $g$  evaluations.

The new solvers that now support event localization all performed reasonably. For this set of models CVode and also Dopri5 performs well, making it together with all the new solvers supporting event location a welcome addition to the toolbox of integrators supporting event location and therefore also FMUs.

For some of the models, it is noted that Runge-Kutta methods performs very well as indicated by the small number steps taken. This is made possible by the sparse occurrence of events and it is worth noting that none of the models here has events occurring with a high frequency. In [8], this was investigated using small balls bouncing around, receiving different frequencies for the events by changing the number of balls.

## 6 Summary and conclusions

It was found that an algorithm based on the Illinois algorithm works well. The improvements include applying the domain formulation, extra safeguarding and

the special case when  $g = 0$  resulting in a bisection step. It was implemented in Assimulo and was shown to locate certain types of events more accurately for an industry-relevant model with clutches than Sundials, without losing much in performance. Much of the performance lost is, of course, because Assimulo's event location is written in Python while Sundial's is written in C. Further improvements can be made reducing this difference by typing the variables using the possibilities of Cython in Assimulo, leading to the code executing more like C code, even though the differences in speed can probably never be fully remedied.

The implementation can be used together with many solvers as it is a separate subroutine, a module that is easily mounted onto solvers. Resulting in the possibility to choose among many solvers when simulating FMUs. Also, solvers with interpolation polynomials of lower order than the method itself still performed well, without any guarantees from the theory.

For the case of a problem containing a large number of event functions, the improvement is being able to choose Runge-Kutta methods, which are good at solving many of the models with sparse occurrence of events. In the case of the extreme opposite, many events occurred with high frequency, CVode with a  $h_{\max}$  matching this frequency would probably perform best.

More work for the future might include the possibil-

ity of supplying the partial derivatives of  $g$  or of calculating these numerically. Uses might be enhanced event location, as with [17] or [1]. Further work in investigating event location for implicit DAEs is also needed, for example implementing consistent event localization [15] and test the gain in accuracy and the loss in computational speed on relevant industry problems.

## Abstract

Adding random disturbances to Modelica models is necessary to represent stochastic fluctuations like sensor noise, air gusts and road irregularities. In this paper, we present a library to specify a pseudo random noise for continuous-time simulations. The random number generator, a probability density function and a frequency spectrum can be defined independently. A new random number generator is proposed to generate a continuous random signal, which is proven to be highly suitable for continuous models. The performance of the noise models is tested in two benchmarks using an academic as well as a realistic model both showing a remarkable increase in simulation speed.

*Keywords: Noise, Stochastic Models, Random Number Generator*

## 1 Motivation

When simulating real-world systems, the problem of introducing disturbances to the nominal system eventually becomes an issue. Especially, when dealing with controlled systems, important tasks are to check whether the controller is able to reject realistic disturbances, and to assess the performance of the system including noise. The problem is not limited to the field of control design, but is also of interest in e.g. specification of aircraft airworthiness requirements with respect to turbulence, estimation of the power outcome of wind energy farms or when interpreting contaminated sensor readings of experiments.

These kinds of distortions are typically taken into

Figure 1: Noise is typically introduced additively into a controlled system.

account by additive injection of a noise signal into the system as shown in Fig. 1. The noise signal can have a strong impact on the system's performance and must thus be specified carefully. However, there are no convenient means of specifying noise properties in Modelica, such that typical approaches implement ad-hoc modifications of a simple random signal.

Additionally, injecting noise into a continuous system typically decreases the simulation speed drastically, because standard noise generators are sampled systems, which generate time events by definition. These time events lead in most cases to integrator restarts, imposing a big penalty on simulation performance.

In this work, we present ways to solve the two issues outlined above in an integrated library:

1. We describe a general procedure to specify a suitable noise signal by means of selecting a high-quality random number generator, a probability distribution and a power spectrum (see Sec. 3).
2. By providing a continuous noise signal formulation using the sample-free generators introduced in Sec. 3.1 and a smooth interpolation (Sec. 3.3), we provide means for continuous noise generation. Avoiding events and using a smoothly filtered signal speeds up the simulation as compared to standard methods (see Sec. 5).
3. The methods and processes are integrated in a library with convenient user interfaces (see Sec. 4). This enables a user to easily specify a desired noise signal and to use it in complex simulation models (see Sec. 6).

## 2 Theoretical Background of Noise

Noise is omnipresent in technical systems. However, it is not usually a physical process per se. The term noise is rather used to describe influences in a system, which are not covered by the model of the system itself.

These influences can e.g. include rough road conditions in vehicle dynamics, wind in aerodynamics or electrical radiation compromising sensor readings. In any case, a suitable model for such influences must be found in order to account for them in simulation, control and signal processing applications.

A common model for noise is *white noise* (see e.g. [1, p. 19]). It is described by a stream of random variables  $w(t)$  dependent on the time  $t$ . The main property of such white noise is that it has a flat power spectrum, i.e. that all frequencies contribute equally to the noise signal. In a statistical sense, this means that all instances of the random signal  $w(t_1)$  and  $w(t_2)$  are uncorrelated:

$$\text{Cov}(w(t_1), w(t_2)) \stackrel{!}{=} 0 \quad \forall t_1 \neq t_2. \quad (1)$$

The second property of white noise is that the probability distribution  $W$  of the signal's values is equal for all time instants:

$$W(t_1) \sim W(t_2) \quad \forall t_1, t_2. \quad (2)$$

However, the actual distribution  $W$  is not specified by the term white noise and must be specified additionally. Gaussian white noise e.g. refers to the case that the signal is normally distributed.

In actual applications, noise is very rarely white but can be specified with a given power spectrum. In aerodynamics e.g. the von Kármán spectrum is used to model turbulence and in signal processing the noise is usually low-pass filtered and sampled. Such signals are referred to as colored noise.

Especially for numerical simulations, this band-limitation of natural noise is very convenient, because signals with infinite frequency contributions cannot be simulated. Using the above observation, we can correctly reflect the influence of natural noise on a simulated system by specifying a distribution of the random process and a suitable filter. The sampling rate of the raw noise can then be chosen just high enough to generate all contributions to the desired spectrum.

Figure 2 illustrates the properties of natural noise from a mechanical test-rig entering a continuous system. The noise is sampled with 6 kHz and passed on as a continuous-time sample-and-hold signal. The power spectral density (PSD) is estimated by oversampling the signal at 50 kHz and using Welch's method as implemented in the Matlab signal processing toolbox.

The noise appears approximately normally distributed. We can see that the noise does not have the flat power spectrum specified for white noise. The power spectrum shows a strong influence of the initial sampling with 6 kHz. In the following sections, we will

discuss how to numerically generate a representative signal of such nature.

Figure 2: A noise sample from a static mechanical acceleration sensor is approximately normally distributed and has a characteristic power spectrum.

### 3 Noise Generation

In order to conveniently generate a realistic noise for use in continuous system simulations, a couple of criteria must be met:

- The noise should be *realistic* with respect to the specifications given in Section 2: The signal should be uncorrelated, match a specified distribution and also match the specified frequency content.
- A *clear and modular* approach should provide support in independently specifying these properties of the desired noise signal.
- It should be possible to evaluate the noise signal *continuously* without the need to incrementally increase the internal states as is the case with conventional noise generators.

To comply to the specifications of above, the process is split in three steps:

1. A *random number generator* (RNG) implements an algorithm to generate a sequence of uncorrelated, uniformly distributed random numbers  $U_i$ .
2. These are transformed according to the same *probability density function* (PDF) for each discrete time instance separately to yield random numbers  $X_i$  with a specified distribution.
3. The random numbers are filtered to match a *power spectral density* (PSD) specified in the frequency domain. This results in a continuous-time noise signal  $r(t)$  with the desired characteristics.

### 3.1 Uniform Random Number Generators

Truly random numbers are difficult to generate in numerical simulations. Fortunately, they are typically not desired to be truly random, because simulations should be repeatable and thus deterministic. Pseudo-random numbers are thus usually used, which are deterministic but appear random to the simulated system.

Pseudo-random numbers are usually generated computationally using recursive arithmetic generators. These generate random numbers  $Y_i$  recursively based in the last random number  $Y_{i-1}$ . The initial value  $Y_0$  is known as the seed of the recursive generator. This discrete state  $Y_i$  of the random number generator must be advanced incrementally, which limits the time steps taken by an integrator to be smaller than the generator's update period.

One of the simplest recursive arithmetic generators is the linear congruential generator (LCG). It uses the parameters  $a$ ,  $b$  and  $m$  to generate random integers  $Y_i$  in the interval  $[0, m-1]$  and uniformly distributed numbers  $U_i$  according to the following formulas:

$$Y_i = (a \cdot Y_{i-1} + b) \mod m, \quad (3)$$

$$U_i = Y_i/m. \quad (4)$$

Better implementations of recursive arithmetic generators are e.g. the algorithms of the WELL family (Well Equidistributed Long-period Linear) [2], which feature much larger repetition periods.

In order to avoid the performance limitation introduced by the discrete state of recursive generators, we propose to use non-recursive arithmetic generators for generating random numbers. These implement a pure function  $Y_i(t)$ , which is solely dependent on the simulation time  $t$ . This allows to evaluate random numbers deterministically in continuous time without using discrete states.

In this work, we introduce the new random number generator **DIRCS Immediate Random with Continuous Seed**. It relies on the quick recovery of LCGs from a poor (i.e. small, non-random) seed  $Y_0$ , a property called diffusion capacity. If a poor seed  $Y_0$  is chosen, an LCG will irrespectively generate high quality random numbers after a few iterations. This property allows to continuously seed an LCG with a very simple function of the time  $t$ , apply a few iterations and treat the resulting number as random, i.e.

$$Y_i(t) = LCG(\dots(LCG(\text{seed}(t)))) \quad (5)$$

The quality of the generated random numbers  $U_i$  can be investigated using a number of different measures. All these measures quantify the fulfillment of the requirements that the random number must be (a) uniformly distributed and (b) uncorrelated for different time lags as requested by Eqs. 1 and 2. Fig. 3 confirms the LCG's diffusion capacity for small seeds between 1 and 200.

The uniformity of the distribution is checked here with the Kolmogorow-Smirnow test. The correlation is tested with a two-sided Z-test of the correlation. The given  $p$ -values indicate the confidence in the assumptions on a scale from 0 to 1.  $p$ -values larger than 0.10 indicate that the property under test is confirmed.

Figure 3: After ten iterations, the random numbers from an LCG can be assumed to be uniformly distributed and uncorrelated with the seed.

Table 1 gives an overview of the quality of the most important random number generators used in this work. They are compared to two standard solutions from the Modelica\_LinearSystems2 library [3] and the Design.Experimentation library [4]. It can be seen that all generators produce uncorrelated uniform random numbers.

Table 1: All RNGs produce uniform and uncorrelated random numbers.

Generator	Uniform	Uncorrelated
WELL1024a	$p = 0.396$	$p = 0.405$
LCG	$p = 0.456$	$p = 0.253$
DIRCS	$p = 0.432$	$p = 0.523$
LinearSystems2	$p = 0.508$	$p = 0.373$
Design	$p = 0.305$	$p = 0.899$

### 3.2 Probability Density Functions

Each uniform random number  $U_i$  generated with the methods presented in the previous section must be transformed to match the desired noise characteristics. The first step is to apply a mapping

$$U_i \mapsto X_i \tag{6}$$

according to a probability density function (PDF)  $f(x)$ . This yields random numbers  $X_i$  with a specified distribution. Informally, the function  $f(x)$  describes the probability that a random variable  $X_i$  equals  $x$ .

There are several methods to achieve this step (see e.g. [5]). If an analytic PDF is given, then often its primitive  $F(x) = \int_{-\infty}^x f(\tilde{x})d\tilde{x}$  can be derived. This cumulative density function (CDF) describes the probability that the random variable  $X_i$  is smaller or equal to  $x$ . Using the inverse of the CDF, a random number with the given distribution can be analytically calculated by  $X_i = F^{-1}(U_i)$ . This method is illustrated below for the heavy-tailed Cauchy-Lorentz distribution with the location parameter  $\mu$  and the scale parameter  $\gamma$ .

$$f_{\text{Cauchy-Lorentz}}(x) = \frac{1}{\pi} \left( \frac{\gamma}{(x - \mu)^2 + \gamma^2} \right) \tag{7}$$

$$F_{\text{Cauchy-Lorentz}}(x) = \frac{1}{\pi} \arctan \left( \frac{x - \mu}{\gamma} \right) + \frac{1}{2} \tag{8}$$

$$F_{\text{Cauchy-Lorentz}}^{-1}(U_i) = \gamma \tan \left( \pi \left( U_i - \frac{1}{2} \right) \right) + \mu \tag{9}$$

$$= X_{i,\text{Cauchy-Lorentz}} \tag{10}$$

If an analytical inverse of the CDF cannot be derived, different methods have to be employed. A prominent example is the normal distribution, which does not have an analytical CDF. To generate a normally distributed random variable, we employ the Box-Muller transform [6]. It uses two uniform random numbers  $U_{1i}$  and  $U_{2i}$  to calculate  $X_i$  according to

$$X_{i,\text{normal}} = \mu + \sigma \sqrt{-2 \ln U_{1i}} \cos(2\pi U_{2i}). \tag{11}$$

Finally, if no direct transformation is given in the literature, some common distributions can also be calculated directly according to their definition. The Bates distribution e.g. describes the distribution of an average over  $n$  uniform random numbers and can be calculated directly from

$$X_{i,\text{Bates}} = \frac{1}{n} \sum_{k=1}^n U_{k-i}. \tag{12}$$

### 3.3 Power Spectral Densities

In the previous sections, we have shown how to generate a discontinuous sequence of random variables  $X_i$  at an arbitrary sampling rate  $\Delta t$ . This sequence has to be processed further, in order to shape a continuous signal  $r(t)$  with a specified frequency content. A common method is to apply a simple low-pass filter to the noise sequence. Although being common practice, this method has two main disadvantages:

1. The simulation speed is limited by the high sampling frequency of the noise signal, the small time-constant of the low-pass filter or both.
2. It is often unclear which statistical properties the filtered signal has. It often differs widely from the PDF of the discrete signal.

For many applications it is thus favorable to compute the continuous signal directly out of the discrete sequence without using dynamic states as in usual implementations of low-pass filters. In this work, we continuously interpolate the discrete sequence using kernel functions.

If a kernel function  $K(t)$  is given, then the interpolation can be expressed as a linear combination of the kernel function with different weights  $X_i$  and offset  $i\Delta t$ :

$$r(t) = \sum_i X_i \cdot K(t - i\Delta t). \tag{13}$$

In order for this sum to be a proper interpolation, the kernel must equal 1 at the origin and 0 at all multiples of  $\Delta t$ :

$$K(i\Delta t) \stackrel{!}{=} \begin{cases} 1 & \text{for } i = 0 \text{ and} \\ 0 & \text{for } i \neq 0. \end{cases} \tag{14}$$

A prominent kernel function, which fulfills these constraints, is the *hat* function used to create a linear interpolation.

$$K_{\text{hat}}(t) = \begin{cases} 1 - \left| \frac{t}{\Delta t} \right| & \text{if } t \in [-\Delta t, +\Delta t] \\ 0 & \text{else} \end{cases} \tag{15}$$

Figure 4: Different interpolations can be applied to the random sequence. The sinc interpolation achieves a very smooth signal  $r(t)$ .

The resulting signal  $r(t)$  is a linear combination of the kernel functions. Its frequency content is thus fully determined by the frequency content of the kernel function. If the sum is truncated by limiting the number of involved sampling points  $X_i$ , additional content is introduced by the discontinuous support. In practice, however, the truncated contributions are often negligible, leading to acceptable approximations. This especially holds true for the hat function, which can be well truncated to only include two random samples.

Another important kernel function is the *normalized sinc* function:

$$K_{\text{sinc}}(t) = 2B \text{sinc}(2Bt) = \frac{\sin(2B\pi t)}{\pi t}. \quad (16)$$

It only contains frequencies up to its bandwidth  $B$ . If  $B = 1/(2\Delta t)$  is chosen to match half the sampling rate, the normalized sinc function also fulfills the constraints of an interpolation kernel. Interpolation with the sinc function can thus be used to apply an optimal low-pass filter to the random sequence.

Figure 4 shows the different interpolation methods described above. The interpolation is applied to a random sequence  $X_i$  generated with 100 S/s. The frequency contents of the signals are compared in Fig. 5. The raw sample-and-hold signal of  $X_i$  contains frequencies higher than the sampling frequency. Using the interpolation with the sinc function, the frequency characteristic can be nicely limited to the desired cut-off frequency of half the sampling frequency. It is important to understand how the interpolation affects the statistical properties of the random signal  $r(t)$ . Since  $r(t)$  is a weighted sum of statistically independent random variables, we can use the following two laws to

Figure 5: The frequency characteristic are shaped by the interpolation function. The sinc function achieves a very good low-pass characteristic.

determine the change of variance for any valid filter:

$$\text{Var}(X_i \cdot c) = \text{Var}(X_i) \cdot c^2, \quad (17)$$

$$\text{Var}(X_i + X_j) = \text{Var}(X_i) + \text{Var}(X_j). \quad (18)$$

Here,  $X_i$  and  $X_j$  denote the statistically independent random variables generated by the RNG and  $c$  denotes a constant weight. The variance of the random variables is fixed by the selected PDF and the constant  $c$  is given by the interpolation kernel. The time-dependent variance of  $r(t)$  from Eq. 13 can thus be expressed as

$$\text{Var}(r(t)) = \text{Var}(X_i) \cdot \sum_i (K(t - i\Delta t))^2. \quad (19)$$

Due to the constraints for interpolation kernels Eq. (14), the variance of  $r(t)$  at the sampling points is equal to the variance of the random variable  $X_i$ . In between the sampling points, the variance of the random signal is a function of the time. We can compute the expectation value of the variance for the entire signal by formulating the integral over the interval  $\Delta t$ :

$$\begin{aligned} E[\text{Var}(r(t))] &= \frac{1}{\Delta t} \int_{t=0}^{\Delta t} \text{Var}(r(t)) dt \\ &= \frac{\text{Var}(X_i)}{\Delta t} \int_{t=0}^{\Delta t} \sum_{i=-n+1}^n (K(t - i\Delta t))^2 dt \\ &= \frac{\text{Var}(X_i)}{\Delta t} \sum_{i=-n+1}^n \int_{t=0}^{\Delta t} (K(t - i\Delta t))^2 dt \\ &= \frac{\text{Var}(X_i)}{\Delta t} \int_{t=-n\Delta t}^{n\Delta t} K(t)^2 dt. \end{aligned} \quad (20)$$

Doing this computation for the linear interpolation using the hat function leads to

$$E[\text{Var}(r(t))] = \frac{2}{3} \text{Var}(X_i). \quad (21)$$

Thus, any linear interpolation reduces the variance of the input signal by one third, independently of the PDF used to generate  $X_i$ . In a similar manner, the result can be computed for the optimal bandwidth limitation. Fortunately,

$$\lim_{n \rightarrow \infty} \frac{1}{\Delta t} \int_{t=-n\Delta t}^{n\Delta t} K_{\text{sinc}}(t)^2 dt = 1 \quad (22)$$

and hence the variance is only minorly affected for  $n$  chosen large enough. In fact, with  $n = 3$ , the expected variance is only changed by less than 5 %.

Not only the variance may be affected but also the shape of the PDF. It is possible to compute this effect for specific PDFs but the most general statement can be drawn from the central limit theorem. It states that a sum of many independent random variables (with finite variance) is approximately normally distributed. Hence we can state that the application of a filter transforms all PDFs with finite variance gradually to look like the normal distribution and that this effect is expected to be stronger the wider the domain of  $K(t)$  is.

Our analysis suggests a very suitable combination for generating a continuous random noise signal: if the discrete noise is generated by a normal distribution and if it is interpolated by an ideal bandwidth limitation, the resulting signal is also of a normal distribution with the same variance and a frequency characteristic below the cut-off frequency that represents white noise. The cut-off frequency will be half the sampling frequency.

## 4 Implementation in Modelica

The concepts laid out in Sec. 3 are implemented in the Modelica Noise library. An overview of the library's components is shown in Fig. 6. The library provides a single block PRNG as the interface to all of its facilities. This block is described here.

In order to provide the user with a convenient interface, the PRNG block combines all parts of the noise generation process described in Sec. 3. The block's parameter pane is shown in Fig. 8.

All three parts of the noise generation can be (almost) independently parametrized. The *Random Number Generator (RNG)* parameters allow the user to select whether a sampling-based or a sampling-free generator shall be used. Two selectors allow to maintain parametrized instances of both variants in the PRNG block. The parameters of the generators can all be set via the PRNG's parameter interface. The criteria listed in Table 1 may assist in choosing a suitable RNG.

The *Probability Density Function (PDF)* can also be selected in the PRNG's parameter pane along with its parameters. Some of the available distributions are shown

in Fig. 7. Cauchy-Lorentz, Irwin-Hall, Bates and Discrete distributions are also available. The distribution should be selected according to the specification of the desired noise. Additional distributions can be implemented according to the literature by filling a common function interface.

Finally, a kernel function for the desired *Power Spectral Density (PSD)* can be selected and parametrized. The kernels are set up with standard parameters to match the update rate of the block. For example, the ideal low-pass filter is set up with a cut-off frequency of half the update rate. The implemented filters are shown in Fig. 9. A typical choice of the PSD would be to use the raw random sequence or the ideal low-pass interpolation with  $n \geq 5$ . Additional kernels can be added easily by the user.

The (*Pseudo-*) *Sampling* parameters of the PRNG block are the same as for most sampling Modelica blocks. A `startTime` determines the first sample to be generated. A `samplePeriod` determines the step-size of the sampler. For sample-free generators, the sampling is relaxed to a pseudo-sampling of the random number, i.e. imposing an upper limit to the update rate. An additional `infiniteFreq` switch can be used to completely disable (pseudo-)sampling and let the simulation tool handle the step-size of the generator based on the desired integration accuracy. This also disables the PSD filtering, because the interpolation needs discrete noise samples.

The *Enable/Disable* parameters finally are used to enable noise generation or to output a simple dummy variable `y_off`. It can be used to parametrically restore the ideal system without noise.

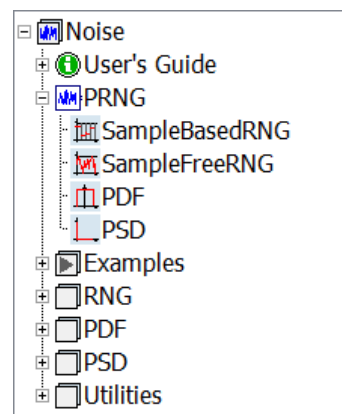

Figure 6: The Noise library provides a ready-to-use noise block as well as a collection of RNG, PDF and PSD implementations.

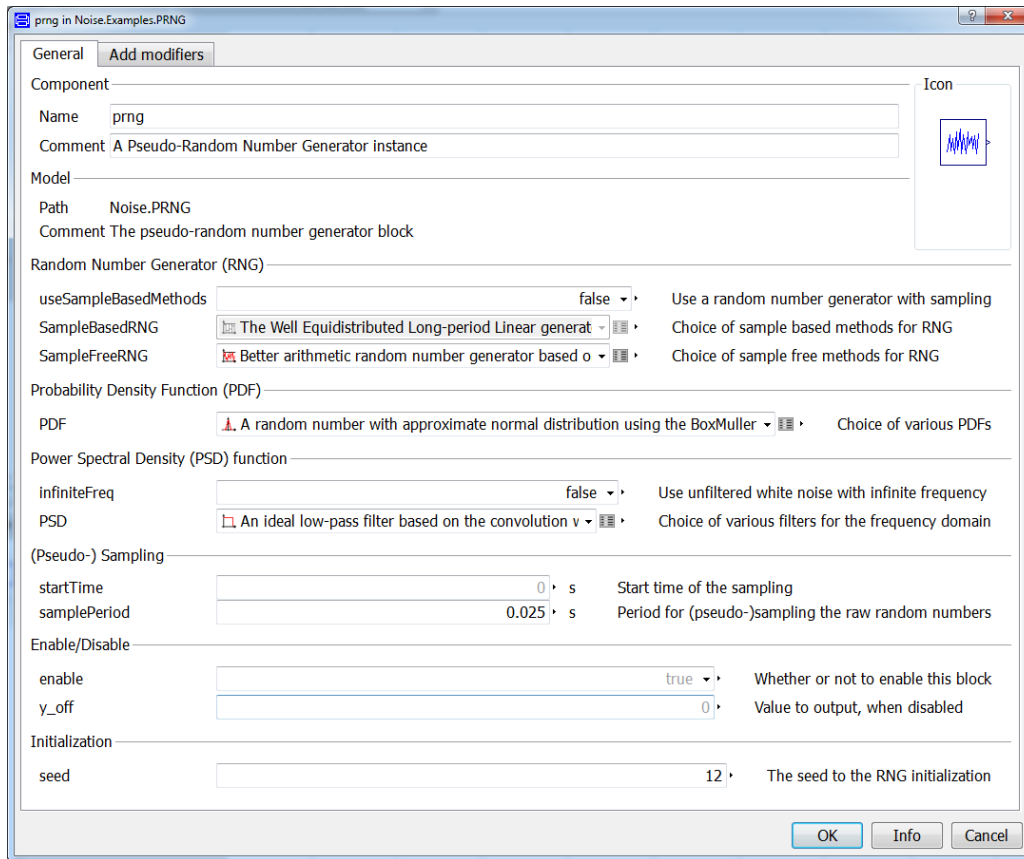

Figure 8: The PRNG block can be used to collectively set up custom noise by modularly combining all available RNG, PDF and PSD implementations. Additional switches are provided to set the samplePeriod, enable sample-free RNGs and enable infinite frequency emulation.

Figure 7: Some of the provided PDFs are a uniform, a normal and a Weibull distribution.

Figure 9: The provided PSDs include an unfiltered white noise, an ideal low-pass filter and a linear interpolation.

## 5 Evaluation of Filtered Noise

Relevant noise in realistic applications is in most cases sampled and filtered (see e.g. Fig. 2). The process of sampling and filtering changes the probability density as well as the frequency content of the signal. In the following sections, we will show how these characteristics can be modeled using the Noise library. First, a synthetic example is used.

In this section, the probability distribution and frequency content of noise generated with a standard approach and with the Noise library are compared. A digital sensor is used as an example. The sensor has a uniform noise distribution with amplitudes between  $-0.05$  rad and  $0.05$  rad. The signal is sampled with

6 kS/s. The signal is subsequently smoothed with a running mean filter using 20 samples and then down-sampled by a factor of 20. This procedure is representative for a typical angular resolver signal used for control purposes. In order to introduce a model of a simple system, a CriticalDamping block from the Modelica standard library is used. It has a fixed cut-off frequency of 10 Hz and a variable number of states.

### 5.1 Model using the LinearSystems library

In Fig. 10a, the reference implementation using the Modelica\_LinearSystems library is shown. Uniform noise is generated with at a rate of 6 kS/s, filtered with a running mean FIR filter and then down-sampled.

Figure 10: Generation of realistic filtered noise using the LinearSystems and the new Noise library.

Figure 11: Histograms of the different noise signals

Figure 12: Frequency analysis of the noise signals.

### 5.2 Model using the Noise library

Using the Noise library, it is possible to generate the filtered and down-sampled noise signal without sampling at a high frequency. In order to achieve an equivalent signal, the PDF must be adjusted to match the distribution of the filtered signal. This is done selecting the Bates distribution described in Sec. 3.2 with  $n = 20$ . The noise signal can then be generated at the down-sampled update rate of 300 S/s. Additionally, the DIRCS generator is used to suppress all time-events in the simulation. The Modelica block diagram is shown in Fig. 10b.

### 5.3 Probability density distribution

The empirical probability density functions of the generated noise signals are shown in Fig. 11. To show that down-sampling the signal has no influence on the PDF, the down-sampled, as well as the original signals are shown. The probability density function of the generated noise signal is obtained experimentally by simulating both noise models for 200 s and by using 250 bins between the minimal and maximal values (-0.05 to 0.05). The results of the analysis show a good match between the different signals.

### 5.4 Frequency content

The frequency content of the signal is an important property of a noisy signal. To show that also the

frequency content of the PRNG block mimics the frequency content of the sampled and filtered signal Welch’s power spectral density analysis is applied to the signals (see Sec. 2). The results are shown in Figure 12. The plot shows that the frequency contents of all signals correspond very well. Especially the low frequency content up till 300 Hz is a very good match.

### 5.5 Simulation times

In order to compare the simulation times of the presented models, the models are simulated again for 200 s. As a reference, a standard noise block from the LinearSystems library without downsampling is included using 300 Samples/s, the same update rate as the PRNG block updates internally. Only 10 output points are generated in order to make sure the output routine does not influence the simulation times. The simulations are performed using Dymola 2014 FD01 Beta 3 on an Intel® Xeon® E5-1620 processor. The results of the simulations are summarized in Table 2. Additionally to the model structure, the number of states in the CriticalDamping system is varied.

The results clearly show the advantage of using the Noise library for modeling noise in a system. The simulation time for the Noise model with a system of second order is six times faster than the standard approach. If the complexity of the system is increased by using a number of 50 states, the Noise model is 26 times faster

Table 2: Simulation times and number of steps of the models with noise for 200 seconds simulation. LS 6kS/s filtered marks the Noise from Figure 10a, LS 300S/s raw marks the simulation results of the noise generation using the LinearSystems library using a direct noise output of the signal and LS 300S/s Bates using a Bates distribution using an averaging of 20 random samples at each timestep.

Model	States	Time	Events
LS 6kS/s filtered	2	45 s	12e6
LS 300S/s raw	2	6 s	60e3
LS 300S/s Bates	2	8.7 s	60e3
Noise	2	7.5 s	0
LinearSystems	50	256 s	12e6
LS 300S/s raw	50	23 s	60e3
LS 300S/s Bates	50	24.5 s	60e3
Noise	50	9.7 s	0

than the model using LinearSystems noise. The approaches without downsampling (LS 300S/s methods) have a better performance. The Bates distribution at 300S/s has a similar calculation time as the method using the Noise library. However, at higher model levels, for a system with 50 states, the speedup ratio is a little over 2. This result show that integrator restarting due to the event generation becomes more expensive at increasing system complexity.

## 6 Industrial Application Example

In order to test the performance of the presented noise models in an application of industrial complexity, the example of an electro mechanical actuator is chosen. This actuator is generated using the Actuator toolbox

Figure 13: Actuator model overview. The motor position sensor is used to include the noise effects.

[7]. In Figure 13, an overview of the model is given.

The position sensor of the motor can be chosen from an ideal sensor or two sensor versions with noise. The sensor readings are used for controlling the motor current as well as the speed and position of the actuator. To obtain the motor speed, position is differentiated. For these reasons, adding noise to the system is expected to strongly influence the system's behavior.

To test the presented noise generation and compare it with a traditional approach, two sensors with noise were derived. The first sensor uses a traditional sampled noise using the blocks from Modelica\_LinearSystems.Sampled, the second uses the Noise library presented in this work. The two noise models are the same as presented in Sec. 5. The noise is assumed to be additive as shown in Fig. 1.

### 6.1 Simulation results

The actuator model is simulated with each of the three sensor versions. The actuator is commanded to follow a change in position of 43 mm at  $t = 1$  s. Figure 14 shows the responses with the three sensor versions. The results match very well. The simulations were carried out using the Dassl integrator with a tolerance of  $10^{-4}$ . For the following comparison, only 10 output intervals are requested in order not to influence the simulation times by the output intervals. The simulation times and generated events are summarized in Table 3.

### 6.2 Time and state events

One of the main benefits of the presented noise model is that no time events are generated. As expected, the sampled noise using the LinearSystems library generates 15000 time events, which is the product of the sample rate and the simulation time. The model built with the Noise library, however, does not generate any time events. The amount of state events generated by

Figure 14: Resulting trajectory of the actuator using the three sensor versions. The actuator follows a commanded position change of 43 mm.

Table 3: Simulation results of the actuator models over 2.5 seconds.

Model	Time	Events	
		Time	State
No Noise	0.037 s	1	12
LinearSystems	27.5 s	15000	1642
Noise	10.5 s	1	1791

both models is roughly the same. These events are generated by the nonlinearities in the model. Mainly the inverter reacts to the high-frequency changes of the demanded current, which is generated by the noisy sensor readings.

### 6.3 Simulation speed

Especially in more complex models the penalty of an event becomes large. Restarting the integrator can use as much time as an integrator step itself. In Table 3, the simulation time of the models is shown. The noise itself has a big penalty on the simulation performance. This is expected, as the position sensor is used in all control algorithms. The simulation time using the Noise library, however, is decreased with respect to the standard implementation due to the reduced number of time events.

## 7 Conclusions and Outlook

We have shown how to properly implement a noise signal in Modelica by selecting a high-quality random number generator (RNG) and by specifying a probability density function (PDF) as well as a power spectral density (PSD) of the desired signal. In order to aid the user in this process, we have proposed a library with modular implementations of the three parts of the noise generation. The library provides a convenient interface to set all parameters. It is further possible for the user to freely implement new modules.

The proposed combination of sample-free RNGs and continuous PSDs provides for a satisfactory increase in simulation speed by a factor between 2.5 in a real world actuator example and up to 26 using an academic model.

Time events due to the noise model can be completely eliminated from the simulation by using the proposed continuous DIRCS random number generator, which relies on continuously seeding a standard RNG with a function of the time.

Further extensions of the library can be seen in taking advantage of the Modelica 3.3 function arguments.

The library could additionally be improved in modularity by introducing separate seeding functions. In this way, also the continuously seeded generator could be modularized. Some convenient features such as global seeding or seeding based on the machine time may also be addressed in future versions. Additionally, the current interpolation filter may be extended to allow for arbitrary filter functions implemented by the user.

## Abstract

For the 0D-1D modelling of thermal-hydraulics systems, it is common practice to use static mixing models to compute the mixing specific enthalpy in fluid junctions such as mergers or splitters. However, this simplification leads to a well known singularity when the mass flow rate inside the junction goes to zero. The origin of the singularity is explained, and a rigorous physical solution is proposed to eliminate the singularity. A prototype implementation has been developed in the ThermoSysPro library for power plant modelling that illustrates the interest of the proposed solution, shows the impact on the structure of the library and enables to evaluate the computing overhead with respect to several possible variants.

*Keywords: thermal-hydraulics; mixing models; convection; diffusion; ThermoSysPro*

## 1 Introduction

When modelling thermal-hydraulics at the system level, such as power plants, it is common practice to use static equations to compute fluid quantities in mixing equipments such as mergers and splitters. This simplification stems from the fact that the volume of mixing is often neglected in junctions, therefore eliminating the differential term in the balance equations. It also occurs when computing isolated operating points that only require static models.

Neglecting diffusion is very common when one deals with large mass flow rates, as diffusion is only significant when mass flow rates approach zero. When diffusion is neglected, the only thermal phenomenon remaining in the model is convection. However when mass flows go to zero, convection disappears. So if diffusion is neglected, when mass flow rates go to zero, as convection also disappear, there is no thermal phenomena left in the model, leading to a possible indetermination of the enthalpy. This indetermination results in a singularity when

static models are used, because in such case there is no differential variable to act as a memory for the enthalpy when mass flow rates are equal to zero.

In subsequent chapters, the mathematical origin of the singularity is explained. Then a rigorous mathematical formulation is proposed based on physical insight to remove the singularity. The idea is to reintroduce diffusion in static mixing models. Finally, a performance benchmark is given, based on a prototype implementation in ThermoSysPro. ThermoSysPro is a Modelica library developed by EDF for the modelling of power plants of all types [1].

## 2 Computing the state of a thermal-hydraulics system

As the objective is to find the origin of the physical singularity before giving a solution for removing the singularity, it is useful to understand how the physical state of a thermal-hydraulic system such as a volume is defined.

A volume is an abstract physical component where incoming flows mix. Figure 1 features four incoming flows. Flows are positive when they enter the volume and negative otherwise.

Figure 1: volume

In general, the state of a physical system is given by the set of independent physical quantities that completely define the state. There are many ways to choose the state variables for a given physical sys-

tem. For a thermal-hydraulic volume  $a$ , a common choice is to use the average pressure  $P_a$  and the average specific enthalpy  $h_a$  inside the volume. Then the state of the volume  $a$  will be defined if  $P_a$  and  $h_a$  can be computed.

In the sequel, we are only interested in computing  $h_a$  which is called the mixing enthalpy in volume  $a$ .

To compute  $h_a$ , one must consider the neighboring volumes of  $a$  which are collectively denoted  $b$  (see Figure 2).

Figure 2: grid scheme

Each volume is assumed to be in thermodynamic equilibrium, so that their thermodynamic state is physically defined. However neighboring volumes may have different physical states, so that pressure and temperature gradients may exist that cause mass and energy flows between neighboring volumes through their common limiting boundary.

Mass flowing from volume  $b$  to volume  $a$  is denoted  $Q(b \rightarrow a)$ . Therefore  $Q(b \rightarrow a)$  is positive if the flow actually occurs from  $b$  to  $a$ , and negative otherwise. So  $Q(a \rightarrow b) = -Q(b \rightarrow a)$ .

Notice that the relation

$$Q(a \rightarrow b) + Q(b \rightarrow a) = 0$$

is not a mass balance equation between volumes  $b$  and  $a$ , but merely states the fact that  $Q(b \rightarrow a)$  and  $Q(a \rightarrow b)$  denote the same physical quantity with opposite sign conventions.

The specific enthalpy of flow  $Q(b \rightarrow a)$  is denoted  $h_{b:a}$ . The meaning of notations is recalled in chapter 7.

The dynamic mass and energy balance equations are given by

$$\frac{d(\rho_a \cdot V_a)}{dt} = \sum_b Q(b \rightarrow a)$$

$$\frac{d(\rho_a \cdot V_a \cdot u_a)}{dt} = \sum_b (h_{b:a} \cdot Q(b \rightarrow a) + J(b \rightarrow a)) + W_a$$

$J(b \rightarrow a)$  is the energy flow through diffusion.

$$J(b \rightarrow a) = -A_{b:a} \cdot k_{b:a} \cdot \nabla T(b \rightarrow a) \quad (1)$$

The static mass and energy balance equations are obtained by eliminating the dynamic terms on the left hand sides.

$$0 = \sum_b Q(b \rightarrow a) \quad (2)$$

$$0 = \sum_b (h_{b:a} \cdot Q(b \rightarrow a) + J(b \rightarrow a)) + W_a \quad (3)$$

As the quantity  $h_a$  does not appear explicitly in the static energy balance equation, it must be computed through the quantities  $h_{b:a}$ . So the relation between  $h_a$  and  $h_{b:a}$  must be established.

To that end, the fluid vein between volumes  $a$  and  $b$  is considered (see Figure 3).

Figure 3: fluid vein

The static mass and energy balance equations in the volume limited by  $dx$  is

$$0 = \frac{\partial Q_x}{\partial x} \quad (4)$$

$$0 = \frac{\partial}{\partial x} \left( h_x \cdot Q_x - A \cdot k \cdot \frac{\partial T_x}{\partial x} + W_x \right) \quad (5)$$

Eq. (4) states that  $Q_x$  is constant. Therefore:

$$Q_x = Q(a \rightarrow b) = -Q(b \rightarrow a)$$

In order to find an analytical solution to Eq. (5), the following relation between  $dh_x$  and  $dT_x$  is considered:

$$dh_x = c_p \cdot dT_x \quad (6)$$

In the sequel, it is assumed that the relation given by Eq. (6) is valid (i.e. outside of the saturation line, for isobaric transformations, or for ideal gases, or when the contribution of the pressure variation to the variation of the specific enthalpy is negligible as compared to the contribution of the variation of temperature).

Under the additional assumption that  $W_x = 0$ , the energy balance equation writes:

$$0 = Q(a \rightarrow b) \cdot \frac{\partial h_x}{\partial x} - \frac{A \cdot k}{c_p} \cdot \frac{\partial^2 h_x}{\partial x^2} \quad (7)$$

Eq. (7) can be solved analytically [2]:

$$h_x = \frac{1}{1 - e^{P_e}} \cdot \left[ h_b - h_a \cdot e^{P_e} + (h_a - h_b) \cdot e^{P_e \cdot \frac{x}{L}} \right] \quad (8)$$

with

$$P_e = \frac{1}{\gamma} \cdot Q(a \rightarrow b) \quad (9)$$

$$\gamma = \frac{A \cdot k}{c_p \cdot L} \quad (10)$$

$h_{b,a}$  is the value of  $h_x$  for  $x = \frac{L}{2}$ :

$$h_{b,a} = h_{L/2} = \hat{s}(P_e) \cdot h_a + \hat{s}(-P_e) \cdot h_b \quad (11)$$

with

$$\hat{s}(x) = \frac{1}{1 + e^{-\frac{x}{2}}} \quad (12)$$

Figure 4 gives a plot of  $\hat{s}$ .

Figure 4: plot of  $\hat{s}$

If diffusion is neglected, then  $\gamma \rightarrow 0$ ,  $P_e \rightarrow +\infty$  and  $h_{b,a}$  becomes:

$$h_{b,a} = s(Q(a \rightarrow b)) \cdot h_a + s(Q(b \rightarrow a)) \cdot h_b \quad (13)$$

where  $s$  is the step function:

$$s(x) = \begin{cases} 1 & \text{if } x > 0 \\ \frac{1}{2} & \text{if } x = 0 \\ 0 & \text{if } x < 0 \end{cases} \quad (14)$$

This is the well known upwind scheme approximation for flow reversal. This relation is widely used, even if the assumptions used in this derivation are not fulfilled.

Note that  $s$  is discontinuous at  $x = 0$ , whereas  $\hat{s}$  is continuous and differentiable everywhere.

### 3 Origin of the singularity in static mixing models

The objective of this chapter is to show that the singularity in static mixing models arises when diffusion is neglected.

So in the sequel diffusion is neglected, which means that  $J(b \rightarrow a) = 0$ . Also  $Q(b \rightarrow a)$  is denoted  $Q_b$  to simplify the notation.

The mass and energy balance equations become

$$0 = \sum_b Q_b \quad (15)$$

$$0 = \sum_b h_{b,a} \cdot Q_b \quad (16)$$

The value of the enthalpy  $h_{b,a}$  is given by the upwind scheme (see Eq. (13)):

$$h_{b,a} = s(Q_b) \cdot h_b + s(-Q_b) \cdot h_a \quad (17)$$

In the sequel, the following relations are used:

$$|x| = \text{sgn}(x) \cdot x \quad (18)$$

$$\text{sgn}(x) = s(x) - s(-x) \quad (19)$$

$$s(x) = 1 - s(-x) \quad (20)$$

where  $\text{sgn}$  is the sign function.

Then using Eq. (15), (16), (17) and (20)

$$\begin{aligned} \sum_b h_{b,a} \cdot Q_b &= \sum_b s(Q_b) \cdot Q_b \cdot h_b + h_a \cdot \sum_b s(-Q_b) \cdot Q_b \\ &= \sum_b s(Q_b) \cdot Q_b \cdot h_b + h_a \cdot \left( \sum_b Q_b - \sum_b s(Q_b) \cdot Q_b \right) \\ &= \sum_b s(Q_b) \cdot Q_b \cdot h_b - h_a \cdot \sum_b s(Q_b) \cdot Q_b = 0 \end{aligned}$$

Therefore

$$h_a = \frac{\sum_b s(Q_b) \cdot Q_b \cdot h_b}{\sum_b s(Q_b) \cdot Q_b} \quad (21)$$

when  $\sum_b s(Q_b) \cdot Q_b \neq 0$ .

To find out when this condition is satisfied, using Eq. (15), (18), (19) and (20):

$$\begin{aligned} \sum_b |Q_b| &= \sum_b \text{sgn}(Q_b) \cdot Q_b = \sum_b (s(Q_b) - s(-Q_b)) \cdot Q_b \\ &= \sum_b s(Q_b) \cdot Q_b - \sum_b s(-Q_b) \cdot Q_b \\ &= \sum_b s(Q_b) \cdot Q_b - \sum_b (1 - s(Q_b)) \cdot Q_b \\ &= 2 * \sum_b s(Q_b) \cdot Q_b - \sum_b Q_b = 2 * \sum_b s(Q_b) \cdot Q_b \end{aligned}$$

Hence:

$$h_a = 2 \cdot \frac{\sum_b s(Q_b) \cdot Q_b \cdot h_b}{\sum_b |Q_b|} \quad (22)$$

when  $\sum_b |Q_b| \neq 0$ .

So when all mass flow rates are equal to zero, the mixing enthalpy  $h_a$  is indeterminate ( $h_a = 0/0$ ).

Although the indetermination occurs only at an isolated point (all mass flow rates equal to zero), it is not obvious to extend  $h_a$  in order to remove the singularity at zero (contrary to other functions with isolated singularities such as  $\sin(x)/x$ ).

In particular, it is not sufficient to replace  $s$  by  $\hat{s}$  (or in other words get rid of the upwind scheme by introducing diffusion in the flow reversing formula given by Eq. (17)) because then

$$h_a = \frac{\sum_b \hat{s}(\hat{Q}_b) \cdot Q_b \cdot h_b}{\sum_b \hat{s}(\hat{Q}_b) \cdot Q_b} \quad (23)$$

with

$$\hat{Q}_b = \frac{Q_b}{\gamma_{b,a}} \quad (24)$$

The singularity still remains since  $\sum_b \hat{s}(\hat{Q}_b) \cdot Q_b = 0$

when all mass flow rates are equal to zero.

However, noticing that

$$s(Q_b) \cdot Q_b = \max(Q_b, 0)$$

Eq. (21) may be written as

$$h_a = \frac{\sum_{Q_b > 0} Q_b \cdot h_b}{\sum_{Q_b > 0} Q_b}$$

Therefore, if one is not interested in the correct value of  $h_a$  near zero flows, which is in general the case when diffusion is neglected, then as suggested in [3] one can replace  $Q_b$  by  $\max(Q_b, Q_\epsilon)$  where  $Q_\epsilon$  is a small positive mass flow rate. Then when all mass flow rates  $Q_b$  are below  $Q_\epsilon$  ( $|Q_b| < Q_\epsilon$ ):

$$h_a = \frac{1}{N_a} \sum_b h_b \quad (25)$$

where  $N_a$  is the number of neighboring volumes  $b$  of volume  $a$ , so the singularity is removed for zero flows.

Noticing that  $\max(x, y) = s(x - y) \cdot (x - y) + y$ , one can even have a  $C^\infty$  way of removing the singularity by (1) considering the function

$$s_p(x) = \frac{1}{1 + e^{-p \cdot x}} \quad (26)$$

by (2) replacing  $s$  by  $s_p$  in the max function above

$$\text{smoothMax}(x, y, p) = s_p(x - y) \cdot (x - y) + y$$

and by (3) properly adjusting the value of  $p$  wrt.  $Q_\epsilon$ .

This solution will not be developed here any further, as a full physical solution is sought. The reason is that replacing  $Q_b$  by  $Q_\epsilon$  when  $|Q_b| < Q_\epsilon$  for computing the mixing enthalpy violates the energy balance fundamental law, so requires a proper choice of  $Q_\epsilon$  wrt. the problem at hand.

As suggested in [3] there are also other ways to write *smoothMax*.

Notice also that  $\hat{s} = s_{0.5}$  and  $s = s_\infty$  (see Eq. (12), (14) and (26)).

## 4 Removing the singularity at zero flows

Diffusion is reinstated in the energy balance equation. Then

$$0 = \sum_b Q(b \rightarrow a) \quad (27)$$

$$0 = \sum_b (h_{b,a} \cdot Q(b \rightarrow a) + J(b \rightarrow a)) \quad (28)$$

assuming without loss of generality that  $W_a = 0$ .

Using Eq. (1) and (6):

$$J(b \rightarrow a) = (A \cdot k)_{b,a} \cdot \left( \frac{\partial T_x}{\partial x} \right)_{L/2}$$

$$= \left( \frac{A \cdot k}{c_p} \right)_{b,a} \cdot \left( \frac{\partial h_x}{\partial x} \right)_{L/2}$$

Taking the derivative of Eq. (8) wrt.  $x$  at  $x = \frac{L}{2}$  yields:

$$J(b \rightarrow a) = r(P_e) \cdot J_0(b \rightarrow a) \quad (29)$$

with

$$J_0(b \rightarrow a) = \gamma_{b,a} \cdot (h_b - h_a) \quad (30)$$

$$\gamma_{b,a} = \left( \frac{A \cdot k}{c_p \cdot L} \right)_{b,a} \quad (31)$$

$$P_e = -\frac{1}{\gamma_{b,a}} \cdot Q(b \rightarrow a) \quad (32)$$

$$r(x) = \begin{cases} \frac{x}{e^{\frac{x}{2}} - e^{-\frac{x}{2}}} & \text{if } x \neq 0 \\ 1 & \text{if } x = 0 \end{cases} \quad (33)$$

$J_0(b \rightarrow a)$  is the energy flux when  $Q(b \rightarrow a) = 0$ .

For easier computation  $r(x)$  may be approximated by the Gaussian

$$\hat{r}(x) = e^{-0.033 \cdot x^2} \quad (34)$$

The plot below compares  $r$  in red with  $\hat{r}$  in blue.

Figure 5: plot of  $\hat{r}$  and  $r$

When all flows  $Q_b$  are equal to zero, the energy balance equation writes

$$0 = \sum_b J_0(b \rightarrow a) = \sum_b \gamma_{b,a} \cdot (h_b - h_a)$$

As the coefficients  $\gamma_{b,a}$  are always strictly positive ( $\gamma_{b,a} > 0$ ), when all flows are equal to zero the mixing enthalpy  $h_a$  is defined and takes the value:

$$h_a = \frac{\sum_b \gamma_{b,a} \cdot h_b}{\sum_b \gamma_{b,a}} \quad (35)$$

If all coefficients  $\gamma_{b,a}$  are equal, then  $h_a$  is the arithmetic mean (see also Eq. (25))

$$h_a = \frac{1}{N_a} \sum_b h_b \quad (36)$$

where  $N_a$  is the number of neighboring volumes  $b$  of volume  $a$ .

As a conclusion to this chapter, when diffusion is taken into account, the energy balance equation is

$$0 = \sum_b (h_{b,a} \cdot Q(b \rightarrow a) + (h_b - h_a) \cdot Q_\varepsilon(b \rightarrow a)) \quad (37)$$

with

$$Q_\varepsilon(b \rightarrow a) = r \left( -\frac{1}{\gamma_{b,a}} \cdot Q(b \rightarrow a) \right) \cdot \gamma_{b,a} \quad (38)$$

The terms  $Q_\varepsilon(b \rightarrow a)$  are in general small but are always strictly positive and have the same physical unit as a mass flow rate (kg/s). So they never go to zero, even when all mass flow rates go to zero. They act therefore as small positive mass flow rates that remove naturally in a  $C^\infty$  way the singularity of the mixing enthalpy at zero flows.

## 5 Benchmark of the proposed solution

To evaluate the computing overhead of introducing diffusion to solve the singularity problem, the benchmark consists in comparing two alternatives for the static energy balance equation (see Eq. (28)):

- Alternative 1: without diffusion, with or without upwind scheme.
- Alternative 2: with diffusion, with or without upwind scheme.

Without diffusion means that

$$J(b \rightarrow a) = 0$$

With diffusion means that

$$J(b \rightarrow a) = \hat{r}(\hat{Q}_b) \cdot \gamma_{b,a} \cdot (h_b - h_a)$$

With upwind scheme means that

$$h_{b,a} = s(Q_b) \cdot h_b + s(-Q_b) \cdot h_a$$

Without upwind scheme means that

$$h_{b,a} = \hat{s}(\hat{Q}_b) \cdot h_b + \hat{s}(-\hat{Q}_b) \cdot h_a$$

$\hat{r}(\hat{Q}_b)$  and  $\hat{s}(\hat{Q}_b)$  are defined by Eq. (12), (24) and (34).

The equations are implemented as a prototype in the ThermoSysPro library using the scheme shown in Figure 6.

Figure 6: grid scheme in ThermoSysPro

The quantities  $(P_a, P_b)$  and  $(h_a, h_b)$  are computed in the multi-port elements with the mass and energy balance equations. Multi-port elements represent the control volumes  $a$  and  $b$ . For this reason, they are also called ‘volumes’. The quantities  $J(b \rightarrow a)$  and  $h_{b,a}$  are also computed in the volumes.

The quantities  $Q(b \rightarrow a)$  are computed in the two-port elements with the momentum balance equations. Two-port elements represent the interfaces  $b : a$  between  $a$  and  $b$ .

The interface  $b : a$  is oriented positively from the blue port to the red port of the two-port element that represents  $b : a$ . So the mass flow rate is positive when the fluid flows along the positive direction of the interface orientation, i.e. from the blue port to the red port. To reflect this sign convention for mass flow rates, the blue port is called ‘input port’, and the red port is called ‘output port’.

The components are connected together via the input and output ports that correspond to Modelica connectors. Input and output connectors have the same structure. In order to handle diffusion, they are somewhat different from the usual fluid connectors used in Modelica fluid libraries, and in particular in the current distribution of the ThermoSysPro library. The meaning of the variables in the connector de-

pends on whether the connector is attached to a volume or to a two-port element.

If the connector is attached to a two-port element representing the interface  $b : a$  :

P	Pressure $P_a$ in volume $a$ , or pressure $P_b$ in volume $b$ , depending on whether the connector is on the side of $a$ or on the side of $b$ .
Q	Mass flow rate $Q(b \rightarrow a)$ of the fluid going through interface $b : a$ .
h	Specific enthalpy $h_{b,a}$ of the fluid going through interface $b : a$ .
h_vol_1	Specific enthalpy $h_b$ or $h_a$ of the fluid in volume $b$ or $a$ located on the side of the input port of the two-port element that represents $b : a$ .
h_vol_2	Specific enthalpy $h_b$ or $h_a$ of the fluid in volume $b$ or $a$ located on the side of the output port of the two-port element that represents $b : a$ .

If the connector is attached to a multi-port element that represents volume  $b$ , and the connector is connected to the two-port element that represents interface  $b : a$  :

P	Pressure $P_b$ of the fluid in volume $b$ .
Q	Mass flow rate $Q(b \rightarrow a)$ of the fluid going through interface $b : a$ .
h	Specific enthalpy $h_{b,a}$ of the fluid going through interface $b : a$ .
h_vol_1	If the connector is an input port: specific enthalpy $h_b$ of the fluid in the neighboring volume $b$ located in the direction of negative flow rates. If the connector is an output port: specific enthalpy $h_a$ of the fluid in volume $a$ .
h_vol_2	If the connector is an input port: specific enthalpy $h_a$ of the fluid in volume $a$ . If the connector is an output port: specific enthalpy $h_b$ of the fluid in the neighboring volume $b$ located in the direction of positive flow rates.

The purpose of  $h_{vol\_1}$  and  $h_{vol\_2}$  is to provide both  $h_a$  and  $h_b$  to volumes  $a$  and  $b$  even if they are separated by a line of connected two-port elements.

When connecting together two connectors, the variables inside the connectors are made equal because they represent the same physical quantities. So connectors are used to assemble the model from the different components, and not to generate extra physical equations (such as balance equations for instance).

This scheme for distributing the equations between multi-port and two-port elements and connecting them together enables to connect together several two-port elements without having to separate them by volumes. The connected line of two-port elements is then equivalent to a single two-port element. Also, there are no infinitesimally small volume elements implied between two connected two-port elements, so the connections do not generate the kind of singularity dealt with in this paper.

The test model is shown in Figure 7.

Figure 7: test model

A mixing volume (VolumeA1) is connected to two fluid sources (SourceQ1, SourceP1) and a fluid sink (SinkP1) via a pipe (Tube) and two control valves (Valve1 and Valve2). The test scenario consists in performing a flow reversal, and then setting all mass flow rates to zero.

SourceQ1	The specific enthalpy is constant equal to 1.e5 J/kg.  The mass flow rate follows the following curve (kg/s vs. s).
----------	---

SourceP1	The specific enthalpy is constant equal to 1.e5 J/kg.  The pressure is constant equal to 3 bars.
SinkP1	The temperature is constant equal to 320 K  The pressure is constant equal to 1 bar.
Valve1	The position varies from 100% to 0% in 2 seconds starting from t = 1 s.
Valve2	The position is constant equal to 100%

Four simulation runs are performed:

- Run 1.1: without diffusion, with upwind scheme
- Run 1.2: without diffusion, without upwind scheme
- Run 2.1: with diffusion, with upwind scheme
- Run 2.2: with diffusion, without upwind scheme

For each run are plotted:

- The mass flow rates at each connected port of the mixing volume (3 curves)
- The specific enthalpy inside the mixing volume (1 curve)
- The specific enthalpies inside each source and sink (3 curves).

Figure 8 gives the mass flow rates for all runs (no difference in results for all runs).

Figure 8: mass flow rates for runs 1 and 2

**Runs 1.1 and 1.2**

Figure 9 gives the specific enthalpies for run 1.1, and Figure 10 gives the specific enthalpies for run 1.2.

**Figure 9: specific enthalpies for run 1.1**

**Figure 10: specific enthalpies for run 1.2**

For run 1.1, when all mass flow rates are set to zero (at  $t = 8$  s), the specific enthalpy in the mixing volume keeps its last value prior to the zero mass flow rates condition, just as though there were some kind of memory holding this value when all mass flow rates become zero. This is probably an artifact due to the numerical methods used to solve the algebraic equations. The result is physically correct, but this looks as sheer luck as the theory predicts that the result is in fact mathematically undefined when diffusion is neglected.

To the contrary, for run 1.2, when all mass flow rates are set to zero (at  $t = 8$  s), the specific enthalpy in the mixing volume continues to vary until it takes a seemingly final constant value. This is a false transient which is of course unphysical because, since the model is static, all values should stay constant when the boundary conditions are constant (after  $t = 8$  s).

In both cases, the theory predicts that the mixing enthalpy can take any value when all mass flow rates are zero and diffusion is neglected, so the result is consistent with the theory.

**Runs 2.1 and 2.2**

Figure 11 gives the specific enthalpies for runs 2.1 and 2.2 (no difference in results for both runs).

**Figure 11: specific enthalpies for runs 2.1 and 2.2**

When all mass flow rates are set to zero, the specific enthalpy in the mixing volume takes the value that corresponds to the thermal equilibrium between the mixing and the sources and sink it is connected with, which is a correct physical result. The transition to thermal equilibrium is sharp but continuous.

The following table gives the computing times in seconds and the sizes of the non-linear systems after manipulation for each run with Dymola.

Run	CPU time	Sizes of non-linear systems
1.1	0.125	{ 3, 1 }
1.2	1.22	{ 3, 1 }
2.1	0.219	{ 4 }
2.2	0.313	{ 7 }

The conclusion from this experiment is that the best solution is to take into account diffusion in the energy balance equation, but still use the upwind scheme, i.e. neglect diffusion in the flow reversal equation. The overhead over the standard approximation of neglecting diffusion everywhere is 75%.

More diverse experiments should be made in order to decide whether it is better to take into account diffusion in the flow reversal formula or not, because avoiding the upwind scheme enables to remove the discontinuity due to the use of the step function.

**6 Conclusion**

Neglecting diffusion in thermal-hydraulics systems is a common approximation when dealing with large mass flow rates, as diffusion is only significant when mass flow rates are near zero.

However, this approximation leads to undefined values for the mixing enthalpies when all mixing mass flow rates are equal to zero. This is due to the fact that convection, which is the only thermal phenomena taken into account when diffusion is neglected, vanishes when mass flow rates go to zero, so there is no physical phenomenon left to describe the thermal physical state inside the mixing volume.

A rigorous mathematical and physical solution to this problem is to reinstall diffusion in the energy balance equation. This solution indeed removes the singularity for zero flows in a continuously differentiable way, as theoretically demonstrated in this paper.

A prototype implementation has been made in the ThermoSysPro library for power plant modelling, developed by EDF. The introduction of diffusion into the library has an impact on the structure of connectors.

The prototype has been tested on a small static model that features a mixing volume connected to fluid sources. The test scenario consists in performing a flow reversal, then bringing all flows to zero. The results are consistent with the theory developed in this paper. They also show that the upwind scheme, which is the equation for computing flow reversal that neglects diffusion, can be kept, as reinstalling diffusion in the flow reversal equation as well does not make any difference in the computing results, but provokes a significant overhead in computing time. However, more numerical experiments should be made to confirm this last point.

## 7 Notations

$P_a$  : fluid pressure in volume  $a$

$h_a$  : fluid specific enthalpy in volume  $a$

$u_a$  : fluid specific internal energy in volume  $a$

$\rho_a$  : fluid density in volume  $a$

$V_a$  : volume of volume  $a$

$W_a$  : external energy brought to the volume  $a$

$Q(b \rightarrow a)$  : mass flow rate of the fluid flowing from volume  $b$  to volume  $a$

$\nabla T(b \rightarrow a)$  : temperature gradient from volume  $b$  to volume  $a$

$h_{b,a}$  : specific enthalpy of the fluid flowing from volume  $b$  to volume  $a$

$(c_p)_{b,a}$  : specific heat capacity of the fluid flowing from volume  $b$  to volume  $a$

$k_{b,a}$  : diffusion coefficient at the interface between volumes  $b$  and  $a$

$A_{b,a}$  : area of the interface between volumes  $b$  and  $a$

$L_{b,a}$  : distance between the centers of volumes  $b$  and  $a$

$G_{b,a}$  : more generally, value of quantity  $G$  at the interface between volumes  $b$  and  $a$

## Abstract

Accurate and computationally efficient borefield models are important components in building energy simulation programs. They have not been implemented in Modelica so far. This paper describes the implementation of an innovative approach to model borefields with arbitrary configuration having both short-term (minutes) and long-term accuracy (decades) into Modelica. A step response is calculated using a combination of a short-term response model which takes into account the transient heat transfer in the heat carrier fluid, the grout and the immediately surrounding ground, and a long-term response model which calculates the boreholes interactions. Moreover, an aggregation method is implemented to speed up the calculations. Validation shows good results and very high computational efficiency.

*Keywords: Borefield; short- and long-term; Modelica; Aggregation method;*

## 1 Introduction

Building energy simulations have gained significant importance in the last decades resulting in several dynamic simulation platforms such as EnergyPlus [1] and TRNSYS [2]. Modelica might become the next generation tool for energy system simulations in buildings and communities as is the aim of the IEA EBC Annex 60 project. To achieve this goal, libraries are developed to simulate a wide variety of energy systems in buildings. Accurate and computationally efficient borefield models have not been implemented in Modelica so far, even though they play and will play an important role in recent and future buildings.

The open-source Modelica Buildings library developed by the Lawrence Berkeley National Laboratory (LBNL, US) is the only freely available library which has a U-tube single borehole model [18]. The borehole

model is similar to the EWS model implemented in TRNSYS (type 451, [17]). The model solves the transient heat flux in the ground by discretizing the surrounding ground in several cylindrical layers up to a radius of 2 meters from the borehole center. The layer temperature at this outer radius is calculated using an approximation of the line-source theory together with superposition. This temperature is updated every week in order to avoid too intensive calculations. The heat carrier fluid (HCF) and the grout (i.e. the filling material of the borehole) are simulated dynamically but their capacities are lumped. A triangle thermal resistance network is used to describe the heat transfer into the borehole heat exchanger (BHX) (i.e. from the HCF to the borehole wall). In the vertical direction, the borehole and the surrounding ground are divided into adiabatic horizontal layers. The model is not suited for multiple borehole simulation.

The E.ON Energy Research Center (Germany) also developed a single borehole model for single U-tube and coaxial type [11]. The pipe model is connected to an axially and radially discretized cylindrical ground model. A fixed temperature boundary condition is used for the ground model. The model does not take the dynamics of the grout into account and multiple borehole simulation is not possible.

Several models are implemented in TRNSYS. The Superposition Borehole Model (SBM), developed by Hellström, gives a detailed three-dimensional model for the transient thermal process in a borefield which has been implemented into TRNSYS [16]. The model can simulate single or multiple, vertical or inclined boreholes. The dynamics of the BHX is not taken into account and the computation time is very high. The Duct Heat Storage model (DST), developed by Hellström, calculates the transient thermal process for multiple borehole configurations, uniformly positioned in a cylindrical volume. The model does not take the dynamics of the BHX into account but it is fast and

it calculates the interaction between the boreholes (it uses pre-computed  $g$ -functions obtained by the SBM). Its TRNSYS implementation (type 557) can be used together with a separate program called BORE to calculate the borehole thermal resistance depending on the flow rate and the temperature [16].

To the author's knowledge, no model has been implemented in building simulation programs so far, which (i) is able to simulate any arbitrary configuration of boreholes, (ii) allows coaxial, U-tube type or double U-tube type BHX, (iii) has short- and long-term accuracy for minute-based year-long simulations, and (iv), is numerically efficient. The aim of this paper is to propose a new model, implemented in Modelica, which meets the above mentioned requirements. No ground water flow is taken into account.

Section 2 describes the model and Section 3 handles the computation of the response function and an aggregation method to speed up the computation. Finally Section 4 and 5 validate the model and give an example including a CPU-time comparison with the existing borehole model of the Buildings library. The main conclusions are summarized in section 6.

## 2 Bore field model

The proposed model is a so-called hybrid step-response-model (HSRM). This type of model uses the borefield's temperature response to a step load input. An arbitrary load can always be approximated by a superposition of step loads. The borefield's response to the load is then calculated by superposition of the step-responses using the linearity property of the heat diffusion equation. The most famous example of HSRM for borefields is probably the  $g$ -function of Eskilson [9]. The major challenge of this approach is to obtain a HSRM which is valid for both minute-based and year-based simulations. To tackle this problem, a HSRM has been implemented. A long-term response model (LTM) is implemented in order to take into account the interaction between the boreholes and the ground temperature evolution of the surrounding ground. A short-term response model is implemented in order to describe the transient heat flux in the BHX to the surrounding ground. The two models are merged into one HSRM in order to achieve both short- and long-term accuracy.

In this section, the long-term and the short-term response models are described.

### 2.1 Long-term response model

The long-term temperature response of the borefield is calculated using the model of Javed and Claesson [12]. This model is the current state-of-the-art and it proposes a compact expression to calculate the mean temperature of the borehole wall (average over the different boreholes of the borefield and over the length of each borehole).

The model is based on the spatial superposition of finite line-sources of equal length, each representing one borehole of the borefield. The finite line-source is calculated from the convolution of a point source of constant power along the depth of the borefield. The mirror of the solution at  $z=0$  is subtracted to ensure that no heat transfer occurs between the ground and the ambient air. After several mathematical manipulations to simplify the calculation, Javed and Claesson obtain the following compact expression for the mean borehole wall temperature:

$$\bar{T}_{mbhw}(t) = \frac{q_0}{4\pi\lambda} \int_{1/\sqrt{4\alpha t}}^{\infty} \left( \sum_{i=1}^N \sum_{j=1}^N e^{-r_{i,j}^2 s^2} \right) \frac{I_{1s}(Hs)}{Hs^2} ds \quad (1)$$

where  $q_0$  is the heat flux per meter length,  $\lambda$  is the ground heat conductivity,  $\alpha$  is the ground heat diffusivity ( $\lambda/(\rho c_p)$ ),  $N$  is the number of boreholes and  $H$  is the depth of the borefield.  $I_{1s}$  is defined by Eq. 2-3 and  $r_{i,j}$  by Eq. 4:

$$I_{1s}(h) = 4 \operatorname{ierf}(h) - \operatorname{ierf}(2h) \quad (2)$$

$$\operatorname{ierf}(x) = \int_0^x \operatorname{erf}(u) du = x \operatorname{erf}(x) - \frac{1}{\sqrt{\pi}} (1 - e^{-x^2}) \quad (3)$$

where  $\operatorname{erf}$  is the error function,

$$r_{i,j} = \begin{cases} r_b & \text{if } i = j \\ \sqrt{(x_i - x_j)^2 + (y_i - y_j)^2} & \text{if } i \neq j \end{cases} \quad (4)$$

where  $r_b$  is the BHX radius and  $(x_i, y_i)$  are the spatial coordinates of the center of each borehole from an arbitrary reference point.

Eq. 1 is valid for  $t > \frac{5r_b^2}{\alpha}$ , i.e after the transient part of the heat transfer through the BHX is completed [9]. The model also makes an important approximation by assuming uniform heat flux for all boreholes. The (long-term) accuracy of the model decreases for long simulation times for configurations with non-uniform heat fluxes, e.g. densely packed rectangular grid. For

more information about this approximation, we refer to Malayappan and Spittle [14]. Finally, the analytical solution assumes a uniform initial ground temperature equal to its average value.

Eq. 1 is implemented as a Modelica function. The integral of Eq. 1 and Eq. 2 are evaluated using the adaptive Lobatto rule implemented in the `Math.Nonlinear` of the Modelica Standard Library. The error function, however, is not implemented in Modelica. The publicly available c-code of Okumura [15] is compiled using the ability of Modelica to call external code.

## 2.2 Short-term response model

The short-term response model (STM) should be able to calculate the transient thermal response of the HCF, the grout and the surrounding ground accurately for time periods ranging from minutes to  $t = \frac{5r_b^2}{\alpha}$  (typically  $< 200$  hours). The interaction between the boreholes for these short times can be neglected, therefore a single borehole model is used.

The implemented STM is able to simulate boreholes with a co-axial, single-U-tube or double-U-tubes configuration. The model can compute the step response of a single borehole or that of a set of boreholes in series. Vertical discretization is also possible in case of an initial ground temperature gradient but no vertical heat transfer is computed except through the HCF. The main STM elements are the HCF, the pipes, the grout, the surrounding ground and the undisturbed ground temperature. Fig. 1 illustrates the model structure for a set of single-U-tube boreholes in series.

The dynamics of the HCF is calculated using the Fluid base classes of the open-source Buildings library [18] (`PartialFourPortInterface`, `PartialTwoPortInterface`, `TwoPortFlowResistanceParameters`, `LumpedVolumeDeclarations`) and the Media library from the Modelica Standard Library. The convection resistance between the HCF and the pipe is calculated by the correlation for smooth pipe in turbulent flow regime of Dittus-Boelter in the case of single- and double-U-tubes. For the circular-tube annulus, the correlation of Petuhkov and Roizen is used. For more information about the correlations we refer to Hellström [10].

The transient heat transfer from the internal wall of the pipes to the borehole wall is calculated using the thermal resistive-capacitive models (TRCM) derived by Bauer et al. [3]. These authors propose to extend the resistance model of Hellström for heat transfer in

the BHX (see [10]) to a dynamic model by adding capacities to it. For the case of a single U-tube, they also propose an empirical formula to approximate the multipole method of Bennet et al., using heat conduction shape coefficients and correction terms depending on the shank spacing divided by the borehole diameter. The correction terms are derived from an extensive set of simulations. The method is developed for coaxial, single U-tube and double U-tube types of borehole. The position of the capacities is calculated to be at the area center of the borehole with an equivalent single pipe.

Finally, the heat transfer from the borehole wall to the surrounding ground is calculated by discretizing the ground using a TRCM. The mesh is generated according to Eskilson's guidelines [9]:

$$\Delta r = [\Delta r_{min}, \Delta r_{min}, \Delta r_{min}, \beta \Delta r_{min}, \beta^2 \Delta r_{min}, \dots] ,$$

$$\Delta r_{min} = \min(\sqrt{\alpha \Delta t_{min}}, H/5) ,$$

with  $\alpha$  the diffusivity of the ground,  $H$  the depth of the borehole,  $\Delta t_{min}$  the minimum resolution time and  $\Delta r$  the size of the cell. The discretization has been tested with the analytical Cylindrical Source Model developed by Carslaw and Jaeger [7] and it shows very good agreement when the mesh is chosen fine enough. The width of the ground layer is by default equal to three meters but it can be adapted. The heat port at the external side of the layer is connected to a constant prescribed temperature equal to the initial undisturbed ground temperature. The heat flux at the external side of the ground layer is indeed very low from short simulation time.

## 3 Computation of the response function and aggregation method

The STM gives an accurate step response of the borefield as long as the diffusion length of the thermal process is small compared to the radius of its ground layer model or to the distance between the boreholes. The LTM is able to correctly compute the step response of the ground for a long time horizon as well as the interaction between the boreholes. It does not calculate, however, the borehole thermal resistance and its transient behaviour, contrary to the STM. The full response function is then obtained by lifting the LTM response to the STM response in the time interval where both models are still valid as shown in Fig. 2. As Javed mentions in his work [12], this interval is quite large (default value in model = 200 hours). Physically,

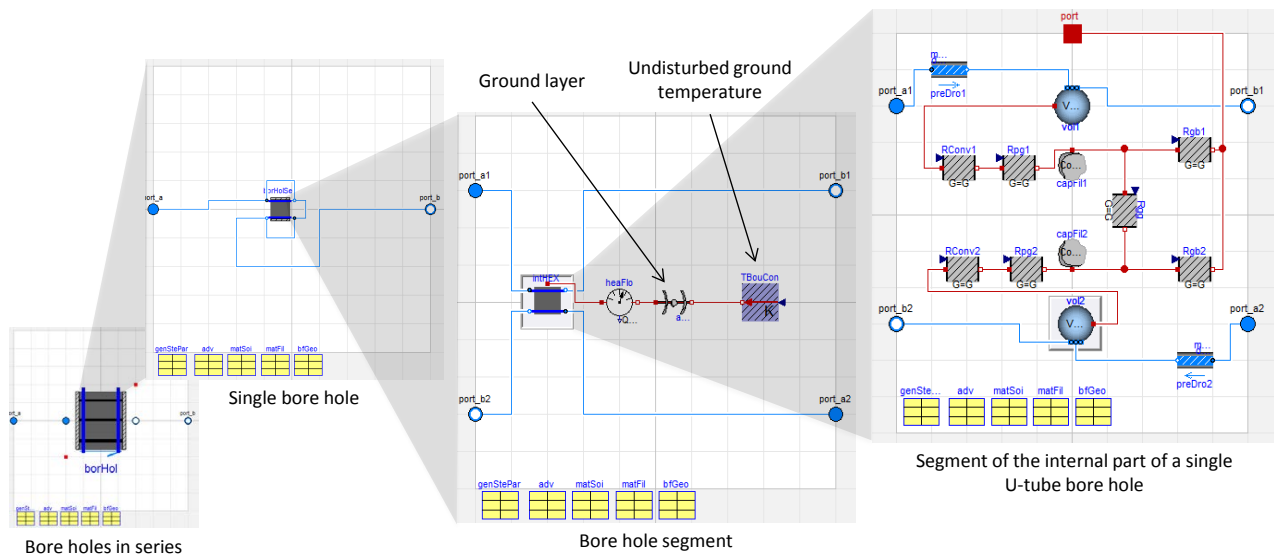

Figure 1: Implementation of the short-term model for boreholes in series in Modelica.

Figure 2: Combination of the long-term temperature step response ( $T_{LTM}$ ) with the short-term temperature step response ( $T_{STM}$ ) to compose the global temperature step response ( $T_{HSRM}$ ).

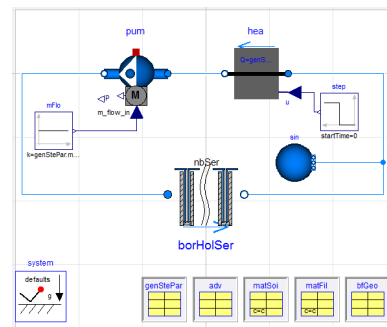

Figure 3: Model for the short-term temperature step response. The boreholes in series (*borHolSer*) are connected to a pump (*pum*) and to an ideal heater (*hea*). All the parameter values are stored in the records (bottom of the figure).

this interval begins when the transient behaviour of the BHX is over and it lasts until the interactions of the boreholes start to appear. The combination of both STM and LTM gives an accurate response function for both short- and long-term.

The response-function can be calculated at the start of each simulation or it can be priorly saved with a sample time equal to time resolution of the model. Until now, only the response of the STM is priorly saved in the implemented model in order to increase the computational speed but to avoid large files containing the full response function. The STM is connected to a pump and a prescribed heater/cooler from the Buildings library (see Fig. 3). A script-function automates the simulation of the STM and it writes the sampling values of its temperature response in the

Dat a package of the model as .txt file. The file is read at the initialization of the model in order to build the full response function of the HSRM.

As described above, g-functions and most of the analytical models give only a step response solution for the borefield. In order to model arbitrary input signals, the inputs need to be represented by a sum of time-shifted step signals and their responses should be superposed.

For minute-based multi-year simulations where the individual step response of each input step should be summed, this approach leads to enormous calculations. This problem is solved by using an aggregation method. The following paragraphs describe the technique of Claessons and Javed [12]. The notation has been adapted to gain clarity.

Assume that the discrete load input to the borefield is  $Q$  and the HCF temperature is  $T_f$ .  $Q$  and  $T_f$  can be written as:

$$Q_v^{(n)} := \begin{cases} Q[(n+1-v)h], & \text{if } v \leq n. \\ 0, & \text{otherwise.} \end{cases} \quad (5)$$

$$T_f(nh) - T_f(0) = \sum_{v=1}^{v_{\max}} \frac{Q_v^{(n)}}{Q_{\text{step}}} [T_{f,\text{step}}(vh) - T_{f,\text{step}}(vh-h)] \quad (6)$$

with  $v_{\max} \geq n$ ,  $h$  the discrete time-step,  $Q$  the discrete load and  $T_{f,\text{step}}$  the response function from HSRM with step load  $Q_{\text{step}}$ . Notice that the model assumes a uniform temperature at time 0.

The idea behind this aggregation is the following: the HCF temperature difference of the borehole system (from an initial steady state) at  $t = nh$  depends on the  $nh$  load pulses which have been applied to the borehole system from  $t = 0$  to  $nh$ . However, the influence of the pulses on the HCF temperature decreases the further they are from the observation time  $nh$ . If the pulses happened long before the observation time, the transient behaviour of the BHX has faded out, and only the net energy injection or extraction of the pulse is important. This net energy injection or extraction will indeed increase or decrease the global temperature of the borefield. An accurate profile of the load, far away from the observation time, is therefore not necessary. On the contrary, the load profile at times close to the observation time is important because they still influence the transient behaviour of the borefield and immediate surrounding ground.

Claesson and Javed proposed an aggregation algorithm grouping (i.e. taking the average of) the load pulses and their coefficients into cells of exponentially increasing size. The cells are themselves grouped into  $q$  levels. Each level has a given number of cells  $p_{\max}$  and each cell of a same level contains the same amount of load pulses  $R_q$ . Javed and Claesson propose to double the size of the cells at each level, in order to have the same number of cells in each level and finally in order to choose this number of cells per level according to the desired accuracy (a higher number of cells per level gives a more detailed load profile but penalizes the computational efficiency).

Eq. 6 is now rewritten to implement the aggregation method. Notice that the temperature difference of the HCF between two time steps in Eq. 6 divided by the amplitude of the step load  $Q_{\text{step}}$  can be considered

as the transient thermal resistance of the borehole for that particular time. Let us define the transient thermal resistance  $R_v$  and the dimensionless factor  $\kappa_v$  as:

$$R_v = \frac{T_{f,\text{step}}(vh) - T_{f,\text{step}}(vh-h)}{Q_{\text{step}}} \quad (7)$$

$$\kappa_v = \frac{T_{f,\text{step}}(vh) - T_{f,\text{step}}(vh-h)}{T_{f,\text{step}}(\infty)} = \frac{R_v}{R_{ss}}. \quad (8)$$

Eq. 6 can now be rewritten as:

$$T_f(nh) - T_f(0) = R_{ss} \sum_{v=1}^{v_{\max}} Q_v^{(n)} \kappa_v. \quad (9)$$

with  $R_{ss}$  the steady state thermal resistance.

As explained above, the aggregation is consisting of  $q_{\max}$  levels, each composed of  $p_{\max}$  cells which have a level-dependent width  $R_q$  defined as:

$$R_q := 2^{q-1} \quad \text{for } q = 1, \dots, q_{\max}. \quad (10)$$

The number of pulses covered by the aggregation is then:

$$v_{\max} := \sum_{q=1}^{q_{\max}} R_q p_{\max} \geq n_{\max}. \quad (11)$$

Define  $v_{q,p}$  as the number of pulses covered from cell 1 at level 1 till (including) cell  $p$  at level  $q$ :

$$v_{q,p} := p R_q + \sum_{i=1}^{q-1} R_i p_{\max}. \quad (12)$$

Define the function  $v(q, p, r)$  numbering each pulse, starting from pulse 1 in cell 1 at level 1:

$$v(q, p, r) := v_{q,p} - R_q + r \quad \text{for } q = 1, \dots, q_{\max}, \\ p = 1, \dots, p_{\max}, \\ r = 1, \dots, R_q.$$

These different definitions are illustrated in Fig.4.

Using these definitions, Eq. 9 can be rewritten as:

$$T_f(nh) - T_f(0) = R_{ss} \sum_{q=1}^{q_{\max}} \sum_{p=1}^{p_{\max}} \sum_{r=1}^{R_q} Q_{v(q,p,r)}^{(n)} \kappa_{v(q,p,r)} \quad (13)$$

Now we apply the aggregation technique by approximating the last sum of Eq. 13 by

$$\sum_{r=1}^{R_q} Q_{v(q,p,r)}^{(n)} \kappa_{v(q,p,r)} \approx \left[ \frac{\sum_{r=1}^{R_q} Q_v^{(n)}}{R_q} \right] \sum_{r=1}^{R_q} \kappa_{v(q,p,r)} := \bar{Q}_{v(q,p)}^{(n)} \bar{\kappa}_{v(q,p)} \quad (14)$$

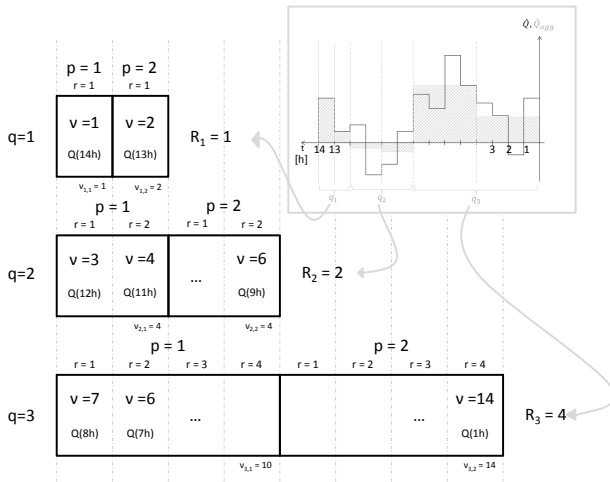

Figure 4: Illustration of the aggregation method for a load of 14 hours with time steps (pulses) of one hour. The number of levels is three and each level has two cells. The size of the cells is doubled at each level.

Finally the aggregation of Eq. 9 gives:

$$T_f(nh) - T_f(0) \approx R_{ss} \sum_{q=1}^{q_{max}} \sum_{p=1}^{p_{max}} \bar{Q}_{v(q,p)}^{(n)} \bar{\kappa}_{v(q,p)}. \quad (15)$$

The term  $\bar{\kappa}_{v(q,p)}$  is a matrix with the transient thermal resistance of each cell of the aggregation and it is independent of the load. This matrix is currently calculated at the initialization of each simulation. For repetitive simulations using the model and the same simulation length, the matrix can be priorly calculated and saved to gain significant calculation time. The term  $\bar{Q}_{v(q,p)}^{(n)}$  is a vector with a length equal to the number of aggregation cells and which is composed of the aggregated past load pulses. At each new discrete simulation time, a new load pulse needs to be added and the previous pulses need to be shifted in the  $\bar{Q}_{v(q,p)}^{(n)}$  vector. This means re-calculating the whole vector. Claesson and Javed developed a method which avoids this time consuming re-calculation by updating instead the load vector from the previous time step. The method is based on the shift of each cell to the next one and it has been applied to our model. An error, however, is introduced due to mixing in the cells. Claesson and Javed concluded after a detailed study that the error can be neglected. For example, in case of a simulation of 20 years using the aggregation method with each level having 5 cells, the error compared to the non-aggregated solution is lower than 0.1 K (for more information about the method and accuracy, see Claesson and Javed [8]).

Note that the left-hand term of Eq. 15 is only an

approximation of its right-hand term due to the approximation made in Eq. 14. The error, however, is negligible if the number of cells is sufficiently high. By default, the number of cells by level is five and the size of the levels increase exponentially with base two.

## 4 Model validation

The STM and the LTM have been verified by their respective developers. To avoid coding error and to check and generalize the validity of the model, the model verification has been extended.

The STM is compared to the widely used sandbox experiment of Beier et al. [5]. These authors have carefully performed a thermal response test using a U-tube BHX. The U-tube is grouted into an aluminium pipe of 18 meters long which is placed into a box filled with homogeneous sand. An electrical heater injects a constant heat rate to the HCF and a pump insures a constant flow rate. All ground and grout properties are presented in the paper, except the heat capacities. The ground capacity has been estimated by Beier using a best fit method ( $c_v = 3.2MJ/m^3K$ ) [4]. For the grout a heat capacity of  $4MJ/m^3K$  is used. The HCF temperature is measured at the in- and outlet as well as the BHX wall and sand temperatures at various depths. It should be noted that the aluminium pipe around the grout acts as a thermal fin which reduces the borehole thermal resistance by evening out its wall temperature. The HCF temperature should therefore be lower for the experiment than for the models which do not take this fin effect into account (see Lamarche 2010 [13]). Fig. 5 compares the average of the in and outlet temperatures of the HCF for the case of the experiment, the Buildings model, TRNSYS model (type 557a, DST) and the implemented HSRM. The Buildings model dynamics is clearly too slow. This is due to the position of the lumped capacity of the grout, as illustrated by Bauer et al [3]. In the Buildings model, the grout capacities are positioned at the pipe wall instead of the area center of each grout zone. Adapting the capacity location (which requires also the adaptation of the resistances), the problem is solved (*Buildings adapted*). TRNSYS DST model and HSRM give similar results. DST, however, does not incorporate the short-term thermal dynamics of the fluid, contrary to the new model HSRM.

The LTM is verified using the well known g-function developed by Eskilson and the infinite cylindrical heat source (CHS) solution for different configurations (the data are taken from the paper of Bertag-

Figure 5: Comparison between the heat carrier fluid temperature from the sandbox experiment ([5]), the borehole model from the Buildings library and its adapted version, type 557a of TRNSYS (DST) and the new hybrid model (HSRM).

nolio [6]). Fig. 6 illustrates the case of a 110 meter deep single borehole. The error of the implemented model compared to the  $g$ -function never exceeds 0.11 K during the 25 year-long simulation. The difference is caused by the so-called end effect of the borehole because the analytical solution uses a finite line-source approximation whereas the Eskilson finite volume model is three-dimensional (boundary difference at the foot of each borehole). The CHS model is clearly unable to model the end effect. Fig. 7 illustrates the case of a borefield with a square 8x8 configuration, respectively. The length of the boreholes is 110 meters and the relative distance between the boreholes to length ratio equals 0.05. Due to the very compact configuration, a large error appears, as Malayappan and Spitler warned for [14]. The error comes from the assumption that each borehole injects or extracts the same amount of heat, regardless of its relative position in the borefield. In reality, the boreholes at the edge of the borefield will inject/extract more than the center ones and as a consequence, the average borefield temperature will be lower. The end effect error is negligible compared to the large error ( $> 7K$  after 25 years for this case) introduced by the homogeneous heat source approximation. However, if the borefield is dissipative enough, the model shows very good results (e.g. see Fig. 8 for a line configuration of eight boreholes). For simulation with yearly thermal ground balance (amount of injected heat = amount of extracted heat), the configuration error is partly counteracted and it will not cause significant accuracy issues.

Figure 6: Average temperature step response of the borehole wall of a single borehole calculated by the  $g$ -function ( $g$ -func), the infinite cylindrical source with aggregation method (CHS-MLAA) and the new hybrid model (HSRM).

Figure 7: Average temperature step response of the borehole walls of a borefield with 64 boreholes in filled square configuration ( $B/H=0.05$ ) calculated by the  $g$ -function ( $g$ -func), the infinite cylindrical source with aggregation method (CHS-MLAA) and the new hybrid model (HSRM).

## 5 Example

This section describes an example of a borefield subjected to a varying non-symmetric load with a time-step of 4 hours proposed by Bernier et al [6]. The CPU and the fluid temperature of the Buildings model and those of the HSRM model are compared for a simulation of one year in the case of a single borehole and the case of three boreholes in series (Fig. 11). The Build-

Figure 8: Average temperature step response of the borehole walls of a borefield with 8 boreholes in line configuration ( $B/H=0.05$ ) calculated by the  $g$ -function ( $g$ -func), the infinite cylindrical source with aggregation method ( $CHS$ - $MLAA$ ) and the new hybrid model ( $HSRM$ ).

ings model is composed of the Buildings component `Boreholes.UTube`, an ideal heater and a pump (see Fig. 9 for the case of three boreholes in series). The  $HSRM$  model uses the same setup but the Building boreholes are replaced by the  $HSRM$  (Fig. 10). A step response of 200 hours is calculated with the STM prior to the simulation, in order to calculate the short term part of the response function. The interaction between the boreholes is taken into account by the  $HSRM$  but not by the Buildings model.

As seen above, the Buildings model underestimates the borehole resistance which is also visible in Fig. 11 where the fluctuations of HCF temperature of the Buildings model have a smaller amplitude than those of the  $HSRM$  model.

The analysis of the CPU times illustrates very clearly the difference between the models. In the case of a single borehole, the  $HSRM$  model is about twelve times faster than the Buildings model. The  $HSRM$  has a longer initialization time due to the calculation of the aggregation matrix, but it calculates the temperature response very fast. In the case of three boreholes in series, the  $HSRM$  is about 60 times faster. The initialization time is longer than for a single borehole because the superposition of the temperature field of the boreholes needs to be calculated. However, once the aggregation matrix is calculated, the calculation time is the same for any configuration. This is not the case for the Buildings model.

Figure 9: Model of three boreholes in series with a variable heat load (described by Bernier et al. [6]) and a constant mass flow rate, using components of the Buildings library.

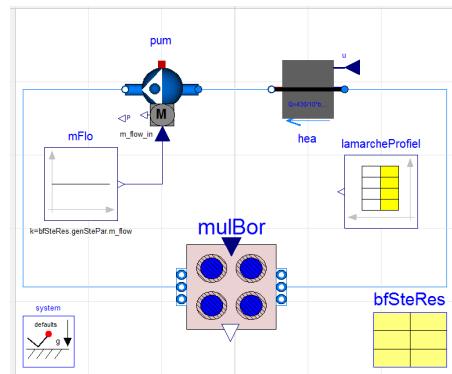

Figure 10: Model of three boreholes in series with a variable heat load (described by Bernier et al. [6]) and a constant mass flow rate, using the new borefield ( $multBor$ ) model and components of the Buildings library.

## 6 Conclusion

A new hybrid model for borefields with arbitrary configuration having both short-term (minutes) and long-term accuracy (decades) has been successfully developed and implemented in Modelica. The model has been validated for both short- and long-term. Thanks to its aggregation method, the implemented model is about twelve times faster than the borehole model of the Buildings library for the case of a single borehole and about 60 times faster for the case of three boreholes in series. The long-term accuracy of the model decreases for compact borefield configuration. This can be solved by plugging a  $g$ -function in the model instead of calculating the temperature step response.

# Superheat Control with a Dynamic Inverse Model

Andreas Varchmin<sup>1</sup> Manuel Gräber<sup>2</sup> Wilhelm Tegethoff<sup>1,2</sup> Jürgen Köhler<sup>1</sup>

<sup>1</sup> Technische Universität Braunschweig, Institut für Thermodynamik

<sup>2</sup> TLK-Thermo GmbH

## Abstract

Superheat control has influence on the coefficient of performance (COP), the stability and the compressor endurance of a vapor compression cycle. In an increasing number of applications electronic expansion valves are used. This leads to more complex control tasks. It raises the question if simulation models can be used for feedforward control to fulfill this function. For building a feedforward control structure a simulation model needs to be inverted. In this paper a continuous submodel of a refrigeration cycle, consisting of models for expansion valve and evaporator, is inverted. The resulting controller is tested in a model-in-the-loop environment and applied on an automotive refrigeration cycle. The advantage of a dynamic inverse model in contrast to a static one is pointed out. Also the results are compared to a standard PI controller.

*Keywords: inverse models; superheat control; vapor compression cycles; feedforward control*

## 1 Introduction

Superheat has several effects on refrigeration and heat pump cycles. The coefficient of performance (COP), the stability and the compressor endurance are dependent from a reasonable degree of superheat. Superheat control is a challenging task since the system dynamics of a refrigeration cycle are highly nonlinear and the control targets can be contrary. A higher degree of superheat leads to a smaller COP but is more secure against damage from liquid drops inside the compressor. Moreover due to the inherent characteristics of vapor compression cycles there exists an instability region at small degrees of superheat that expresses in a fluctuating temperature. This region can be described by the minimum stable superheat line (MSS) [1, 2]. Hence, the target of control structures is to set a small degree of superheat with considering the robustness against crossing the MSS line.

In the last years electronic expansion valves (EXV) are used in an increasing number of applications, e.g. electronic vehicles. With EXVs superheat and thus stability and COP can be controlled directly in contrast to thermostatic expansion valves (TXV) or orifice valves. New control approaches can benefit from this additional degree of freedom.

In the last decade a lot of effort has been made to build models for describing the behavior of vapor compression cycles. Model libraries like *TIL* or *Air Conditioning* have been developed to simulate various systems. It seems consequential to use this knowledge not only for simulation but also for control. One approach for model based control is inverting the simulation models.

Using inverse models for feedforward control is common in control theory [3]. Inverting a model means to swap inputs and outputs and reform the model equations so that the inputs can be calculated when having knowledge of the outputs. In this way the actuating variables can be calculated depending of the desired system output. Modelica is convenient for inverting models since it is an equation-based language instead of signal-oriented. One of the main purposes of every modelica tool is to transform ODE- and DAE-systems. This is exactly the challenge of inverting models. For a convenient introduction in inverting models in Modelica see [4].

Often static models are used for feedforward control. In this paper a dynamic model is proposed for controlling the superheat. This has advantages if the desired system output is not a constant or if measurable dynamic disturbances act on the system.

## Structure of the Paper

In section 2 a continuous system model of the refrigeration cycle is introduced. One part of the model, a submodel consisting of expansion valve and evaporator, is needed for feedforward control. The complete system model is used for model-in-the-loop tests and as an observer during measurement. In section 3 the

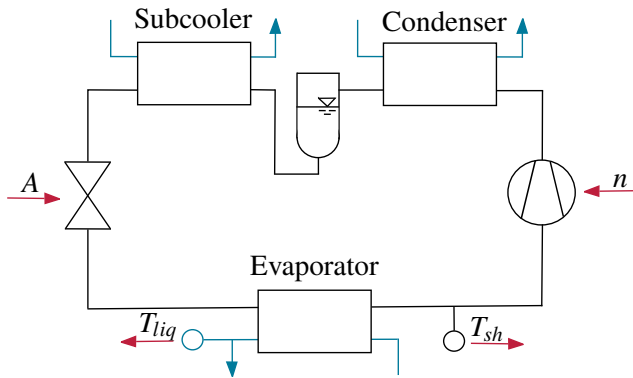

Figure 1: Modelled Refrigeration Cycle

inversion of the submodel is shown. The developed inverse model is tested in a model-in-the-loop environment in section 4. The potential of the transient inverse model in relation to a static one is also presented. Section 5 describes the test bench setup and shows how the complete system model is used as an observer. Measurement results of the inverse feedforward control are shown in section 6 as well as closed loop control where the inverse model is coupled with a PI controller. The measurement results are compared with regular PI control results.

## 2 System Model of the Refrigeration Cycle

The modelled system is a basic refrigeration cycle consisting of a compressor, an EXV, three plate heat exchangers and a receiver (see figure 1). R134a is used as refrigerant. The compressor is a variable speed scroll compressor. On the high pressure level there are two heat exchangers: condenser and subcooler. In between lies the receiver to ensure that subcooling exists in all operating points. In the outlet of the evaporator the degree of superheat is measured. A 50/50 mixture of water and glycol flows in the secondary paths of all heat exchangers. In terms of control the valve opening  $A$  and the compressor speed  $n$  can be defined as inputs and the actual degree superheat  $T_{sh}$  and the temperature of the cooled liquid  $T_{liq}$  as outputs.

Most of the model approaches are based on the model library *TIL* (see [5]). For the inversion new models with functions and interfaces were developed. All physical properties are calculated with *TILMedia* by use of refrigerant and liquid objects or explicit function calls (see [6]).

The dynamic compressor model is loss-based and has a suction and a discharge volume where the phys-

Figure 2: Inverse Model

ical properties of the refrigerant are calculated. The model parameters are fitted to the compressor in the test bench described in section 5. The EXV model originates from Bernoulli's principle and is therefore a static model. Delays that may come from the actuator of the valve are not considered even if they can not be neglected. Section 3 deals with this problem. All heat exchangers are modelled with a variable number of finite volumes. Per volume exist three cells, one for the refrigerant, one for the liquid and one for the wall dividing the fluid paths. The refrigerant cell includes transient mass, energy and momentum balances. The time derivative of pressure is constant over all refrigerant cells of a pressure level [7]. The liquid cell includes transient balances for mass and energy. Pressure drop is neglected in both liquid and refrigerant cells. The wall cell includes a transient energy balance. The receiver between the two high pressure heat exchangers is modelled as a volume with transient mass and energy balances and a varying filling level.

## 3 Inverting the Submodel

For representing the complete system dynamics for feedforward control it is desirable to invert the whole system model described in the previous section. With linear analysis of the refrigeration cycle it can be shown that an inversion of the complete model is not reasonable due to possible non-minimum phase characteristics. This would lead to an unstable system model. Hence, in this paper only a submodel is used for feedforward control. The inverted model consists of the evaporator and valve models.

The resulting inverse model is shown in figure 2. The easiest way creating it is using the MSL Block *InverseBlockConstraints* that changes in- and outputs. The desired superheat  $T_{sh}$  is now an input and the resulting valve opening  $A$  an output. The outlet liquid temperature of the evaporator, that is equivalent to

the cooling capacity, shall be controlled by the compressor speed and is therefore not needed for superheat control. Since the inverse model does not include the whole system dynamics boundary conditions are needed. One combination of possible boundaries is shown in figure 2. High and low pressure as well as the refrigerant inlet enthalpy of the valve are needed to simulate the model. Moreover the mass flow rate and temperature of the evaporator inlet need to be known. This information can be provided by simulation data when using the inverse model in a model-in-the-loop environment. For use as a hardware controller measurement data and/or data from an observer can be used (see section 5).

The valve opening is dependent from the opening actuator time delay. This delay can be approximated as a first-order time delay. Reforming the ODE system gets more complicated because of an additional continuous state that makes it necessary to derive more equations and to give access to second derivatives with respect to time of physical properties. For these reasons including the valve actuator delay was not possible at the time of writing this paper.

The inverse model forms an ODE with 15 continuous states. For calculating the saturation temperature dependent from pressure, that is needed for calculating the superheat, a function from TILMedia is used. Also the time derivative of this function is provided. For comparison also a (nearly) stationary inverse model is build. When eliminating the continuous states several systems of nonlinear of equations result. To prevent these hardly solvable systems the capacities of the continuous states are chosen very small so that a nearly stationary model is generated.

## 4 Simulation Results

This section starts with results regarding the sole inverse model and continues with model-in-the-loop (MiL) tests. In figure 3 the response of the inverse model to a change of the superheat is shown. The superheat follows the reference trajectory besides a small difference. This comes from a filter that smoothes the reference trajectory to make it differentiable. Otherwise the model would not be invertible (see also [4]). The actuating variable, the valve opening area, fluctuates mainly at the changes of the reference trajectory derivative at 0s and 5s. A real-world EXV may not be able to follow the actuator trajectory. The high peaks, especially at 5s and 6s, are mostly important to follow the gradient of the set point change.

In most applications it is not necessary to follow this gradient exactly.

Figure 3: Behavior of Inverse Model to Setpoint Change of Superheating Degree

Figure 4 shows a set point change in a MiL environment. A transient and a static inverse model work as feedforward controllers in this example. It is obvious that the transient model can make the system model follow the reference trajectory a lot better. The static model is not able to represent the dynamics of the system and can not follow the reference trajectory. In both simulations the set point is not reached exactly. This arises from model uncertainties between inverse and system models. The valve opening fluctuates more than in the previous simulation of the sole transient model. Because of the two pressures and the valve inlet enthalpy there exists a coupling between the whole system model and the inverse model in MiL simulations. This leads to a more dynamic system. Summarizing the transient feedforward control offers a big potential for the response to setpoint changes.

Besides the response to setpoint changes the behavior towards disturbances is a main attribute for reliable and robust control. One of the advantages of feedfor-

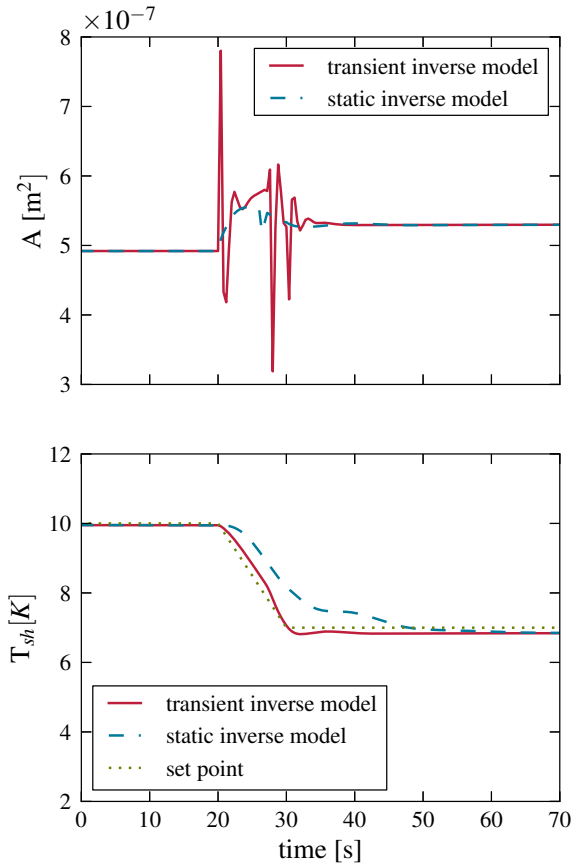

Figure 4: Comparison between Static and Transient Inverse Model Control (Model-in-the-Loop)

ward control combined with feedback control is that these behaviors can be divided. Mostly the feedforward part is mainly responsible for responses to set-point changes so that the feedback part can be designed for reacting on disturbances and model uncertainties. If the disturbances are measurable also feedforward control can handle them and even improve the control scheme. In the described process model disturbances can be imagined as changes in input temperatures of the secondary loop cycles or as changes in the compressor speed. The compressor speed can be controlled as well and is therefore known. A change in compressor speed has influence on pressures and mass flow rate of the refrigerant cycle. This information is provided to the inverse model that can react on this disturbance. An example is shown in figure 5 where the compressor speed is raised from 2000 rpm to 3000 rpm at time 0. Results are shown for feedforward control including a model uncertainty and a PI controller. The PI controller reacts as recently as the measurement signal deviates from the set point. The superheat rises from 10 K to approximately 15 K. The feedforward

controller reacts at time 0 when the compressor speed rises. The superheat stays under 11 K. Even if the PI controller could be optimized further for reacting on this disturbance it can never react as fast and precise as the inverse model.

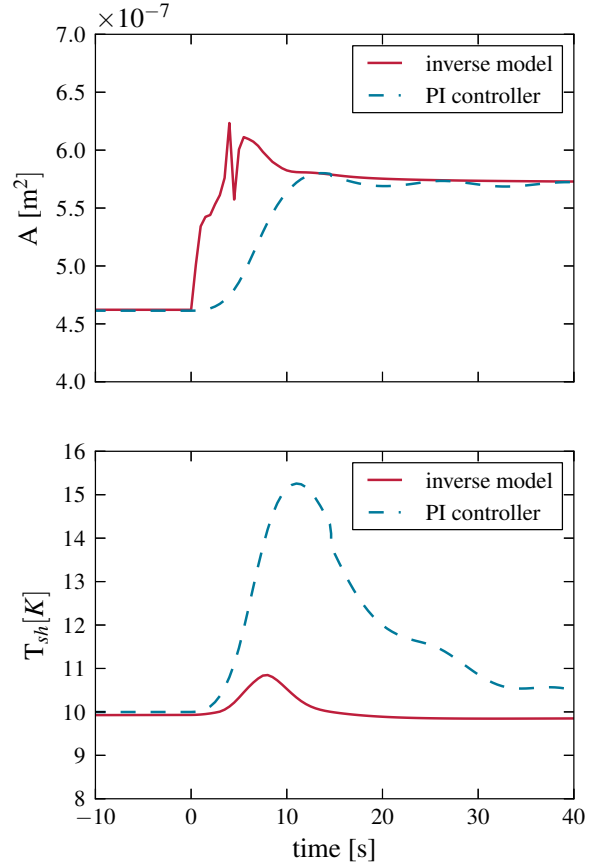

Figure 5: Behavior of the System Model towards Disturbance (Change of Compressor Speed): Comparison between Inverse Model Control and PI Controller

## 5 Test Bench Setup

The developed controller is tested on a refrigeration cycle that has the dimension of an automotive air conditioning application (see figure 6). The compressor is a direct current scroll compressor with variable speed as it is used in electric vehicles. As heat source and sink controllable secondary loop cycles filled with a glycol water mixture are connected with the plate heat exchangers. The EXV is driven by a stepper motor with constant adjusting speed. The motor needs a voltage signal for positioning the actuator. The voltage is calculated by a linear correlation with the valve opening area as input. The degree of superheated is measured with two thermocouples, one at the inlet and

one at the outlet of the evaporator. The difference of the measured temperatures will equal the superheat if there exists two-phase refrigerant at the inlet which is the case during all measurements. The measured inlet temperature can be verified by the measured inlet pressure that is bound to the evaporation temperature.

Figure 6: Test Bench with compressor, evaporator, condenser and expansion valve

A system model of the complete cycle (see section 2) is used as an observer. The current compressor speed and measured liquid temperatures and mass flow rates at evaporator, condenser and subcooler are made available to the observer. With this information it calculates high and low pressure and the valve inlet enthalpy that are needed by the inverse submodel.

The controller, consisting of the described inverse model for feedforward control and an optional PI controller for closing the control loop, and the observer are modelled in Dymola. The control scheme is shown in figure 7. Dymola is coupled with Labview in a co-simulation environment. Labview reads the measurement data and sends process inputs, e.g. valve opening area. One time step has a length of 0.1 s.

Figure 7: Inverse Model in Combination with PI Controller for Closed Loop Control

## 6 Measurement Results

In this section the developed model-based controller is applied to the test bench described previously. Results with the lone inverse model and combined with an PI controller are shown. For comparison also results generated with a lone PI controller are shown.

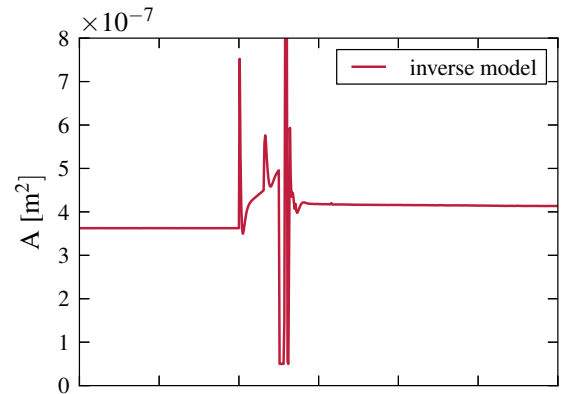

Figure 8: Comparison of model-based controller to setpoint change

In figure 8 the refrigeration cycle behavior to a set point change is shown. The setpoint follows a five second lasting ramp from 15 K superheat to 12 K. At 0 s the degree of superheated lies at approximately 13 K. The deviation arises from model uncertainties. In particular the uncertainties come mainly from a differing mass flow and unexact calculation of the heat transfer coefficients. Since no feedback loop is implemented in this case there is a stationary deviation. The sensor value drops nearly as fast as the setpoint and reaches its stationary value after circa six seconds. The measured superheat change is smaller than the demanded which also results from the described model uncertainties. The shown valve opening area does not picture the achieved opening area but the demand of the in-

verse model. The high peaks arise from the harsh bend in the set point ramp and the missing actuator delay in the inverse model. These peaks are filtered before directing the signal to the valve. Omitting the peaks the valve opening area rises nearly linear, then drops to a point beneath the new stationary value and rises again to the new stationary value. Summarizing apart from an error in stationary values the inverse model feedforward controller can change the degree of superheat fast and as demanded.

In the following the feedforward controller is combined with a PI controller to compensate the mentioned model uncertainties. There exist several rules to design the parameters of a PI controller when combined with feedforward control. In this case the feedforward controller gets information from the observer, especially the actual pressures. This means that the inverse model, even if called feedforward controller in this paper, has a kind of feedback loop implemented. High and low pressure react on a changing valve opening which for its part has influence on pressures. Hence, designing the PI controller is more challenging and standard design rules can not be used without adaptation. In this paper the parameters of the PI controller for combination with the inverse model are therefore iteratively chosen and will not be optimal.

For comparison with a standard PI controller typical design rules can be used for parametrization. In this paper the from Åström and Hägglund as a Ziegler-Nichols replacement introduced *AMIGO* method [8] is applied. For using this approach a measured step response is needed. The aim is to maximize the integral gain by modeling the step response with a dead time and a first-order block. Hence, three parameters have to be tuned to represent the step response. With knowledge of these parameters the PI control parameters can be obtained by simple, explicit equations.

In figure 9 a comparison between the developed model-based controller and a lone PI controller is shown. Compared to the lone feedforward control (fig. 9) the measured superheat meets the set point since the integral gain can compensate model uncertainties. The developed controller is able to drop the superheat more quickly but does undershoot the new setpoint a bit. This probably comes from the non-optimal cooperation of inverse model and PI controller. Improving this could lead to a fast and sharp response as with the lone model-based controller. The PI controller is slower but does less undershooting. It is important to mention that the PI controller is tuned for this exact operating

point. Providing this quality for other operating points would mean to have an at least two-dimensional gain scheduling to compensate different compressor speeds and evaporator inlet liquid temperatures. The actuating variable in figure 9 is shown as voltage since the lone PI controller does not give an opening area value. It can be seen that the model-based controller can calculate a more transient actuator signal.

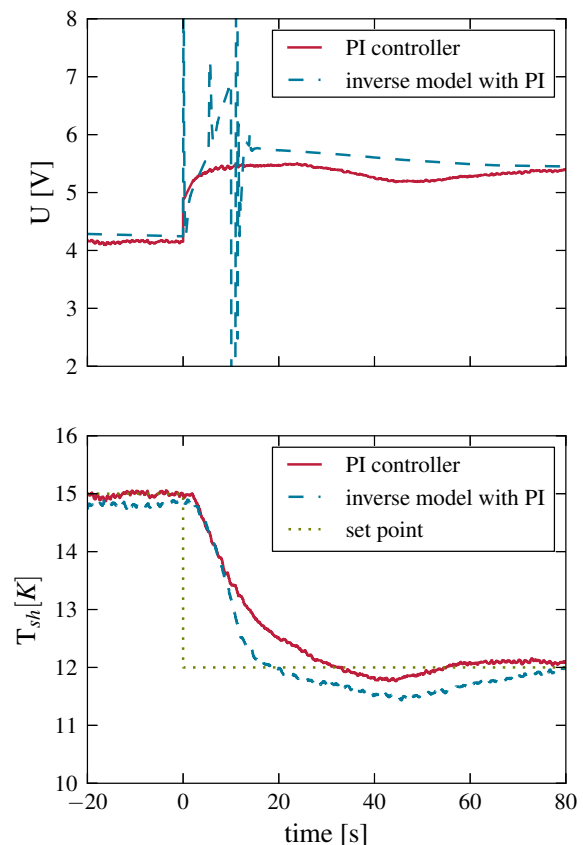

Figure 9: Comparison between reactions of model-based controller (including PI controller) and PI controller to setpoint change

## 7 Conclusion

In this paper a superheat controller based on an inverse model of valve and evaporator was developed and tested in simulations and measurements. The controller can react faster on set point changes than an optimized PI controller. The biggest advantage is the compensating reaction on measurable disturbances like changing compressor speed / cooling capacity. In contrast to PI control the model-based controller works in several operating points without parameter changes or gain scheduling. Further improvements

can be accomplished by including the valve actuator delay in the inverse model. Furthermore the interaction with a PI controller for compensating on model uncertainties and non-measurable disturbances can be enhanced.

## Abstract

A library for dynamic modeling adsorption based thermal systems like chillers, heat pumps, thermal storages or desiccant units is presented. Adsorption devices can serve a wide range of applications but usually consist of the same basic components. By modeling these basic components, the presented model library allows to investigate any interesting topology. Thereby this adsorption library gives the user the opportunity to design and optimize adsorption systems quickly and efficiently. To demonstrate the flexibility of the library and the accuracy of the simulations, three validated examples are presented: A desiccant unit; a thermal storage; and an adsorption chiller.

*Keywords:* adsorption; simulation; validation; modular; chiller; thermal storage; heat pump; desiccant

## 1 Introduction

Physical adsorption of a fluid on a solid surface is a reversible exothermic process which can be efficiently employed in energy systems. Adsorption phenomena can be used to build a wide variety of thermal devices: e.g. heat driven chillers and heat pumps; high density storages; or desiccant units [1, 2]. Since all these devices enable the use of waste heat or solar heat, they can provide heating and cooling demand more efficiently than conventional devices, and thereby help to reduce CO<sub>2</sub> emissions. To exploit this CO<sub>2</sub> reduction potential, adsorption based thermal devices have

to be well designed. The design of adsorption systems is challenging due to their intrinsic dynamic nature: During operation, adsorption devices switch between ad- and desorption phases, meaning they work discontinuously. In addition, they have a characteristic energy output peak at the beginning. Besides, adsorption devices consist of several components, all being influencing the performance. In an optimal design, these components need to be balanced avoiding oversized components on the one hand and bottlenecks on the other. To meet this optimal design challenge, time-dependent models have been developed to describe and improve adsorption based devices (see e.g. [3, 4, 5]). These models have been developed mainly to study the performance of one specific configuration. To enable the library presented here to describe all kinds of adsorption based thermal devices, a generic modular approach is taken to model the adsorption process. To the best knowledge of the authors only the model of Schicktanz and Núñez describes an adsorption chiller by using a modular approach [6]. By dividing the chiller in its basic components, this approach allows components to be exchanged. Joos et al. presented a modular Modelica library for separation processes including adsorption [7], that can be used to model separation processes, but is not designed for thermal applications, in contrast to the presented library in this paper.

In Section 2, the adsorption phenomenon is described briefly. In Section 3, the library structure and both its basic and enhanced models are described. To illustrate the library, Section 4 contains three examples of validated adsorption systems.

## 2 Adsorption

Adsorption describes the process of attaching fluid molecules to the surface of a (porous) solid, so called sorbent. For a detailed introduction, the reader is referred to Kärger, Ruthven and Theodorou [8]. The internal energy  $u$  of the adsorbed fluid is lower than of the liquid phase and the vapor phase, leading to an exothermic process:

$$u_{ad} < u_l < u_v . \quad (1)$$

This difference between the energies of the liquid and the adsorbed phase is called bond energy. The amount of fluid (adsorbate) adsorbed by the sorbent is described by the loading:

$$w = \frac{m_{ad}}{m_{sor}} , \quad (2)$$

and depends on both the system temperature  $T$  and pressure  $p$ . The relation between loading, temperature, and pressure is described by the thermodynamic equilibrium, which is specific for every working pair. Working pairs (solid / fluid) often used for thermal applications are for example zeolite / water, silica gel / water, and active carbon / methanol. Equilibrium data is used to determine start and end points of adsorption processes. The system dynamics are determined by heat and mass transfer which occur simultaneously: the fluid has to reach a free surface location where it can be adsorbed, while heat has to be transported within the porous solid at the same time. Mass transfer takes place by convective and diffusive processes. Heat transfer can usually be modeled by a mixture of heat conduction in the materials and contact resistances between them.

To control and use the adsorption process in thermal devices, sorbent material and working fluid are heated or cooled in a defined way. For this purpose, either sorbent or working fluid are connected to heat exchangers, building key components of an adsorption device: evaporator; condenser; or adsorber. By connecting the different components in the right way, it is possible to build chillers or heat pumps, thermal storages, as well as air drying units. For more information regarding the design of specific devices see also [9] and [10].

## 3 Library structure

The presented model library follows a modular approach. By coupling a reusable model (working pair

is exchangeable) of the adsorption process to heat exchangers, it enables the user to model a wide range of adsorption based devices.

The presentation in this section follows the library structure shown in Figure 1, by classifying the models as media, basic components, and enhanced components.

Figure 1: Structure of adsorption library

### 3.1 Media

As described in Section 2, the core of every adsorption based device is the working pair. The media model describes the working pairs characteristic properties: equilibrium data; internal energy of the adsorbed fluid ( $u_{ad}$ ); and specific heat capacity of both sorbent ( $c_{sor}$ ) and adsorbate ( $c_{ad}$ ).

In literature, many approaches describing adsorption equilibria can be found, e.g. the model of Langmuir [11], assuming adsorption only in one layer, the Brunauer, Emmet and Teller model (BET) [12], allowing adsorption in more layers, or the Dubinin model

[13], which is based on Polanyi's potential theory [14]. Which approach is used is not important for the media model as long as adsorbate pressure  $p_{ad}$  at equilibrium state can be described as a function of temperature  $T$  and loading  $w$ :

$$p_{ad} = f(T, w) . \quad (3)$$

The specific energy in the adsorbed state ( $u_{ad}$ ) is derived from the used adsorption model.

The total heat capacity of sorbent and adsorbate  $c_{tot}$  is the sum of the individual heat capacities:

$$c_{tot} = c_{sor} + w c_{ad} . \quad (4)$$

In the present library, most equilibrium data are described using the Dubinin model.

The properties of the fluid are based on TILMedia [15], a library provided by TLK-Thermo GmbH.

### 3.2 Basic components

The following components are the smallest units the library consists of. All extended components and device models are based on these basic components.

#### Adsorbent

In the adsorbent model, equilibrium data, provided by a media model, and mass and energy balances for sorbent and working fluid are combined. The adsorbent is described by a lumped model; i.e., with a homogeneous temperature, loading and pressure distribution. State variables of the model are temperature  $T$  and loading  $w$ . Mass of fluid vapor within the adsorbent can be neglected, in other words, all working fluid within the adsorber is assumed to be in adsorbed state. The adsorbent model contains heat and fluid ports, allowing for heat and mass transfer (see Figure 2).

Figure 2: Scheme of adsorbent including the state variables: loading  $w$ ; and temperature  $T$ , as well as the connection ports: fluid (blue); and heat (red)

The mass balance of the working fluid is given by:

$$\frac{dm_{ad}}{dt} = m_{sor} \frac{dw}{dt} = \dot{m}_{fluid,in} - \dot{m}_{fluid,out} . \quad (5)$$

The energy balance is given by:

$$c_{tot} \frac{\partial T}{\partial t} + u_{ad} \frac{\partial w}{\partial t} = \frac{1}{m_{sor}} (\dot{m}_{fluid,in} h_{in} - \dot{m}_{fluid,out} h_{out} + \dot{Q}) . \quad (6)$$

The fluid is leaving the adsorber as vapor with adsorber temperature  $T$  and equilibrium pressure of adsorbent  $p_{ad}$ . The media model used can be changed easily, allowing for a high flexibility. For example, it is possible to investigate the influence on system performance of a changed working pair.

#### Heat transfer

The heat transfer model connects the adsorbent to a heat exchanger or to the environment. The heat flux is described by:

$$\dot{Q} = \alpha A \cdot \Delta T . \quad (7)$$

The implemented heat transfer coefficient  $\alpha$  can be changed. For example, it can be chosen to be a constant parameter or to be dependent on the flow velocity as in the air drying unit described (Section 4).

#### Mass transfer

Mass transfer to or from the adsorbent is described similarly to the heat flow as a linear function of a driving potential (LDF approach). As driving force, either the pressure difference between the pressure on the outside and adsorbate pressure ( $p$  and  $p_{ad}$ ), or the difference between actual and equilibrium loading ( $w_{ad}$  and  $w_{eq}$ ) can be used:

$$\dot{m} = \beta_p (p - p_{ad}) ; \quad (8)$$

or

$$\dot{m} = \beta_w (w_{ad} - w_{eq}) . \quad (9)$$

In this library, both equations are implemented. Since fluid entering the adsorbent is assumed to be adsorbed instantaneously, the mass transfer coefficient  $\beta$  includes not only convective flow resistances but also diffusive resistances occurring within the adsorbent. It is also modeled modular, allowing the user to choose between different models to determine mass transfer coefficient  $\beta$ , similar to the heat transfer coefficient (see also Section 4).

### Tube (heat exchanger)

Heat exchangers for closed adsorption systems are represented by a tube model based on TIL library [15]. The tube model is discretized in flow direction. Heat transfer on the inside is described similarly to equation (7) also using a changeable  $\alpha$ . For liquids, e.g Dittus-Boelter [16] or Sieder-Tate [17] correlations can be used. Also heat conduction within the tube wall is modeled.

### Gas volume (heat exchanger)

An open adsorption system is a system which is not sealed and therefore allows mass transfer between adsorption system and ambient. The ambient, more specifically the surrounding moist air, fulfills two tasks simultaneously: it allows for heat and for mass transfer. Therefore the ambient can be regarded as both, a form of heat exchanger as well as a form of evaporator or condenser. The surrounding air is modeled by a gas volume (see Figure 3). The state variables of the gas volume are gas temperature  $T$ , water mass fraction  $X$ , and air density  $\rho$ . To allow for a gas flow through the volume, the model has two gas ports. It also contains a heat port and a fluid port which are connected to the adsorbent to exchange water (working fluid for open systems) and heat.

Figure 3: Scheme of gas volume including the state variables: temperature  $T$ ; water mass fraction  $X$ ; and density  $\rho$ , as well as the connection ports: fluid (blue); heat (red); and gas (yellow)

The mass balance of the inert gas component (dry air) is:

$$\frac{dm_{\text{dryair}}}{dt} = \dot{m}_{\text{dryair,in}} - \dot{m}_{\text{dryair,out}} \quad (10)$$

The mass balance of water is correspondingly:

$$\frac{dm_{\text{water}}}{dt} = \dot{m}_{\text{water,in}} - \dot{m}_{\text{water,out}} + \dot{m}_{\text{water,ads}} \quad (11)$$

which can also be written as:

$$m_{\text{air}} \frac{dX}{dt} = \dot{m}_{\text{air,in}} X_{\text{in}} - \dot{m}_{\text{air,out}} X + \dot{m}_{\text{water,ads}} \quad (12)$$

with the water mass fraction:

$$X = \frac{m_{\text{water}}}{m_{\text{air}}} \quad (13)$$

The energy balance of the gas volume is given by:

$$\frac{dU_{\text{air}}}{dt} = \dot{H}_{\text{air,in}} - \dot{H}_{\text{air,out}} + \dot{H}_{\text{water,ads}} + \dot{Q} \quad (14)$$

Water is assumed to leave the gas volume as vapor with gas temperature  $T_{\text{gas}}$  and partial pressure  $p_{\text{water}}$ .

### 3.3 Enhanced components

The main component of an adsorption system is the adsorbent. For closed adsorption systems, also the evaporator and condenser are of major importance. The library already includes prebuild enhanced components, consisting of basic components. By parameter choice these enhanced components can be adapted for many applications.

#### Closed Adsorber

The closed adsorber model consists of an adsorbent model, a heat exchanger model, as well as models for heat and mass transfer (see Figure 4).

Figure 4: Scheme of closed adsorber model consisting of adsorbent (see Figure 2), heat exchanger (right), mass resistances ( $\beta_1$  and  $\beta_2$ ), and heat resistance ( $\alpha$ )

#### Moist Air Adsorber

The moist air adsorber model consists of an adsorbent volume, a gas volume and a wall volume. These volumes are again connected by models for heat and mass transfer (see Figure 5). The moist air adsorber model can be discretized in flow direction.

Figure 5: Scheme of moist air adsorber model consisting of an adsorbent (see Figure 2), a gas volume (see Figure 3), a mass resistance ( $\beta$ ), heat resistances ( $\alpha_1$  and  $\alpha_2$ ), and a wall model

## Evaporator / Condenser

The evaporator / condenser model consists of a vapor-liquid-equilibrium (VLE) fluid volume and a heat exchanger. The fluid volume is thermally connected to the heat exchanger and is assumed to be in the two-phase region. The model has a liquid and a vapor port. At the vapor port, the fluid leaves as saturated vapor; at the liquid port it leaves as saturated liquid.

## 4 Validated examples

The library presented in Section 3 is used to model several adsorption based devices. To demonstrate model accuracy, three validated examples are presented: an air drying unit; an adsorption thermal storage; and an adsorption chiller.

### 4.1 Adsorption dryer

An adsorption dryer or desiccant unit is used to simultaneously reduce air humidity and preheat the air. During adsorption, cold humid air enters the dry adsorber.

Until equilibrium state is reached water is adsorbed and the adsorption enthalpy is released. For regeneration of the unit by desorption, hot dry air flows through the adsorber. The air leaves the adsorber with a higher water loading and decreased temperature.

The adsorber model is validated using experimental data by Pesaran and Mills [18]. The used adsorber has a cylindrical shape and is filled with silica gel (Equilibrium data of silica gel is given in [19]).

The driving potential used for mass transfer is pressure difference  $\Delta p$  (equation (8)). Coefficients for mass and heat transfer are modeled by correlations dependent on the Reynolds number based on Hougén and Marshall [20]. Since the model determines the outlet temperature and mass fraction from the inlet values, geometries and input parameters, the model is predictive.

Figure 6 and 7 show temperature and water mass fraction during an adsorption process at adsorber inlet and outlet.

Figure 6: Air temperature  $T$  at inlet and outlet during adsorption

Figure 7: Water mass fraction  $X$  at inlet and outlet during adsorption

Validation shows good agreement in both, temperature  $T$  and mass fraction  $X$ . The input conditions are

changed suddenly at  $t = 0$ s, resulting in a step function. The output is reacting by an increase in outlet temperature due to adsorption heat emitted. Around 5 min after start, temperature peaks at  $46.9^\circ\text{C}$  and afterwards declines only slightly. By reaching a temperature of  $45.4^\circ\text{C}$ , simulation corresponds well to the measured peak after around 5 min. Water mass fraction between inlet and outlet is reduced by about  $0.01 \text{ kg}_{\text{water}}/\text{kg}_{\text{air}}$  with nearly dry air at the outlet. Measured and simulated water loading fit almost perfectly. Pesaran and Mills [18] have experimentally varied input parameters, adsorber length, and particle size of adsorbent grains in their experiments. For all six tested input variations simulation and the experiments agreed well (not shown).

## 4.2 Thermal adsorption storage

Thermal energy, stored in an adsorption storage, can be divided into a sensible and a latent part. Sensible heat increases with system temperature, while at the same time, latent heat is stored by desorption of water. The desorbed water leaves the adsorber as vapor and is condensed afterwards in the condenser. During condensation, low grade heat is emitted at medium or low temperature level, that can be either used or emitted to the ambient. When using the stored heat (discharging the storage), water is evaporated using low grade heat. The evaporated water flows to the adsorber where it is adsorbed and heat at process temperature is released.

The storage model is validated using experimental data from a storage prototype at our institute [21]. Figure 8 illustrates the thermal adsorption storage model. Since temperature difference between adsorber and evaporator is high and there is no insulation between these components, they are thermally connected in the model. For further details regarding the experimental setup see Binkert [22].

The working pair used in the experiments is zeolite 13X / water. Equilibrium data for this pair can be found in Núñez [23]. Heat and mass transfer coefficients were fitting experimental and simulation data. Optimization criterion used to determine fit accuracy is the root mean square deviation (RMSD) of adsorber heat. Figure 9 shows the adsorber heat flow during desorption, Figure 10 during adsorption. Desorption temperature increases to almost  $200^\circ\text{C}$ , with a condensation temperature of  $90^\circ\text{C}$ . After around 3 hours, the operation mode is switched from desorption to adsorption (loading to unloading). Adsorption takes about 30 min with adsorption temperature falling from  $200^\circ\text{C}$  to  $120^\circ\text{C}$ . Evaporation is kept at  $60^\circ\text{C}$  during

Figure 8: Scheme of thermal adsorption storage consisting of an adsorbent (see Figure 2), two heat exchangers (right), mass resistances, heat resistances, and an evaporator / condenser model

adsorption. Although time varies by factor 6 and heat flow even by factor 10, comparison between experimental data and simulations shows good agreement for both, desorption and adsorption. During desorption, the peak in heat flow at 15 min is slightly overestimated by the simulation, for adsorption it can be observed that the trend fits well. At the end of adsorption phase, slight differences between experiment and simulation occur, but they are still in a tolerable range.

Figure 9: Heat flow  $\dot{Q}$  of adsorber during desorption

## 4.3 Adsorption Chiller

The investigated adsorption chiller consists of an adsorber, an evaporator, and a condenser. These components are separated by valves, allowing to disconnect the adsorber from the evaporator and condenser separately. Because adsorption and desorption phases take place successively (Section 1), an adsorption chiller with only one adsorber bed operates discontinuously. During the adsorption phase, water is evaporated at a low temperature level (cooling output). The water

Figure 10: Heat flow  $\dot{Q}$  of adsorber during adsorption

flows to the adsorber where it is adsorbed and heat is emitted. Thus, the adsorber has to be cooled, which occurs at a medium temperature level. During the desorption phase, the adsorber bed is regenerated. By using the heat exchanger, heat is passed into the adsorber at a high temperature level. The desorbed water vapor flows to the condenser, where it is condensed at a medium temperature level again. The high temperature level is determined by the heat source available: mostly waste or solar heat. The medium temperature level is usually determined by the ambient temperature; and the low temperature level by the cooling application. An experimental setup of the described adsorption chiller at our institute is used for model validation. Figure 11 shows a schematic picture of the model, representing the experimental setup.

Figure 11: Scheme of adsorption chiller consisting of an adsorbent (see Figure 2), evaporator, condenser, mass resistances, heat resistances, and a water reservoir model

The model was investigated for both silica gel and zeolite 13X. In this paper we show validation for silica gel. A more in-depth validation can be found in Lanzerath [24], discussing the effects of varying input parameters and changed adsorbent materials. Equilibrium data for silica gel are implemented using the Dubinin approach from Schawe [25].

Coefficients for heat and mass transfer are used as fitting parameters. They are determined by using the experimental data of a complete cycle (adsorption and desorption) and minimizing the RMSD of heat flows between experimental and simulation data. The fitted heat and mass transfer parameters were kept constant for all variations of experimental settings and proved to be robust [24]. Figure 12 shows the adsorber heat flow, Figure 13 the heat flows of evaporator and condenser. Although only lumped models are used for adsorber, evaporator and condenser, it can be observed, that system dynamics, as well as steady state conditions, are predicted well.

Figure 12: Heat flow of adsorber

Figure 13: Heat flows of evaporator and condenser

## 5 Conclusion

An adsorption library, capable of modeling a wide variety of adsorption devices is presented. The models were validated using three examples: a desiccant system; an adsorption thermal storage; and an adsorption chiller. All examples show very good agreement of simulation results with experimental data. Thereby, the library is shown to be a valuable toolbox for research purposes, allowing to describe, analyze and improve the design and topology of adsorption based devices.

## Abstract

The HDF5Table library is an open-source solution for the efficient handling, exchange and interpolating access of typical data sets in system simulation. The library consists of C-functions, python scripts and examples and can be used with different applications like Modelica or Simulink. Furthermore a comprehensive set of tools that allows the user to create, migrate, edit, compare and manage the datasets is available.

The application range covers data import from measurements or other simulations, integration of datasets in preprocessing routines, the usage of the datasets in the simulation and the post processing of simulation results. To eliminate a major source of errors after data exchange between simulation tools or different companies and to validate the datasets each dataset can have a physical unit and quantity attached to it. The table data can be easily accessed with different methods for inter- and extrapolation. To persist and exchange the data sets a subset of the HDF5 standard is used. With the HDF5 API the data access is fast for large files with many variables containing millions of values and the datasets can be opened in many other tools.

*Keywords: HDF5; lookup tables; unit and quantity safety; interpolation; extrapolation*

## 1 Introduction

Lookup tables traditionally play a major role in industrial simulations. They are used in a wide range of applications where physical models or parameters are not available or the evaluation of the existing models is computationally too expensive. Real-time simulations and hardware-in-the-loop setups are two prominent examples. In these systems lookup tables are used to re-play recorded stimulus from measurements as well as pre- and post-processed data from

test benches. Another application is pre-calculated lookup tables from long running system or finite element simulations.

A number of solutions exist for Modelica and other simulation platforms some of which are discussed in detail in the following section. All of these solutions suffer from different limitations and problems the proposed implementation together with a set of supporting tools is trying to solve.

## 2 Existing Solutions

The Modelica Standard Library (MSL) provides a number of tables in its Blocks Package. A general separation is done based on the provided input functionality. Here the prefix Combi shows the capability of the table to either take direct user input in the form of parameters from the Modelica environment or to read data from files. In industrial applications the second option is nearly solely used as it is more convenient even for tables of modest size.

Table blocks for different needs are provided and therefore are split into the Blocks.Sources and the Blocks.Tables package. The separation into the packages is done as the tables in the Sources package implicitly define the single input of the table as the simulation time. These tables are mainly used for the playback of recorded continuous stimulus e.g. steering input or velocity signals over time. As these tables have a single input and are well suited for time series simulation they are not in the focus of this paper.

This leads to the Blocks.Tables package. These tables are often used to cover effects that cannot be modeled based on physics with reasonable effort or performance. Therefore tables are used to approximate the behavior depending on a varying number of inputs. Still for the tables in Blocks.Tables the number of inputs is limited to one or two which becomes a limiting factor in many applications. Therefore Dymola provides the DataFiles package that contains the TableND which extends the number of inputs to

a theoretically unlimited amount. As indicated by the missing prefix, data can only be read from .mat files. The DataFiles Package contains a number of functions that support the user with the generation of the necessary .mat files. Additionally some Matlab scripts are provided to support the data storing process.

Now at first glance for Dymola users there is the possibility to have capable tables in their simulations using either the MSL's Tables package or the DataFiles package. Still there are a couple of limitations to that which we want to point out now. The TableND's data format is limited to version 4 .mat files which limits the names in the file to 19 characters and – much more of interest here – limits the number of possible dimensions stored in the files to two. Therefore the multi-dimensional tables cannot be stored in their natural format but have to be converted. This problem is overcome by generating three vectors by convention named `dim`, `grid` and `table`. The length of the vector `dim` equals the number of dimensions of the table each entry indicating the amount of scale values in that dimension. In the variable “`grid`” the scales for all dimensions are stored implying that the length of `grid` has to be equal to the sum of the elements in `dim`. Finally in the table variable finally all values of the multidimensional table are stored in one vector. All of this makes it very hard to interpret the values in the table without suitable conversion scripts.

Another disadvantage of this solution is the different behavior of CombiTables and TableND when it comes to extrapolation. Whereas the CombiTables extrapolate linearly the TableND keeps values constant when exiting the defined area. For version 3.2.1 of the MSL efforts have been completed to make the implementation of the MSL tables open source and to enhance their functionality. New features include that outputs of tables can now be differentiated once, and newer .mat File formats are supported [7]. Still that does not have any influence on the limiting factors mentioned before, as this is only valid for the tables contained in the MSL.

### 3 Goals of the new Implementation

The goal of the proposed implementation is to come up with a library that provides a superset of the features of the existing solutions that is entirely open source and accompanied by comprehensive set of tools to leverage its functionality and ease the transition from existing solutions. The scope of possible applications for both tables and tooling goes beyond Modelica models since the tables can be easily port-

ed to other simulation platforms (e.g. Simulink, CarMaker) or integrated into custom C-based solutions. This takes the concept of separation of model and data to a higher level as data can be used independently from the simulation tool.

Furthermore one of the basic concepts of Modelica, namely unit and quantity safety is adapted for table-based data. Every dataset regardless of its dimensions can have a physical unit and quantity (and other attributes) attached to it which allows the table block to validate the data upon loading and eliminates a major source of errors that arises from incompatible data being used in the simulations.

Future versions of the library will also be able to record signals from a simulation and provide support for ‘compiled-in’ data which is especially useful for platforms that do not have a file system or to protect the intellectual property contained in the data.

## 4 Features

To provide a one-stop solution for all uses of table based data the table block features different methods to inter- and extrapolate the sampled data which are briefly presented in the following sections.

### 4.1 Interpolation

Generally two major uses of tables in models can be distinguished: the first is the playback of recorded continuous stimulus e.g. steering input or discrete data like bus events. Both types are usually one-dimensional and have the time as abscissa.

The second major use case for tables is found in models that cannot be physically modeled and thus use measured data to approximate their behavior or are too complex to be simulated e.g. in a real-time context. These table-based models usually depend on more than one parameter and thus require multi-dimensional tables. A prominent example in which both types of tables can be found are hardware-in-the-loop test benches.

The HDF5Table block provides three interpolation methods that can be configured on a per-instance basis: ‘Hold’, ‘Linear’ and ‘Akima’.

‘Hold’ will simply return the previous value in the respective dimension and can be used to playback time discrete data where interpolation does not make sense e.g. the selected gear in a vehicle.

‘Linear’ interpolates linearly between the neighboring sample points in each dimension.

‘Akima’ uses a spline based interpolation method proposed by Akima [5] where the interpolated func-

tion passes through the sample points and its first derivative is continuous.

Figure 1 Interpolation Methods

This has a positive impact on the stability of models that use the derivative in their calculations. Figure 1 shows the three interpolation methods applied to a one-dimensional dataset with six equally spaced sample points of a sine function.

#### 4.2 Extrapolation

Five methods are provided for extrapolation:

- Hold
- Linear
- Loop
- PingPong
- None

Similar to the interpolation ‘Hold’ simply repeats the last sample value in the respective dimension. ‘Linear’ uses the last two samples to linearly extrapolate. For the playback of time series it is often desired to infinitely repeat a given set of samples. ‘Loop’ repeats the recorded signal using the selected interpolation method.

The ‘PingPong’ method works similarly to the loop method but instead of starting over it goes back and forth along the respective axis. This method is especially useful for lookup tables used for devices that

have a symmetric characteristic field like electric machines. To better understand this method consider the following example of the loss characteristics of a permanent magnet synchronous machine (PMSM) given as the power losses versus rotational speed as the abscissa and the torque as the ordinate. Three different types of lookup tables are common for PMSMs: first quadrant, first and second quadrant and all four quadrants corresponding to the motor, motor and generator and motor and generator for positive and negative rotation directions. With the ‘PingPong’ method one table block can be used for all three types of tables without conditional instantiation or additional logic inside the model. Figure 2 shows the extrapolated curve of the five methods for a one-dimensional dataset with four equally spaced and linearly increasing samples. The extrapolation method “None” disables extrapolation and raises an error when requested value is outside the range of the table.

Figure 2 Extrapolation Methods

## 5 HDF5 File Structure

In order to efficiently store and exchange the data for the tables a subset of the HDF5 standard is used. Every table is stored as n-dimensional dataset of type Float64. The scales for each dimension are stored as separate datasets. For every dimension one scale dataset is attached to the table dataset using the HDF5 dimension scales API [3].

To store metadata like the physical units and quantities a set of attributes has been defined that is evaluated when reading the datasets. The following table lists the attribute names together with the required data type and an example value.

Attribute Name	Type	Example
QUANTITY	String	“AngularVelocity”
UNIT	String	“rad/s”
DISPLAY_UNIT	String	“1/min”

QUANTITY and UNIT denote the physical quantity and unit of the stored data. DISPLAY\_UNIT is the unit that is used to display the values to the user e.g. when editing them. The literals used to represent the units and quantities are the same as in Modelica and can be found in the Modelica.SIunits and Modelica.SIunits.Conversions.NonSIunits packages of the MSL.

Scales must always be one-dimensional and strictly monotonic increasing and there must be at most one scale attached per dimension whose length matches the extent of the dataset in the respective dimension. For a three-dimensional dataset with extent 2×3×4 the scale for the second dimension must have exactly three values.

Users may add custom attributes and datasets to store additional metadata, documentation or results and use groups [6] to structure the datasets.

## 6 Modelica

The HDF5Table Modelica library comes as a .mo file that contains the blocks, functions and examples together with the C header files and pre-compiled object libraries for the table and HDF5 as a ready-to-use package. The Modelica functions and blocks are presented in detail in the following sections.

### 6.1 Functions

To directly read and write scalars, vectors and matrices from and to HDF5 files the library includes the following functions that are similar to the readMAT\*

/ writeMAT\* functions in the DataFiles package that ships with Dymola:

- writeVector
- writeMatrix
- attachScale
- readScalar
- readScalarChecked
- readVector
- readVectorChecked
- readMatrix
- readMatrixChecked
- attachScale

The “checked” versions of the functions take the expected unit and quantity as an additional parameter and return an error code if the parameters do not match the unit or quantity stored in the loaded dataset.

The attachScale function attaches a dataset as the scale for the dimension of another dataset. All functions are realized as external C code that can be linked into the model or be called directly using the simulation tool as shown in the figure below.

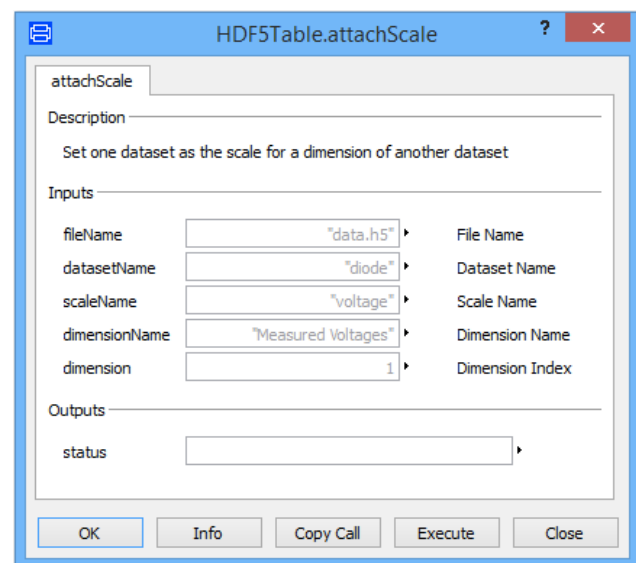

Figure 3 attachScale Function Dialog

The library can also read / write higher dimensional arrays (up to 32 dimensions). Entering higher dimensional arrays however can be cumbersome, as e.g. Dymola does not provide UI support for editing values with more than two dimensions.

### 6.2 Blocks

The core of the library is the NDTable block that loads and interpolates the data during the simulation. It takes the file name of the HDF5 file, the dataset

name and optionally the expected units and quantities of the dataset and scales as input and returns the inter- or extrapolated value for every time step. Figure 4 shows the parameters of the NDTable block with all quantities and units set for a dataset that holds the power losses of an electric machine as a function of rotational speed, torque and source voltage.

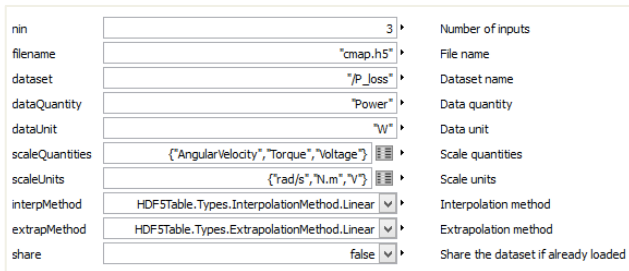

Figure 4 Parameters of the NDTable block

The DatasetRecorder block takes the scales as parameters and sweeps successively over the volume spanned by the scales by applying the actual scale values to the vector output. When a rising edge is detected on the trigger port it records the value on the in-port and applies the next set of scale values to the input until all samples in the volume have been recorded. Using this block tables with a large number of sample points can be generated without the overhead of restarting the simulation which can save a considerable amount of time.

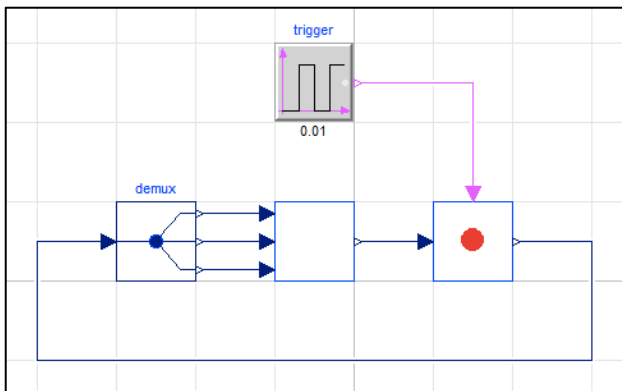

Figure 5 RecorderBlock Example Model

Figure 5 shows the RecordTable example model where the DatasetRecorder block is connected to a dummy model that has three in-ports and whose output is recorded upon every rising flank of the trigger.

## 7 Matlab / Simulink

Matlab and Simulink are two of the most commonly used simulation and scripting environments. Therefore the HDF5Table library also includes a Simulink

S-Function and Matlab scripts that allow users to reuse their existing datasets without changes on this platform. The Simulink table block has the same inter- and extrapolation methods as the Modelica library and the underlying S-Functions are based on the same C-sources which can be a major advantage when porting models to this platform that rely on the specific behavior of the implementation. Just like the Modelica library the Simulink library ships as a pre-compiled shared library that can be instantly used in Simulink.

## 8 Tooling

To leverage the tables in the simulation they are accompanied by a comprehensive set of tools that allow the user to create, migrate, edit, compare and manage the datasets. All tools are included in an Eclipse distribution that is used as an integration platform but can also be obtained and used separately.

The tools include a Python library based on matplotlib [8] and NumPy [9] to read, write, manipulate and plot data that can be debugged and run directly from within Eclipse using the PyDev environment [10]. Python's support for a large number of data formats allows the user to write import and export scripts for their existing data with minimal effort based on the provided examples. With the included Python scripts both the text based and binary data files used by the Blocks.Tables and Datafiles blocks can be converted to HDF5.

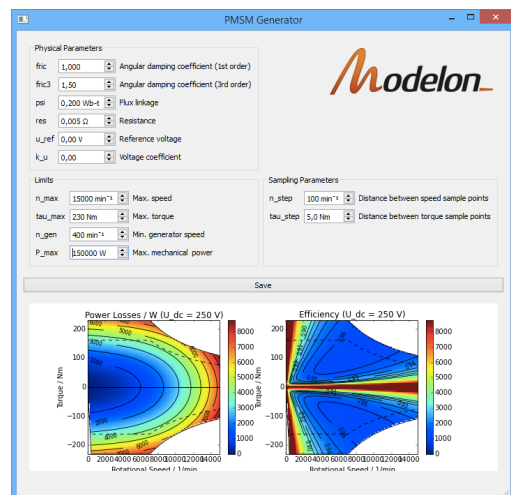

Figure 6 Python script with graphical UI

Figure 6 shows an example Python script with a graphical user interface that allows the user to create characteristic maps of electric machines for use with the NDTable block and that can serve as a basis for custom HDF5 generators or processors.

Furthermore an EMF [11] based editor is included that allows the user to conveniently view, edit and validate the data files. Finally the datasets can be compared and merged with the included EMF compare editor [12].

The figure below shows the HDF5 editor viewing the content of a three-dimensional characteristic map dataset with scales.

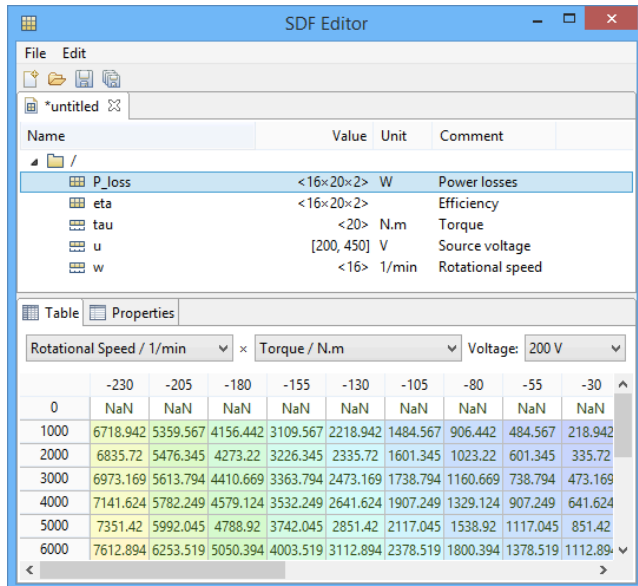

Figure 7 HDF5 Editor

In the editor values are displayed in “display units” and can be conveniently entered as expressions like “sin(pi/4)” to get the sine of a 45 degree angle or “ones(2, 3)” to get a 2×3 matrix of ones. All operations performed in the editor like copy & paste, move, delete etc. can be undone with the standard shortcuts or menu items. Drag & drop is supported to move datasets between groups and even between files.

## 9 Future Work

Currently the library is developed in Visual Studio 2010 for Windows. It is planned to port the library to the hardware and software platforms listed below.

Hardware Platforms:

- Windows 32 and 64 bit
- Linux 32 and 64 bit
- dSPACE SCALEXIO

- dSPACE DS1006

Compilers:

- Microsoft compilers (VC6 and  $\geq$  VS2005 (Win32 and x64))
- MinGW (GCC 4.4.0 and GCC 4.7.2)
- Cygwin (GCC 4.3.0)
- GCC 4.x on Linux

We are also planning to further extend the tooling and to include a comprehensive documentation and examples that showcase common uses and best practices. A future version of the library will include additional inter- and extrapolation methods (e.g. boundary slope extrapolation for the Akima method) and support for the Der() derivative of the interpolated values to reduce simulation time and improve accuracy [1].

## 10 Conclusions

The implemented library and its extensions show that most features of the existing tables in the MSL’s Blocks.Tables and the DataFiles package can be combined in a single table simplifying the application for the user. Additionally the error-proneness of the overall simulation process can be reduced substantially based on unit and quantity checks.

The use of open standards like HDF5 and Modelica guarantee that this open-source implementation is expandable and can be customized for different needs including wider tool support. To enable fast adaption of the presented library a set of tools is provided enabling the user to quickly generate new or migrate existing datasets.

{beutlich, kurzbach, schnabel}@itisim.com

## Abstract

This article reveals some implementation details regarding the C code of the revised table interpolation blocks released with the Modelica Standard Library (MSL) 3.2.1. The emphasis is placed on the unique features of the `CombiTimeTable` which are the discontinuities by time events and the periodic extrapolation. Basic information on the interpolation by Akima splines and the available table array memory optimization options are mentioned.

*Keywords:* univariate interpolation, bivariate interpolation, periodic extrapolation, time events, Akima splines

## 1 Introduction

For many years there has been no (open source) implementation of the table interpolation blocks of the MSL. Thus, Modelica simulation tools either did not support the table blocks or needed to provide a custom implementation that could lead to different simulation results. One objective of releasing a backward compatible MSL 3.2.1 was to provide an open source implementation of the table blocks based on the Modelica external object interface. This table implementation was named *Modelica Standard Tables* and comprises the following four blocks for univariate and bivariate interpolation

- `Modelica.Blocks.Sources.CombiTimeTable`,
- `Modelica.Blocks.Tables.CombiTable1D`,
- `Modelica.Blocks.Tables.CombiTable1Ds` and
- `Modelica.Blocks.Tables.CombiTable2D`.

The C header and source files of the Modelica Standard Tables are publicly available from <https://svn.modelica.org/projects/Modelica/trunk/Modelica/Resources/C-Sources>.

`//svn.modelica.org/projects/Modelica/trunk/Modelica/Resources/C-Sources`. The C interface functions all start with prefix `ModelicaStandardTables_`. The constructors and destructors of the external table objects have suffix `_init` and `_close`, respectively. If the table data is to be read from an ASCII text file or a MATLAB MAT-File, an interface function with suffix `_read` is used, i.e. file I/O is not part of the construction of the external table object. The actual interpolation functions are labeled by trailing `_getValue` and `_getDerValue` for the interpolation function and the interpolated derivatives, respectively.

## 2 CombiTimeTable

The block `Modelica.Blocks.Sources.CombiTimeTable` is different from standard univariate interpolation since discontinuities (by time events) and periodic extrapolation are considered. For instance, periodic and discontinuous signals like saw-tooth or square-wave w.r.t. simulation time can be modeled in a very convenient and compact way.

### 2.1 Time events

Time events always occur at the table boundaries ( $t_{min}$  and  $t_{max}$ ) of the sample points, i.e. if interpolation switches to extrapolation.

- In case of linear interpolation, additional time events can be modeled by repetition of sample points in the table array. It is guaranteed that there are no time events at interval boundaries with a simple sample point only. Thus the time coordinates are not required to be strictly increasing but monotonically increasing.
- In case of interpolation by constant segments, every interval boundary (defined by the sample

points) leads to a time event, whether or not there is an actual discontinuity in the ordinate values. The time coordinates are not required to be strictly increasing but monotonically increasing. In fact, repeated sample points are not appropriate for the interpolation result.

- Additional time events are not possible in case of interpolation with Akima splines. The time coordinates are required to be strictly increasing. (Thus care must be taken when changing the interpolation smoothness if there are repeated sample points.)

The static function `isNearlyEqual` from source file `ModelicaStandardTables` is used to tell if two double-precision floating-point numbers are (nearly) equal with relative threshold `_EPSILON` (set to  $10^{-10}$  by default).

The calculation of the next time event  $t_E$  is performed in the interface function `ModelicaStandardTables_CombiTimeTable_nextTimeEvent`. For numerical reasons related to the floating-point arithmetic used, the current time  $t$  is incremented by a small fraction of the time table length, that is  $\_EPSILON \cdot (t_{max} - t_{min}) > 0$ . It is guaranteed that  $t_E$  is greater than the current time  $t$  and that no time events are missed if the distance between two consecutive time events is greater than this numerical increment.

If no future time event is found `\_nextTimeEvent` returns `DBL_MAX`. Hence, care should be taken by a Modelica simulation tool to avoid floating-point overruns during the event handling.

For debugging purposes, time events can be traced (by means of `ModelicaFormatMessage`) by defining `DEBUG_TIME_EVENTS` where each message line corresponds to one time event. For instance, linear interpolation and extrapolation of the  $4 \times 2$  example time table  $[0.25, 30; 0.5, 40; 0.5, 10; 0.75, 30]$  results in three time events (Fig. 1).

Figure 1: Linear interpolation of time table  $[0.25, 30; 0.5, 40; 0.5, 10; 0.75, 30]$  results in three time events.

The four messages (including the initial event) are

```
At time 0.00000: 1. time event at 0.25000
At time 0.25000: 2. time event at 0.50000
At time 0.50000: 3. time event at 0.75000
No more time events for time > 0.75000
```

In order to return the correct function values at the time events (i.e. during the event iterations), the interface functions `\_getValue` and `\_getDerValue` require not only the next event time but also its pre-value as input arguments.

## 2.2 Periodic extrapolation

For tables with periodic extrapolation, the numerically stable detection of periodic time events is rather tricky.

A first implementation was discarded as it turned out that the periodic time events were not reliably detected in all cases. The main reason is due to the IEEE 754 binary floating-point arithmetic where  $t$  and  $t - n \cdot T$  cannot be used simultaneously to detect the exact location of an event interval or periodic time event. Here,  $t$  denotes the floating-point number (FPN) of the current time and  $T = t_{max} - t_{min}$  the FPN of the period of the table. Variable  $n$  is a signed integer and denotes the multiple of the period. Furthermore, let  $t_E$  be the FPN of the event time (to be detected) and  $t_i$  the FPN of the corresponding event interval boundary time from the table. There are FPNs such that the inequality  $t \geq t_E = t_i + n \cdot T$  is true, i.e. indicates a time event, but where a simple rearrangement of the inequality to the form  $t - n \cdot T \geq t_i$  does not hold. This illustrates the fact that floating-point operations cannot be used to exactly evaluate floating-point comparisons, and therefore cannot be used to reliably detect periodic time events.

The final implementation is based on (nonnegative) integers

- `nEventsPerPeriod`, the number of time events per period and
- `eventInterval`, the (discrete) event interval marker.

During the very first call of function `\_nextTimeEvent`, the number of time events per period is determined from the time coordinates of the table array. There is always a time event per period at the

table boundary, thus  $n\text{EventsPerPeriod} \geq 1$ . Furthermore, the start and end indices of each of the so-called *event intervals* are determined and stored in the integer array *intervals*.

As an example, the  $5 \times 2$  time table  $[0, 10; 0.25, 30; 0.5, 40; 0.5, 10; 0.75, 30]$  is considered.

- There are two time events per period in case of linear interpolation. The indices of the event intervals are  $[0, 2]$  and  $[3, 4]$ , i.e. the first interval ranges from time 0 to time 0.5 and the second interval from 0.5 to 0.75 (Fig. 2).

Figure 2: Two time events per period

- There are three time events per period in case of interpolation by constant segments. The indices of the event intervals are  $[0, 1]$ ,  $[1, 2]$  and  $[3, 4]$ . Repeated sample points are ignored since their ordinate values can never be taken by the interpolating function (Fig. 3)

Figure 3: Three time events per period

The event interval marker `eventInterval` uses one-based indexing. It is properly initialized once in the very first call of function `_nextTimeEvent` since interpolation does not need to start in the first event interval by default. Along with both integer variables and the event intervals array, the initial offset time  $t\text{Offset} = n \cdot T$  is determined and stored.

Each subsequent call of `_nextTimeEvent` now increments the event interval marker by one and resets it to 1 once it overruns, i.e. gets greater than the number of time events per period. This can be derived from the fact that the input variable (time) is usually increasing (w.r.t. time). Then it is known that there is exactly one time event per event interval. There is

an event interval correction implemented in functions `_getValue` and `_getDerValue` that sets the time to be interpolated to either the left or right event interval value in case of floating-point inaccuracies. This implementation guarantees that no time events are missed and that the correct function values of the interpolating function at the event interval boundaries are returned.

## 3 Interpolation by Akima splines

Hiroshi Akima's original articles [1, 2] were used for the implementation of the univariate and bivariate interpolation by Akima splines. His reference implementation (in FORTRAN 77) was not used. Furthermore, the FORTRAN 90 code of SOSIE [3] from Laurent Brodeau was studied for an efficient calculation of the coefficients for bivariate splines.

### 3.1 Spline coefficients

There are different possibilities to calculate and store the polynomial spline coefficients of the interpolating function.

1. Pre-calculate all coefficients during the initialization and store them within the external table object.
2. Calculate the coefficients whenever needed (and possibly store only the last calculated set of coefficients if used for evaluating the partial derivatives in the same simulation time step).
3. Allocate enough memory during initialization to store all coefficients, calculate them whenever needed and store them whenever calculated. The advantage is that for very large tables where only a few different data parts are accessed there will be no superfluous calculation at all and initialization time is short. The disadvantages are the high memory usage and the unpredictable execution time of a simulation time step (as it is never known if the calculated coefficients are already available).

This implementation of the Modelica Standard Tables uses the first option where all required coefficients of the entire table array are calculated during initialization in function `spline1DInit` (for univariate Akima splines) and `spline2DInit` (for bivariate Akima splines).

### 3.2 Differentiability

The current univariate Akima spline interpolation always uses non-periodic table boundary conditions which may lead to a discontinuous interpolating function or derivative at the table boundaries for periodic extrapolation with the `CombiTimeTable` (Fig. 4).

Figure 4: Periodic extrapolation of time table  $[0.25, 10; 0.5, 0; 0.75, 10]$  by Akima splines results in an interpolating function that is not (continuously) differentiable.

In all other cases it is guaranteed that the univariate or bivariate Akima spline interpolating function is continuously differentiable everywhere, especially at the table boundaries (Fig. 5).

Figure 5: The boundary slopes of the Akima splines are used to linearly extrapolate the one-dimensional table  $[0.25, 20; 0.5, 0; 0.75, 10]$ .

## 4 Array memory optimizations

Advanced array memory optimization features are implemented and explained below.

### 4.1 Shared table arrays

If multiple table objects refer to the same table array of the same file, this table array is read and stored in memory multiple times since external objects are mutually independent by default. In order to avoid superfluous file input access and to decrease the utilized memory there is a C++ implementation of a global table array management on top of the C implementation,

guarded by predefined macro `__cplusplus`. The C or C++ compilation can be toggled by compiler flag `-x c` and `-x c++` for GCC or flag `/TC` and `/TP` for Microsoft Visual C++. In the case of a C++ compilation an additional static variable of type `TableShareMap` (using the `std::map` container from the STL) with reference counting is introduced. Write access of this global variable `tableShare` (e.g. insertion or erasure of tables) is thread-safe, i.e. guarded by a critical section (on Windows platforms) or `pthread_mutex` (on Linux platforms) and implemented by `struct CriticalSectionHandler`.

A table array update is usually not required and therefore not implemented. Shared arrays of spline coefficients are also not implemented, i.e. each external table object always calculates and locally stores the spline coefficients it requires.

### 4.2 Shallow copy of table arrays

This optimization is only relevant if the table array is defined within the simulation model, i.e. if it is known at compile-time and not read from the file at simulation run-time. The complete table array memory that is passed from the simulation model to the constructor (the `_init` function) of the external table object is allocated and copied (“deep copy”). This is the safe default case as nothing can be assumed about the lifetime of the table array of the simulation model. Thus the table memory is (temporarily) held twice: locally within the external table object and at the outside model. If the outside table array is known to be constant and to have a longer simulation lifetime than the external table object, the deep array copy can be avoided by defining `NO_TABLE_COPY`. In this case, the outside table array memory is used within the external table object (“shallow copy” of the passed array pointer).

## 5 Conclusions

An open source implementation of the table blocks

- `Modelica.Blocks.Sources.CombiTimeTable`
- `Modelica.Blocks.Tables.CombiTable1D`
- `Modelica.Blocks.Tables.CombiTable1Ds`
- `Modelica.Blocks.Tables.CombiTable2D`

is available with the MSL 3.2.1 as of August 2013. The Modelica code is provided under Modelica License 2. The C/C++ code of files `ModelicaStandardTables` and `ModelicaMatIO` [4] is provided under the new BSD license. As a result, all parts of the MSL are now available in a free implementation.

Additionally it should be mentioned that this implementation added new features to the table blocks.

- The new option `ConstantSegments` was added for the `Smoothness` parameter.
- The new option `NoExtrapolation` was added for the `Extrapolation` parameter.
- The table outputs can be differentiated once (with exception of the potentially discontinuous `ConstantSegments`).
- All MATLAB MAT-File formats are supported by an adapted library `libmatio` [4] (provided by `ModelicaMatIO` header and source file). Whereas MAT-File formats v4 and v6 are supported without additional dependencies by `libmatio`, the v7 format requires the `zlib` [5] library and compilation with preprocessor macro `HAVE_ZLIB=1` and the v7.3 format requires the `hdf5` [6] and `gzip` [7] libraries and compilation with preprocessor macro `HAVE_HDF5=1`.
- The support of tables provided as static C arrays in the user header file `usertab.h` was revised. This is relevant for real-time systems without a file system and where the table data is known at compile-time.

Last but not least, 120 test models in `Modelica-Test.Tables` with reference results have been created.

## 6 Acknowledgement

The presented work was paid for by the Modelica Association.

Grateful acknowledgements go to

- Martin Otter for the first implementation (from 1997 till 2001) of the table interpolation blocks and for constructive discussions on the improvement of the new implementation,
- Hans Olsson and Martin Sjölund for valuable advice on the improvement of the implementation,

- Christopher C. Hulbert for sharing a MAT-File C library and providing a patch of `Mat_VarReadDataLinear` [4],
- David Zaslavsky for initiating an `interp2d` library compatible with the GNU Scientific Library (GSL) [8],
- John C. Beatty for sharing a simple utility to concatenate multiple C source files into a single C source file [9] that was used to merge header and source files of [4] to single files `ModelicaMatIO.h` and `ModelicaMatIO.c`,
- Laurent Brodeau for sharing a bivariate Akima algorithm (in FORTRAN 90) [3].

# The DLR Visualization Library

## Recent development and applications

Matthias Hellerer Tobias Bellmann Florian Schlegel  
German Aerospace Center (DLR), Institute of System Dynamics and Control  
82234 Wessling, Germany

### Abstract

Modelica models are mathematical descriptions and therefore their simulation output typically shows numerical variable trajectories. While universal for all kinds of simulations, this representation is oftentimes difficult to understand. In the field of multi-body simulations, 3D visualizations present a way of displaying vast amounts of numerical data in an intuitive way which is instantly understandable, even by people without specialized knowledge. For integration of visualization in Modelica multi-body simulations, the "DLR Visualization Library" has been developed. This paper presents the newest additions to the library and shows their application in several DLR projects.

*Keywords: Visualization, Simulation, DLR Visualization Library, Modelica, interactive Simulation*

## 1 Introduction

The visualization of simulation data is an important element of advanced simulations. With the increasing complexity of modern multi-body simulations, concerning for example flexible bodies, thermal dissipation, or contacts, the demands for a realistic, real-time capable visualization of the simulation also rise. Using Modelica as modeling language allows the user to pack model functionality in reusable sub-models, e.g. as a replaceable block for a suspension, an engine, etc. This also enables the integration of visualization definitions into the single sub-models, eliminating the need for an additional visualization definition in a separate program.

In 2009, the "DLR Visualization Library" for Modelica has been introduced under the now deprecated name "DLR External Devices Library" [1]. The library features a variety of visualization blocks to be used directly as visualizers within Modelica. Visualization elements like configurable rigid bodies (e.g.

sphere, box, gearwheel) or rigid and flexible bodies generated from CAD files can be displayed by connecting their respective Visualizer block to the corresponding frame in the multi-body model. Figure 1 shows an example scene created in Modelica and its visualization. Using the C-interface of Modelica, the visualization information is transmitted to the external visualization software which is started automatically

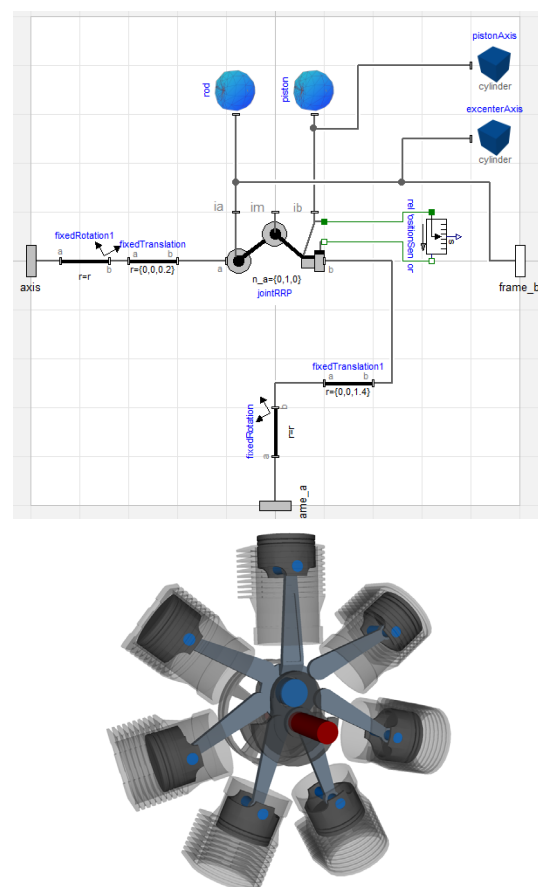

Figure 1: Top: Modelica model for a single cylinder, showing the integration of model and visualization. Bottom: The corresponding 3D visualization of a radial engine.

with the simulation and allows the user to replay and observe the simulation run in real-time and export it as video. Furthermore, as a result of the latest development, the library features a feedback channel, allowing the visualization to influence the simulation. This makes it possible to interact with the simulation using a graphical user interface (GUIs / HUDs), defined in the Modelica model, and to evaluate collisions between visualization elements, this is for example required in contact force calculations.

The following sections shall introduce the newly added features to the "DLR Visualization Library" and present some application examples of its use in ongoing research topics at DLR.

## 2 State of the art

The first attempts to create 3D Visualizations with Modelica was in 2000, when Engelson [2] started a discussion about techniques for the integration of visualization information with Modelica code. In his paper he presents a set of annotations for 3D graphic primitives and standardized simple geometries. Visualization would then have to be implemented by IDE tool vendors. Even though it brought up the idea of creating visualizations from Modelica models, the presented techniques were never implemented on a larger scale.

Yet, the idea of creating 3D visualizations from Modelica simulations persisted and in 2003 Otter et al. [3] revived the "MultiBody Library" of the Modelica standard library. This change introduced a new sub library called "Visualizers", containing shape objects for simple 3D forms as well as more complex objects from files. These are Modelica blocks and as such may easily be integrated in existing models or may be used in the creation of submodels which contain both simulation and visualization information. The visualization itself is redirected to the ModelicaServices library, responsible for all vendor specific implementations. So the Modelica standard library provides a standardized visualization description, to be implemented by Modelica IDE vendors. This technique is now part of all major simulation environments.

In 2008 Hoeft et al. [4] revisited the ideas of Engelson, this time integrating the powerful X3D standard in Modelica annotations. X3D, short for Extensible 3D Graphics, is an open international standard, developed for web applications. It is a representation of a 3D environment with XML. They present new annotations with X3D code and show an implementation of

the technique in the MOSILAB simulator.

Furthermore the Modelica3D library was presented by Höger et al. at the 2012 Modelica Conference [5]. It implements a scene graph in Modelica and uses the C-interface to connect the simulation front-end with the visualization back-end via interprocess communication. Besides their Modelica library, two different back-ends are presented. One based on the OpenSceneGraph 3D library and one based on the Blender 3D graphics software.

Unsatisfied with the existing visualizers, provided by "MultiBody Library", we implemented the "DLR Visualization Library". It is based on the ideas of Engelson and Otter, but tries to take those to the next level with more complex 3D environments, visualizations of mass and power flow, flexible deformation of objects and many other features in a high fidelity rendering.

## 3 New Functions

### 3.1 3D-Elements

#### 3.1.1 Dynamic textures

Given a 2D Matrix of 3D points, the flexible surface element may be used to display arbitrary shapes, with the ability to deform during the simulation. More details may be found in [1].

A new addition to flexible surfaces is the ability to display videos as textures, both local files as well as video streams from a network, as shown in figure 2. For local files the video is synced with the simulation time stamp. For network streams this is not possible and the surface will always display the last received image. The supported network protocols and the URL definitions for opening streams are inherited from the underlying FFmpeg library and are described in [18] in detail. Most commonly used protocols are thereby supported, such as: RTP, FTP, MMS, HTTP and HLS.

Figure 2: Full HD MPEG Video image from a presentation of the DLR Robotic Motion Simulator [9], rendered onto a flexible surface.

Figure 3: On the left a simple 3D scene; on the right this part is rendered on a flexible surface using a virtual camera, symbolized on the upper left side. All parts are in the same scene.

Besides Videos, images from virtual cameras can be rendered onto a flexible surface. For this purpose a standard camera from the "DLR Visualization Library" is placed in the scene and its output mode is set to "render to texture". The camera output can then be selected as texture for the flexible surface. The result is a camera image, drawn on the surface in the same way it would otherwise be drawn on screen. An example of this is illustrated in figure 3. The whole image shows one scene. On the left side a few objects are arranged and on the right side a flexible surface is depicted which shows the left part of the scene again, as seen from the virtual camera above the arrangement, rendered as a texture on a flexible surface.

### 3.1.2 Feedback - HUD

In [1] all communication was strictly from the simulation to the visualization. The following, new elements abandon this concept. They not only send data from the simulation to the visualization but also receive data, which may then be used to influence the simulation.

The first interactive objects presented here are interactive HUD elements. The base class for all of these elements is the button class. This defines an invisible HUD object in the visualization and with outputs in the simulation which are dependent on user input on the visualization. By combining the button object with HUD elements for the representation and Modelica logic for reactions, typical user interfaces, like buttons or sliders, can be created and used as interactive input for simulations. The button base class is capable of reacting to mouse-over events while the mouse cursor hovers over them, mouse clicks and dragging of the element by moving the mouse while a button

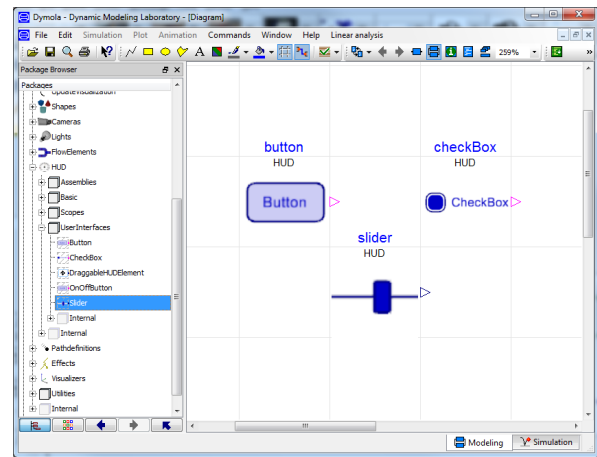

Figure 4: At the top part simple HUD elements are presented and below that their representation in the Modelica graphical designer.

is clicked. The "DLR Visualization Library" contains with a selection of predefined GUI elements, using the described button base class. The following HUD elements are depicted in figure 4:

- Buttons are by default visualized as simple squares with a label. They have a Boolean output value which is "true" for as long as the user presses it and "false" otherwise.
- Check boxes have a different look but actually behave very similar to buttons, except the output value behaves like a flip-flop. Permanently changing its value with every click.
- Sliders for simple adjustment of continuous values

### 3.1.3 Feedback - Collision detection

The description of complex 3D geometries usually uses geometric meshes. Reading the according data from files, interpreting it and running collision detection algorithms from Modelica is complicated. Physical simulations, especially in the area of multi body simulations often require to measure the distance between objects or contacts between objects. The required data, especially the interpretation and arrange-

Figure 5: Collision detection with visualization of the contact. The red line represents the collision detector, the sphere shows the contact point and the arrow displays the surface normal.

ment of 3D mesh data, is already present in the visualization. To make this data accessible for the simulation the collision detector object is introduced. The collision detector is a line in the 3D scene with a defined start and end point. If the line intersects another element in the visualization it produces an output for the simulation. The output data includes a Boolean value, indicating whether or not a collision occurred, the distance of the first collision, measured from the start point and the surface normal vector of the colliding object at the position of the collision. The collision detection may also be visualized as shown in figure 5. The simulation and the visualization are running independently at different frequencies. In our example (see section 4.3), the Modelica simulation of the contact forces runs at a rate of  $1kHz$ , but the visualization calculating the collisions is bound to the frame rate of the graphics card and is as such dependent on the complexity of the scene and the hardware. By subsampling the communication calls from the simulation to the visualization, a minimum frame rate of about  $30 - 100Hz$  for the visualization is defined. If the visualization fails to achieve this frame rate, the simulation is slowed down below real-time speed as it has to wait for the answer of the visualization system providing the collision data. Because the simulation requires the collision data for each integrator step, a sample and hold interpolation is performed on the collision data, which saves the last received collision data until new ones are available. A high-level overview of this principle is depicted in figure 6.

### 3.1.4 Weather effects

To enhance the realistic impression of the simulation, the "DLR Visualization Library" provides a selection

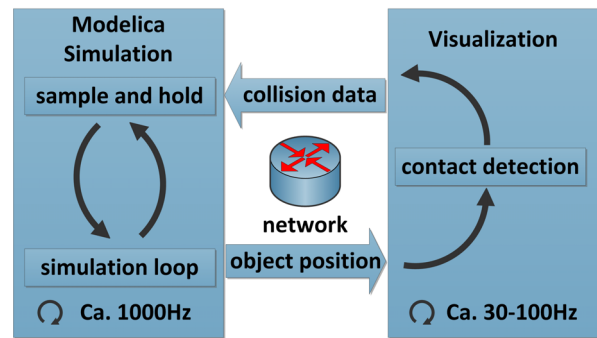

Figure 6: High level view of the collision detection system

of the most common weather effects for the simulation. These include: Rain, snow and fog. An example of the rain effect is shown in figure 7. For precipitation both the intensity of the effect as well as the wind direction and speed can be set. Wind can be used to simulate the effects of wind on the direction of precipitation. Fog is parameterized with three values: a starting distance for the fog effect and an end distance, where the view is completely blocked by the fog. Also the color of the fog can be adjusted. The applicability of those effects is not necessarily limited to the simulation of weather but could for example be used in under water simulation to show the effects of murky water.

Figure 7: An exemplary scene with rain effect

### 3.1.5 Paths

Visualizations often require complex motions of cameras and objects through space. This is type of predefined movement is seldom used in multi body simulations and therefore it is complex to define using the Modelica standard library. To simplify the creation of visualizations, new path definitions are provided. Paths are a multi-body connector frame with a time dependent output. Four different kinds of paths are

Figure 8: Top to bottom: circular, linear, Bezier, cubic spline; spheres: control points.

available as shown in figure 8: The first type shown here is a circular movement. The circle is defined by a center point with orientation and the radius. The simplest paths are point to point connection. A list of points is supplied and the resulting path is a linear interpolation between those. For smoother paths, Bezier curves can be used. The path is only guaranteed to pass through the first and the last point the remaining points only "stretch" the path towards them. The fourth kind of paths is based on cubic spline interpolation. Like Bezier curves these provide very smooth paths. In contrast those the line is always guaranteed to pass through all points. This often simplifies the definition of paths but might lead to overshooting in certain constellations.

### 3.1.6 Trace shape

Following the 3D movement of multiple objects at once can be hard. To display this motion, a trace-shape can be attached to any object. The trace-shape object then generates a line trail as the object it is attached to moves through space, thereby intuitively representing the objects trajectory. For the illustration of multiple trails, the line thickness, color and length can be adjusted by the user as needed. An example can be seen in figure 9.

### 3.1.7 Sky-Box

"Empty" space, areas on screen in which no object is defined, are by default filled with a solid color. This is suitable for small animations or abstract illustrations but for many applications a more realistic representation is required. For example in outdoor scenarios those areas should show the horizon and the sky. For this purpose the sky box is introduced. The sky box

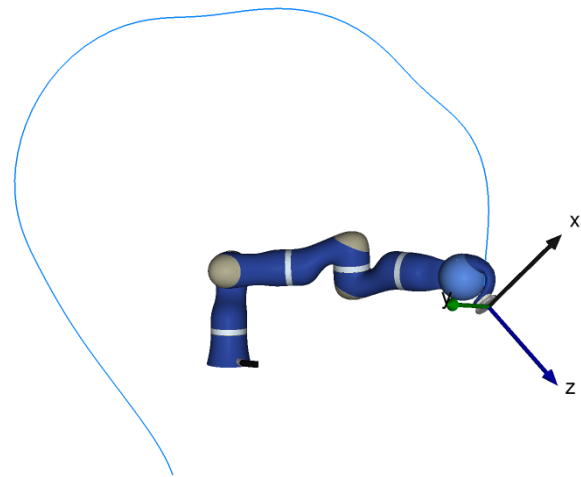

Figure 9: Movement of a robots tool tip visualized using the trace shape.

is always depicted as infinitely far away and is composed of two layers. The front layer is used for displaying some sort of horizon. An example would be distant hills or a tree line. The user has to supply six images (It is designed as a cube with the view point in the middle. One image per side). Behind this layer, visible through transparent areas in the images, the sky is drawn. The user has to provide a date, the time and a position on earth in form of longitude and latitude. The OsgEphemeris library [13] then uses this information to calculate the correct position of the sun and the moon during the day and an astronomically correct star field during the night time. The result is a realistic background for the simulation.

### 3.1.8 Particle System

The particle system is used for displaying objects, consisting of many sub-objects and cannot be modeled as traditional meshes. Examples for these kinds of objects include streams of water, fire, smoke and dispersed dust. Those objects are visualized using a large number of small objects, showing a simple image, called particles. Those particles are send out randomly from an emitter, follow a certain path while potentially turning, changing color and transparency, until the path reaches a certain length and the particle disappears. Using the right image, a large number of objects, and a specific movement, this raises for example the impression of water flowing from a pipe.

The Modelica blocks for modeling particles are divided by emitter type. The emitter is the area, from which the particles are shot. The three types available in the "DLR Visualization Library" are: Point emitter,

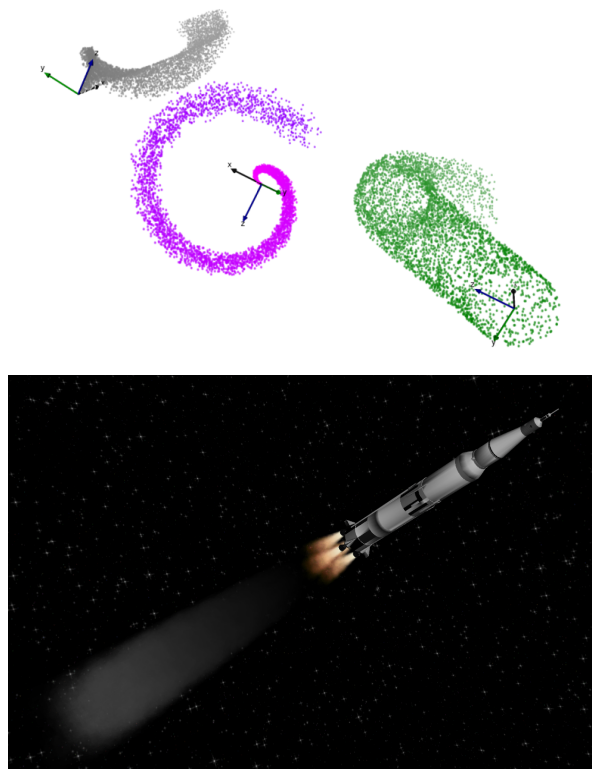

Figure 10: Top: Three types of particle emitters. From left to right line emitter (along  $z$ -axis), point emitter, and area emitter (circular shape in  $x - z$ -plane); Bottom: Particle effects used to display exhaust from a space rocket.

line emitter and area emitter. Examples for each type are depicted in figure 10. The particles are created randomly within certain bounds, such as mean number of particles per second, configurable for each emitter. Furthermore the particle may change its color, transparency, size over its life time. The final set of parameters then determines the path particles will follow.

### 3.1.9 Virtual Planet Builder and large scale terrain visualization

The visualization engine is based on the open source library OpenSceneGraph [12], allowing its use in conjunction with another OpenSceneGraph application, which is itself not part of the library: Virtual Planet Builder [14]. Using digital elevation data, like it is commonly produced in aerial surveys with special cameras, Virtual Planet Builder can produce 3D sceneries at scale of whole planets. This is accomplished by auto generating different levels of detail and by converting the scenery in a special file format. The planet surface is tiled into junks. When viewed from a faraway distance large areas are combined into

one large tile with very little detail. As the camera moves closer to a certain area the corresponding tile is split into smaller junks with more detail. This process is reiterated while the camera closes in until a maximum degree of detail is reached. For the viewer the switchover is not visible for the lower level detail at which a tile is rendered from afar, is not visible. Of special importance is the way the data is preprocessed and stored in a special format, allowing the renderer to load certain parts at different levels of detail as needed, very efficiently. This technique makes it possible to show extremely large areas while retaining a high level of detail. Figure 11 shows an earth model, created with Virtual Planet Builder from satellite images.

When rendering these planetary scale images in conjunction with small, close up objects, in setups like the satellite simulation in figure 11, graphical glitches appear. During the rendering process, each pixel is assigned a depth value to determine how objects overlap each other from the cameras perspective. The technical implementation of this uses a so called depth buffer or  $z$ -Buffer which saves each pixel distance from the camera (the depth or  $z$ -value). This is a, typically 24-bit on modern machines, fixed point value in the range  $[0, 1]$ , where 0 represents the near plane (minimum distance from camera) and 1 the far plane (maximum distance) of the view frustum. Therefore, with increasing distance between the near and far plane, the depth buffer resolution decreases. When the depth value of two points is so small that the depth buffer is unable to represent the difference graphical glitches become visible [15]. The minimum depth difference representable by the depth buffer  $\Delta z_{min}$  can be calculated with equation (1).  $z$  is the depth value,  $n$  is the near

Figure 11: A model of planet earth, generated using virtual planet builder, in a satellite simulation; Logarithmic  $Z$ -Buffering allows for a detailed satellite model in the foreground and an earth model at real scale behind it.

plane distance and  $b$  is the depth buffers resolution in bit. The higher resolution at low distances is caused by perspective effects.

$$\Delta z_{min} \approx \frac{z^2}{2^b n - z} \quad (1)$$

Logarithmic depth buffers are a well known technique which seeks to attenuate this problem by applying a logarithm to the depth value before it is written to the depth buffer, thereby increasing the resolution for close objects, where small difference are more likely to be important at the expense of the resolution for distant objects where small differences are less likely to become visible. Equation (2) show the conversion from the original value  $z$  to the new value  $z_{log}$ . The addition parameter  $C$  is used to adjust whether close or distant objects are preferred.

$$z_{log} = \frac{2 \ln(Cz + 1)}{Cf + 1} - 1 \quad (2)$$

Using a logarithmic depth buffer alters the depth buffer resolution. It can now be calculated with equation (3). [16]

$$\Delta z_{log min} \approx \frac{\ln(Cf + 1)}{(2^b - 1) \frac{C}{Cz + 1}} \quad (3)$$

For example, the satellite visualization requires a render distance of  $1m$  to  $15000km$ . With a  $24bit$  depth buffer this results in a minimum depth separation of less than  $1mm$  at the satellites distance of  $100m$ , but between  $\approx 550m$  and  $\approx 1100km$  at the earths distance of  $300km - 13000km$ , causing visible problems with its rendering. Using logarithmic depth buffers with a  $C$  Value of  $0.001$  the minimum separation for the satellite also lies below  $1mm$ , yet for earth it is in the range of about  $\approx 20cm - 7.5m$  which is well below the visible range at this distance.

### 3.1.10 Oculus Rift Integration

The Oculus Rift is head-mounted virtual reality display, currently under development by Oculus VR. At the time of this paper, it is only available as a developer preview version with a finalized consumer product in development. The head-mounted system depicted in figure 12 includes a display with a resolution of  $1280 \times 800$ , two fish eye lenses stretching the image to a field of view of about  $90^\circ - 110^\circ$  and a three degree of freedom rotational acceleration sensor [17]. With this device it is possible to generate a fully immersive experience in a 3D environment, nearly filling the user's entire field of view and following his motion as he moves his head. The "DLR Visualization

Figure 12: The Oculus Rift head-mounted virtual reality device.

Library" supports the currently available Oculus Rift Development Kit as alternative display device for any kind of already integrated cameras. All setup steps and the camera orientation change as reaction to the users head movement are handled fully automatically.

### 3.1.11 HUDs

Head-Up-Displays are a two dimensional layer in front of the three dimensional scene. The possible applications for this kind of display range from overlaying logos, over the display of model state variables to complex interactive user interfaces. All user interfaces are composed of five base elements: The first element is text. Text can change dynamically and therefore be used to display model states or variables. Also typical text formatting methods such as different fonts, bold text and so on are supported. The second type of elements is a line drawn along a list of user pro-

Figure 13: Various HUD elements used to recreate a plane's cockpit instrumentation with artificial horizon, speed and altitude meters alongside a compass and engine status displays.

vided points. Next are free form faces, displaying a filled form based on polygon points provided by the user. Lastly, for more complex images, graphics files can be included. Of course the HUD elements presented here can be combined in the creation of new more complex elements. A small selection of such elements is included with "DLR Visualization Library". An example is a scope for the presentation of variable trajectories, a combination of lines, images and text, or the airplane cockpit instrumentation in figure 13. The last type is an interactive button base class which will be discussed in a later section.

Attention has to be paid to the arrangement of HUD elements for the size of the window they are drawn is variable even at runtime. Therefore it would be impractical to use absolute coordinates and instead relative coordinates are employed. For the adaptation to a changed display size the user can choose of the following four techniques:

1. The horizontal coordinate value spans over the horizontal display size and the vertical value is adjusted to its size in such a way that aspect ratio is preserved.
2. The same as 1 but for the vertical instead of the horizontal coordinate value.
3. The program automatically changes between technique 1 and 2, depending on the smaller side.
4. Relative coordinates range for both horizontal and vertical coordinates range over the whole display.

Figure 14: The "DLR Robotic Motion Simulator"

play size. The aspect ratio might be distorted depending on the display window setup.

## 4 Applications

This section exemplifies the real world application of the previously introduced visualization objects with help of their implementation in the "DLR Robotic Motion Simulator". An experimental motion simulation platform, currently under development at DLR. The system is depicted in figure 14.

### 4.1 ROboMObil GUI

The ROboMObil is a robotic car, developed at the DLR with four separately rotatable wheels, granting a new level of maneuverability. To make use of it, the specialized user interface in figure 15 was developed, using the previously described HUD elements. It is displayed on a touch screen device in the cockpit of the real prototype car

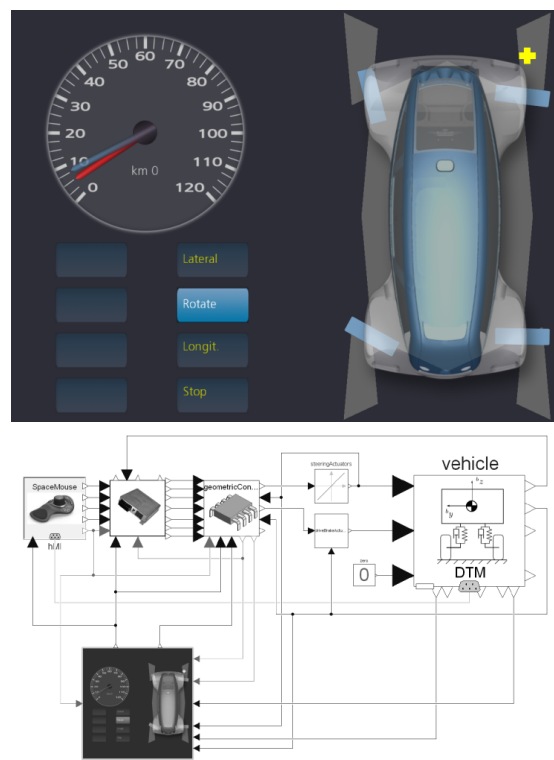

Figure 15: The ROboMObil GUI, as shown on the touch sensitive device of the ROboMObil cockpit, as well as the graphical Modelica designer. Left bottom: the user can choose between different operational modes; right: Enter additional options for the selected mode. In the rotational mode shown here, the user can select an instantaneous center of rotation

and in the simulators cockpit mockup. The concept is explained at full detail in [8]. The upper left part shows the current and the target speed. Below that the driving mode can be selected and the right part is selecting a rotation center point, required for certain driving modes. The second part of this image shows the full integration of the GUI with other parts of the simulation directly in the model description with Mod-  
elica.

## 4.2 Flexible trajectory planning

The design of a complex trajectory in 3D space, for a predefined movement of objects or cameras, can be a rather difficult and time consuming task, if it has to be accomplished by the direct manipulation of numeric parameters. Therefore the interactive Trajectory Designer has been developed to provide a convenient way of creating control point parameters for a B-spline interpolated movement of position and orientation. The trajectories velocity is interpolated with a two times derivable sinusoidal function.

In order to generate a smooth trajectory through accurately defined bases containing a position and orientation, we use quaternions for orientation and B-Splines for interpolation between these bases. A B-Spline curve  $T(x)$  consists of control points  $P_i, i \in 1 \dots n - p$  and B-Spline base functions  $N_{i,p,\tau}, i \in 1 \dots n - p - 2$ :

$$T(x) = \sum_{i=1}^{n-p} P_i N_{i,p,\tau}(x). \quad (4)$$

The control points  $P_i$  each contains seven elements; three for position and four for the orientation represented as quaternion. A base function  $N_{i,p,\tau}$  is defined as a polynomial piece with order  $p$  and knot vector  $\tau$ :

$$N_{i,0,\tau}(x) := \begin{cases} 1, & x \in [\tau_i, \tau_{i+1}] \\ 0, & \text{otherwise} \end{cases} \quad (5)$$

$$N_{i,p,\tau}(x) = \frac{x - \tau_i}{\tau_{i+p} - \tau_i} N_{i,p-1,\tau}(x) + \frac{\tau_{i+p+1} - x}{\tau_{i+p+1} - \tau_{i+1}} N_{i+1,p-1,\tau}(x) \quad p > 0 \quad (6)$$

The knot vector  $\tau = [\tau_0, \dots, \tau_{n-1}]^T, n \geq 2p, \tau_i \leq \tau_{i+1}$  and  $\tau_i \leq \tau_{i+p}$  has to be chosen. The algorithms of our implementation set the first and last  $p$  knots equal. There are different approaches setting the remaining values, see [11] [10, p161]. For the trajectory designer we use a base functions with degree 3 in order to get a smooth trajectory with a continuity of the second derivative. The parameter  $x$  defines the position on the trajectory,  $T(x)$  returns the interpolated

value  $P(x)$  containing the three-dimensional position and an interpolated quaternion. The quaternion interpolation corresponds to a linear quaternion interpolation (LERP)[6]. Therefore the resulting  $L_2$ -Norm of the vector is less than 1 and has to be normalized resulting in a unit quaternion which leads to an varying but continuous rotational velocity. Furthermore the trajectory designer provides the functionality to set a velocity at each control point. The behavior of the velocity between the points is computed through sinusoidal functions:

$$v(\lambda) = (\lambda - \frac{1}{2}\pi \sin(2\pi\lambda))(v_{i+1} - v_i) + v_i; \quad (7)$$

with  $v_i$  the velocity of the left and  $v_{i+1}$  the velocity of the right control point within the interval between  $P_i$  and  $P_{i+1}$ . The second derivative of this sinusoidal function is continuous and zero at the left and right end providing a smooth transition at the control points. The integration of the velocity  $v$  leads to the current position on the trajectory  $x$ . Therefore,  $v_i \geq 0, i \in 1 \dots n - p$ .

The tool is operated by a small selection of keyboard commands and offers three operating modes to manipulate the position, the orientation and the associated velocity of the control points. In all modes control points can be removed or inserted. For verification of the resulting interpolated movement a live preview, adjusting to the manipulation of control points in real-time, is available. The preview shows a coordinate system traveling along the spline in the main scene and

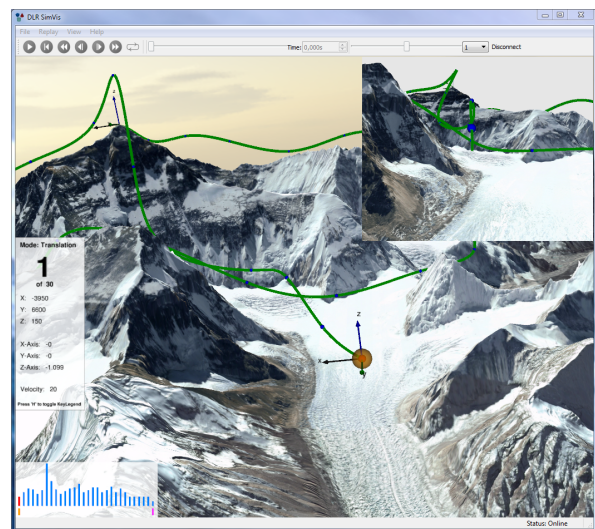

Figure 16: The trajectory designer tool showing a path (green line) above Mt. Everest. In the upper right corner a window previews the camera's trajectory while working on it.

a point of view rendering, adequate for the preview of camera movements, in a separate picture-in-picture preview area. The complete interface is depicted in figure 16. The coordinates, orientations and velocities are finally stored as vectors in a text file, which can be used to reload the control points for further manipulation or later playback.

### 4.3 Wheel ground contact

The simulation of cars requires the modeling of contacts between wheels and the ground, realized using the collision detector elements. An abstracted model is shown in figure 17. This contact model is then the basis for far more complex models, such as the car shown in figure 18. In this simulation the load on the wheels will shift when driving on uneven terrain and the suspension reacts accordingly. The ground plane in the simulation can be any 3D shape.

The wheel vertical force is calculated according to the following equation. The contact force  $f$  is the sum of a spring force  $s$  and a damping force  $d$ .

$$\vec{f} = \vec{s} + \vec{d} \tag{8}$$

The spring force is calculated using the penetration depth of the collision object and an other object  $p$ , as well as a spring constant provided by the user  $S$ , to push the wheel away from the other object, along the

Figure 17: Wheel ground contact in the graphical Modelica designer and as 3D visualization.

Figure 18: A car driving on a plane. White arrows indicate surface normals for contact points.

objects surface normal at the point of contact.

$$\vec{s} = S \cdot p \cdot \vec{n} \tag{9}$$

Just using a spring force would result in a constantly bouncing wheel. To model energy dissipation, a damping force  $d$  is introduced. It is calculated using the collision objects speed  $\dot{r}$  in the direction of the surface normal  $n$ , a user provided damping constant  $D$  and the resulting force, just as the spring force, acts in the direction of the normal. Lastly the damping force should only be present during impact. Otherwise the wheel would act as if it was glued to the surface.

$$\vec{d} = D \cdot \min(0, \dot{r} \cdot \vec{n}) \cdot \vec{n} \tag{10}$$

This way of simulating object collisions does come with certain draw backs. First of all, it intrinsically requires the two colliding objects to interpenetrate. While problematic for rigid bodies, it is a reasonable approximation for flexible objects like the car tires in the presented example. When trying to minimize the interpenetration a further problem arises. The larger the spring constant  $s$ , the stiffer the simulation gets, requiring ever smaller simulation time steps. Otherwise the interpenetration from one step to the next can be so large, the resulting force from equation (9) gets unrealistically large, hurling the wheel away. The same problem can occur when the wheel is moving with high speed and the ground inclination changes. The sample-and-hold technique used in the communication, delays the point in time when the simulation is able to "see", the changed ground inclination. This is depicted in figure 19. The wheel on the left moves at high speed to the right but due to the slower visualization time steps, the ground inclination change is communicated to the simulation with delay, causing the wheel to penetrate the ground.

Figure 19: Wheel moving at high speed from left to right. Due to the fact that the simulation does run faster than the visualization, the inclination change is recognized to late. Dotted line: ground level as detected by the simulation; red line: error due to sample and hold technique

For small and fast moving objects, it is even possible for object collisions to be missed completely. The collision detection object only detects collisions with object surfaces so if an object moves so fast towards another, that the position "jump" between time steps is larger than the collision object length, the collision might get missed. This case is described by equation (11) where  $v_1$  and  $v_2$  the speed of the two objects and  $i_1$  and  $i_2$  are start and end point of the collision object.

$$\left\| \frac{v_1 - v_2}{\|v_1 - v_2\|} \cdot \frac{i_1 - i_2}{\|i_1 - i_2\|} \right\| \frac{1}{f} > \|(i_1 - i_2)\| \quad (11)$$

#### 4.4 Image warping

The capsule in figure 20 is part of a simulator project. At the back, besides the head of the pilot, are two projectors. The projection screen is the open capsule shell to the top right. The shell has a complex geometry, deforming the images projected onto it. In order to present a rectified image to the pilot a reverse deformation has to be applied to the image prior to projection. This preprocessing utilizes the render image to texture functionality on a flexible surface. Due to the fact that a flexible surface is used, the image can be warped as needed (see figure 20) and with the correct configuration, the final image appears restituted to the pilot.

#### 4.5 Manned vehicle simulation

The "DLR Robotic Motion Simulator" uses the capsule shown in figure 20 and an industrial robot to which the capsule is attached as shown in figure 14. The robot is then used to apply accelerations, in accordance with the simulation, on the pilot, thereby creating an immersive motion simulation. A detailed description of the "DLR Robotic Motion Simulator" can

Figure 20: The piloting capsule of the "DLR Robotic Motion Simulator"; On top the stereo images after warping; The images are projected on the capsule and appear restituted; In front of the pilot is a touch sensitive display.

be found in [7]. In this application all of the previously shown applications are utilized. The pilots' main screen is restituted using the render to texture feature on a flexible surface; the console in front of the pilot shows an input GUI on touch screens, and the vehicle simulation uses collision detection objects for the wheel ground contact analysis.

## 5 Limitations

The presented library does have certain limitations in its current state, of which the following three are currently under investigation for improvements. The first one is the design of the collision detection system: it only allows for collisions with a line object, limiting its use to applications where the point of contact is predictable, such as the presented tire, where the contact point can be assumed to be in the direction of gravity, while arbitrary contact points, like the collision of a car with a pole, can not be modeled in a similar fashion. Also the underpinning architecture, as introduced in [1], only permits retroactive collision detection. It only detects interpenetration of the collision object with another object after it happened and without any possibility of detecting the exact time of contact. Any contact model relying on the collision data has to account for this. The second item for improve-

ment is the graphical fidelity. While the current system provides very high fidelity compared to other products for scientific visualization, it does not hold up when compared to state of the art graphics as seen in modern computer games. The visualization of simulation data might not require such graphics, yet in virtual reality applications the best graphics possible are desired to maximize the users level of immersion. For comparison between our solution and a modern computer games engine see figure 21. For better visibility a very simple scene was selected here. On the top our solution is shown, with shadows enabled. Below that, the same scene is displayed using the Unity3D engine [19], with deferred lighting, advanced soft shadows, field of view and screen space ambient occlusion among other effects. Even though it is very simple, the second scene looks more realistic. Finally, the visualization library is based on Modelica's multi-body library. In virtual reality applications a large number of visualization elements gets connected using frame connectors. Even for static and fixed compositions the number of resulting equations gets extraordinarily high. An empty scene, with only the multi-body world object and the visualization libraries update-Visualization object, requires 1073 equations. Each

Figure 21: A simple scene for comparison between our current visualization on the top and below a modern computer games engine

additional ElementaryShape (e.g. a simple box) introduces 217 equations and each fixedRotation object used to arrange the objects in the scene further requires 102 equations. Clearly this modeling is too complicated and for complex simulations it can lead to performance problems. Since described problem is caused by Modelica's design of the multi-body library, we propose a simplification of the connector for the case that no masses are involved, when the multi-body library gets reevaluated in the future.

## 6 Conclusion

Visualization is an important, if not necessary, augmentation for a multitude of simulations. The "DLR Visualization Library" provides a sophisticated visualization framework for the Modelica modeling language. The paper presented the new additions to the library: videos and camera images rendered on flexible surfaces, advanced user interfaces, a collision detection system, weather effects, paths, the trace shape, a particle system, sky-boxes and integration with Virtual Planet Builder and support for virtual reality hardware. Furthermore, real-life applications for these new elements were presented as they are used in the development of the "DLR Robotic Motion Simulator".

In comparison with the other existing libraries, our implementation is not based on annotations and therefore does not rely on vendor specific annotations. Also it is not only possible to render all visualizers described in the standard MultiBody library but it also heavily augments its rather limited possibilities. In relation to other solutions, the "DLR Visualization Library" provides the richest feature set along side high fidelity results.

The visualization component is currently developed for Windows XP, 7, 8 and a Linux version is in Beta test with a installation package for Ubuntu 12.04 available. The library itself utilizes the Modelica C-interface and should therefore be compatible with a wide range of simulation environments but currently only Dymola has been tested extensively and is officially supported.

In conclusion, the library proves useful for gaining an intuitive understanding of multi-body simulations, the creation of presentable results and the creation of interactive virtual reality environments.

# Automated Modelica Package Generation of Parameterized Multibody Systems in CATIA

Daniel Baumgartner, Andreas Pfeiffer

German Aerospace Center (DLR), Institute of System Dynamics and Control  
82234 Wessling, Germany

Daniel.Baumgartner@dlr.de, Andreas.Pfeiffer@dlr.de

## Abstract

In early stages of the product development process computer-aided design (CAD) and multibody simulation (MBS) work concurrently to build a virtual mechanical system. While CAD handles the geometric design and space analysis, MBS leads to a deeper understanding of the dynamic behavior of the future system. The CAD system has to provide physical and geometrical data, such as mass, inertia and connecting frames in order to improve simulation results. Automation at this point helps to create consistent simulation and design models and shortens the amount of time needed to produce realistic simulation results. Based on Visual Basic for Applications (VBA) a method is implemented to automatically generate an isolated Modelica model package or a single Modelica model from CATIA assemblies or parts. The introduction of design controlling parameter variables in addition to the multibody data enables optimization loops between multibody simulation and the related CAD model. An example demonstrates the three main steps of the presented method, divided into model processing, package generation and parameterized package update. Furthermore, the update process is integrated in a manual parameter variation as well as an automated optimization routine to enable parametric design studies coupled with multibody simulation.

*Keywords: CATIA, Modelica, Dymola, Multibody Simulation, Parameterized Models, Package Generation, Optimization*

## 1 Introduction

Multibody simulation and computer-aided design are gaining significantly in importance during the virtual product development process. Typical tasks of multibody analysis include the computation of dynamic behavior, coupling forces or modal analysis. CAD systems on the contrary provide a three-

dimensional representation of virtual assemblies and subordinate parts. During the development process both engineering disciplines need to exchange data in the loop. Figure 1 clarifies the relations between the two domains. Physical and geometrical data is extracted from CAD and used as input for MBS. Dynamic simulation and optimization proposes changes in the design. Traditionally both domains have independent experts for the applied software. The generated data is shared manually between them over agreed-upon fixed interfaces. Automating this time consuming and error-prone repetitive procedure is a step toward the improvement of the product development process. The automation approach depends on the used design and simulation software. In the context of the presented work Modelica [1] is used as modeling language for multibody simulation and CATIA [2] as design software.

Existing methods for automated translation from CATIA to Modelica take different boundary constraints into account. The approach in [3] is based on a kinematic skeleton in Modelica. This Modelica file is imported in CATIA and the user maps CATIA data to the kinematic skeleton through a graphical user interface. Finally the multibody data is exported to the Modelica file. In this approach the design and the simulation work is divided and executed by different persons. The design process is the master. [4] presents a method for kinematic coupling of CATIA models with Modelica. The basic requirement for this method is a working kinematic structure in CATIA. The kinematic structure from the CATIA

Figure 1: Relation between MBS and CAD

kinematics workbench is translated to Modelica Code with attention to kinematic loops and special treatment of redundant joints.

In some cases, however, this time-consuming setup of a kinematic structure in CATIA is not desired or not possible due to open kinematic chains. In terms of dynamic preinvestigation at early stages of the product development process, however, it can be helpful to focus on the simulation process as master in order to generate fast results. Therefore a workflow is presented here, which matches the aforementioned requirements. An isolated package or a model is generated from CATIA assemblies and parts to be used for simulation and optimization in a Modelica simulation environment, based on the Dymola framework. The mandatory model preparation work can be executed solitarily by a simulation expert with basic CATIA experience.

The upcoming sections of this paper are organized as follows. Section 2 gives a detailed overview of the used software and presents the classic manual approach of virtual development. The following section presents an automated translation approach divided into model processing, package generation, parameter handling and package updating. A bicycle rear suspension serves as example and demonstrates the usage of this method in Section 4. Section 5 summarizes the main conclusions together with an outlook to future work.

## 2 Multibody Simulation and Computer-Aided Design

This section presents the tools used in the context of the paper. Firstly, multibody simulation in Modelica with Dymola is described. The following subsection focusses on the design process in CATIA. Subsection 2.3 finally describes the classic workflow of product development between the presented domains.

### 2.1 Multibody Simulation in Modelica/Dymola

In general, multibody models consist of rigid bodies and joints. The bodies are modeled as a skeleton of fixed translations  $r_{0n}^0$  and rotations  $T_{0n}$  between connecting frames together with body mass and inertias representing the real products shape (Figure 2). Joints between the components allow certain degrees of freedom and determine the kinematic behavior of the mechanical system. The Modelica Standard Library provides algebraic and dynamic models for multibody systems [5]. These can be combined

Figure 2: Geometric skeleton of a rigid body in a multibody simulation

graphically in Dymola to create multibody systems for dynamic model simulations. Based on the equilibrium of forces Differential Algebraic Equations (DAE) are formulated and solved. The outputs of the simulation experiments are motion, forces and modal behavior of the considered system. Model parameters can be adapted in optimization loops to enhance the system dynamics to match the desired behaviors.

### 2.2 Computer-Aided Design in CATIA

The design process in CATIA is mainly carried out by using the Part Design and the Assembly Design Workbench. The Part Design Workbench is used for modeling of single parts made from basic geometric elements such as points, lines and planes. These elements are combined to create two-dimensional sketches. Elementary operations transform these sketches to surfaces and volumes. Parameterizing variables, in the following referred to as design parameters, can be defined on top-level to create different representations of a part. In order to determine the part's mass and inertia, its density has to be defined through the assignment of materials.

The Assembly Design Workbench, on the contrary, is used to design mechanical systems from existing parts or sub products. Geometrical constraints, like coincidences and offsets, represent the locked degrees of freedom by the connecting joints between

Data Type	Parameters	Workflow
Physical Data	Mass, Inertia, Center of Gravity (CoG)	CAD to MBS
Geometrical Data	Connecting Frames, Points of Interest	CAD to MBS
Visualization	Shape representation	CAD to MBS
Design Parameters	Lengths, Angles	MBS to CAD

Table 1: Workflow between MBS and CAD

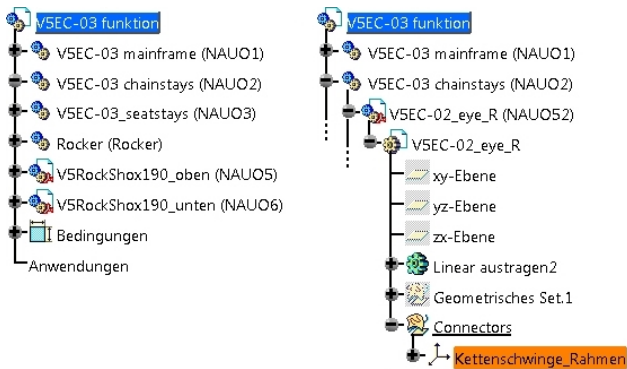

Figure 3: Top-level and connector level structure of an assembly in CATIA

the components. These relations allow manipulation according to the system's degrees of freedom for space and collision analysis. As previously mentioned multibody data is needed as input for the simulation work. There are different types of data: physical information, geometry, visualization and design parameters. Table 1 shows the workflow between MBS and CAD.

CATIA is organized in a hierarchic model structure. Figure 3 shows the top-level products and the nested structure on connector level. Each component of an assembly can consist of further products and parts on various levels. In terms of kinematic investigations it is sufficient to focus on the top-level of the product structure where the moving parts of a mechanism are located. Therefore the physical and geometrical data of the sub products is transformed to the first level of the assembly structure. Mass, inertia and center of gravity is computed for all sub products individually and merged to a single representative data set.

### 2.3 Classic Workflow

Traditionally the workflow can be described as follows. After the conceptual phase of the product design the kinematic structure is defined and initial modeling work in MBS and CAD is triggered. Important interfaces between both domains are fixed in order to establish consistent data exchange. Based on the early design model multibody data is extracted by the CAD expert and passed to the simulation expert. This data is used by the MBS expert to update the related simulation models. Accordingly, the MBS expert analyzes the dynamic model behavior and suggests changes to the design to match predefined objectives. In the next step these changes are applied to the design model and the multibody data is updated. These elemental tasks are repeated in the loop

until the dynamic behavior of the system meets the desired requirements.

Automating the repetitive data extraction from CAD to MBS helps to create consistent data and shortens the amount of time needed to produce realistic simulation results. As already mentioned, different approaches exist to improve the mutual work of design and simulation experts. At early stages of the product development process it can be more helpful to focus on the simulation process as master to rapidly generate simulation results. The presented approach in the next section handles the kinematic structure exclusively on the simulation side.

## 3 Automated Modelica Package Generation

The main contribution of the presented work is a method for an automated Modelica package generation with specific characteristics. The introduction of design parameters in addition to the multibody data allows parameter variations with MBS and CAD in the loop. Furthermore, the simulation expert is able to create simulation experiments based on an early design version while CAD work is still in progress.

The workflow of automated model generation is divided in three main steps. First, existing CAD data has to be processed in CATIA according to a defined structure. Second, after the preparation work an initial package or a model in Modelica is generated and used to setup simulation experiments. Finally, due to variation of design parameter values or manual changes to the CAD part or product the simulation model or package is updated in the loop. In what follows of this section, we will briefly analyze each one of these steps.

### 3.1 CATIA Model Preparation

Starting point is either raw CAD data from other software or existing CATIA parts or products. In terms of package generation the top-level structure of the root product has to be reorganized to match the kinematic structure of the considered mechanism. The generation of connector frames in Modelica is based on CATIA axis systems. Therefore specific geometrical sets with axis systems are created in selected parts of the product structure. These axis systems are either connecting points for joints or other points of interest such as measurement or load points used in simulation. These preparation steps are mandatory for the export of the multibody data. In order to increase usability for the optimization-based de-

sign process, additional design parameters can be defined on the part level. These parameters are either lengths or angles that are linked to certain geometrical constraints of the part. The design parameters change the parts appearance and hence it's mass, inertia and geometrical information. Design parameters need special treatment during the update process as described in the next subsection. The output of the model preparation work can be summarized as follows:

- Top-level product structure equal to kinematic structure,
- Assignment of appropriate materials (densities) to every part of the product structure,
- Connector frames as axis systems in geometrical sets on part level,
- Optional design parameters linked to constraints of the design model on part level.

### 3.2 CATIA Model Conversion to Modelica

Depending on the type of available CAD data different Modelica model structures are produced. CATIA parts (\*.CATPart) are converted to Modelica models and CATIA products (\*.CATProduct) to Modelica packages. Figure 4 shows a CATIA model with two connector frames and the corresponding model structure in Modelica. The Modelica model consists of components from different Modelica libraries parameterized by CAD data. The Modelica MultiBody

Figure 4: CATIA model (above) and corresponding Modelica model (below)

Figure 5: Nested product structure of an assembly in CATIA

Library [5] provides connecting frames (frame\_a, frame\_b1 in Figure 4) that represent the axis systems in the CATIA model. These frames provide cut-forces and cut-torques that are transferred over joints between two components. The first axis system in the connector set of a part or a sub product is set as initial frame\_a for this model. The remaining axis systems are translated to connector frames frame\_b1 to frame\_bn and connected over fixed rotations (fixedRotation) with frame\_a. These models need the relative direction matrix and components of the transformation matrix between the frames as input.

Figure 5 illustrates an example of a nested product structure. Every product has its own body fixed axis system  $e^n$  that can be rotated and moved in relation to the axis system on a higher level. CATIA provides the direction vector  $r_{nn+1}^n$  and the transformation matrix  $T_{nn+1}$  of every component in the related body fixed axis system  $e^n$ . In this case axis system  $e^{c1}$  is chosen as frame\_a. The inputs for the fixed rotation from frame\_a to frame\_b1 are  $r_{c1c2}^{c1}$  and  $T_{c1c2}$ . Equations (1) and (2) allow a recursive transformation of every axis system to  $e^1$ :

$$\begin{aligned} r_{1c1}^1 &= r_{12}^1 + r_{23}^1 + r_{3c1}^1 \\ &= r_{12}^1 + T_{12}^{-1}r_{23}^2 + T_{12}^{-1}T_{23}^{-1}r_{3c1}^3, \end{aligned} \quad (1)$$

$$T_{1c1} = T_{12}T_{23}T_{3c1}. \quad (2)$$

The relative direction vectors and rotations between  $e^{c1}$  and  $e^{ci}$  in axis system  $e^{c1}$  are calculated with the help of equations (3) and (4):

$$r_{c1c2}^1 = r_{c2}^1 - r_{c1}^1, \quad (3)$$

$$r_{c1c2}^{c1} = T_{1c1}r_{c1c2}^1. \quad (4)$$

Figure 6: Visualization of a CAD assembly exported from CATIA in DLR SimVis

In addition to the geometric skeleton a body model is introduced containing the mass, a vector to the center of gravity and the body's inertia in respect to the initial frame. If assemblies are translated a model like previously described is generated for every product on top-level that contains connector sets. They are grouped together in a Modelica package.

The visualization is either run internally as Dymola animation with display of the multibody skeleton or externally animated by DLR's SimVis software [6]. SimVis integrates \*.STL (Surface Tessellation Language) files generated from the CAD package as three-dimensional shaded shape representations (Figure 6). Every frame has a visualizer in form of a coordinate system corresponding to the CAD package to simplify simulation work.

Design parameters are integrated as user input parameters on model level. The multibody parameters are either written in the Modelica model as fixed values or stored in a separate textual data file. In the second case the parameters are read into the model over the function `readRealParameter()` to enable parameterized simulation work based on the textual data file.

Figure 7: Graphical User Interface for model generation in Dymola

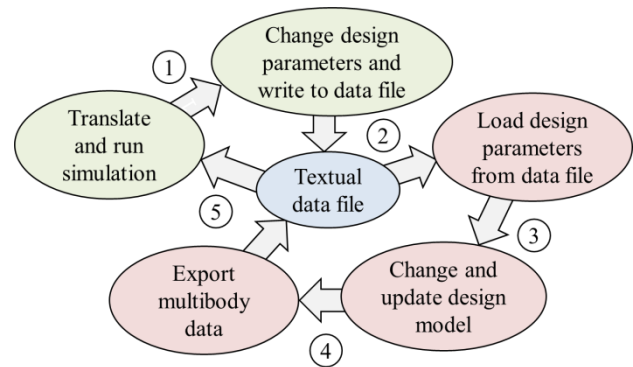

Figure 8: Update process in Dymola (green) and CATIA (red)

The model generation routine is triggered by a Modelica scripting function in Dymola that executes CATIA and runs macros from a VBA Library. Figure 7 shows the Graphical User Interface of the function for model generation with input parameters. The multibody parameters are either stored directly in the model as fixed values or optionally separated from the model in a data file. Furthermore the user can choose to export a three-dimensional shape representation for visualization and activate batch processing. The generated models are manually integrated in simulation experiments by the user in order to investigate the kinematic behavior of the mechanic system. Therefore a multibody structure with joints has to be set up and fitted into testing environments in Dymola.

### 3.3 Updating the Modelica Model Parameters

Throughout the development process changes to the design are applied due to consequences of simulation results or other new requirements. The design model data is either manually modified or changed by design parameters. Isolating the multibody parameters by a text file from the simulation model enables changes to physical and geometrical data without having to reload the model or package in Dymola. Figure 8 leads through the update process and shows the interaction between the different domains. In a first step the design parameter values of the Modelica model are changed in Dymola and written to a textual data file. Then an update routine in the CAD system is triggered by Dymola. The design model is opened in CATIA and the design parameters are read from the data file. After that they are changed in the CATIA design model. The part or assembly is updated in the CAD system and the modified multibody data is exported to the data file analogous to the model generation process in Subsection 3.2.

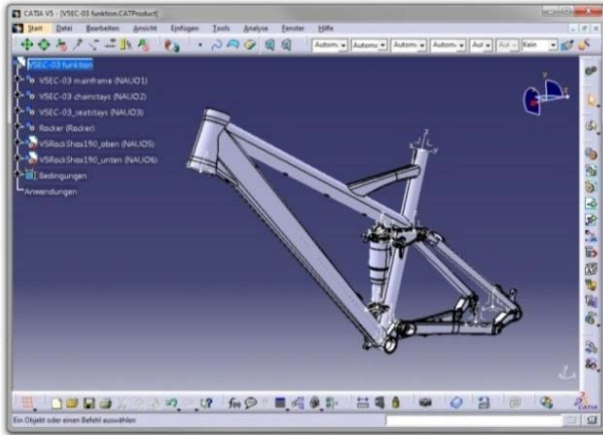

Figure 9: Bicycle rear suspension in CATIA

Finally, the corresponding Modelica simulation model is updated with the multibody parameters through the `readRealParameter()` function reading the parameter values from the text file into the model.

### 3.4 Optimization Loop

The commercial Optimization Library [7] provides several numerical optimization algorithms for solving different kinds of optimization tasks. Multiple tuner parameters with complex optimization criteria allow automated investigations to support the engineering design process. The goal of the optimization task is to minimize user defined criteria with optional equality and inequality constraints. A detailed view on the used optimization and evaluation algorithms can be found in [7]. In order to use the algorithms of the Function Optimization toolbox, the aforementioned update process is implemented in a Modelica function and fitted to the following defined structure:

```
partial function PartialCriteriaVariables
  input Real tuners[:];
  output Real criteria[:];
end PartialCriteriaVariables;
```

In this criteria function, the optimization tuner parameters are mapped to the design parameters defined in CATIA. Based on the tuner values an update routine in CATIA is triggered, followed by a simulation run in Dymola using the changed multibody data as described in chapter 3.3. Then, the simulation results stored in the corresponding `*.mat` file are loaded into workspace through the `readTrajectory()` function. Finally, the values from the loaded

trajectories can be used to formulate the optimization criteria.

## 4 Examples

The following section shows the previously described workflow of model preparation and package generation for an existing bicycle rear suspension from a 2012/13 Fatmodul Ant [8]. After that, the update process is demonstrated in a manual parameter variation followed by an automated optimization utilizing the Optimization Library.

Starting point of the model preparation work is CAD data in `*.STEP` (Standard for the Exchange of Product model data) format. At first the model has to be reorganized with respect to the kinematic structure. The rear suspension is designed as linkage driven single pivot. The shock and the swingarm are connected over additional linkages to generate a progressive leverage ratio between wheel travel and shock absorber travel. The shock, the swingarm (Chain stays) and the upper linkage (Rocker) are mounted in the fixed main frame. The seat stays complete the planar kinematic loop. Figure 9 shows the reorganized model structure on top-level in CATIA. In the next step connector frames are attached to the different parts of the assembly representing the connecting joints between the moving parts. Additionally important load points are defined such as the inertial axis system located in the bottom bracket and the rear dropout. For demonstration purposes a design parameter is defined which refers to the wall thickness of the seat stays. At this point the preparation work in CATIA is finished and the remaining steps are executed in Dymola.

Figure 10: Automatically generated Modelica package of the rear suspension in Dymola

Figure 11: Modelica model of the bicycle rear suspension

A function call in Dymola triggers the package generation in the working directory of the CATIA assembly product. Figure 10 shows the automatically generated Modelica package structure in Dymola. A Modelica counterpart is created for every top-level product from the CATIA design model.

The Modelica package and the associated multibody data file are stored in subfolders of the working directory together with \*.STL visualization data. Based on the kinematic structure a new Modelica model is manually set up by the user to include the generated models. Figure 11 shows the assembled kinematic model of the rear bicycle suspension. The different components of the package are connected via rotational joints with each other. Additional Modelica models complete the overall model. The shock is modeled as springDamper and an input force at the rear dropout is implemented.

Figure 12: Shock force over time for vertical force step in rear dropout

Figure 13: Cut through seat stays with wall thickness  $t = 1 \text{ mm}$  and  $t = 3 \text{ mm}$

Figure 12 shows the step response of the cut force in shock for a force step along the vertical axis of the rear dropout. An overshooting behavior due to predefined spring and damper parameters can be seen. The CAD model consists of 88 parts in 6 top-level products. The Modelica model for this experiment contains 989 components with 963 time-varying variables formulating 18381 equations. The overall process is executed on a X5650 @ 2.67 GHz Workstation with 12 GB RAM. The execution time for the parameter update process in CATIA together with translation and simulation in Dymola based on an already generated Modelica package is 57 s, which contains 29 s for updating the CAD assembly.

Figure 13 shows the inside of the seat stays with different design parameter values. With the help of the update process the wall thickness of the seat stays is changed between 1mm and 6mm in multiple steps. For every loop of the parameter variation the same routine is executed repetitively.

At first, the current design parameter values are written into the corresponding multibody data file. Then the CAD assembly is opened in CATIA and the design parameter values are read from the previously mentioned file. The parameter values are changed in the CAD product structure and the assembly is updated. In the next step, the updated multibody data, such as mass inertias and geometry, is overwritten in the textual data file by CATIA.

Finally, the model is translated in Dymola in order to reread the changed multibody data from the data file and the simulation experiment is run. The simulation

Figure 14: Different shock forces due to variation of wall thickness

results are saved and the next design parameter value is investigated. In this example, no changes to spring stiffness and damping constant were applied during the variation. Figure 14 compares the step responses of the different configurations. Faster response and less overshoot are observed with decreasing wall thickness.

Utilizing the Optimization Library [7], as mentioned in chapter 3.4, allows to investigate the system behavior under complex optimization criteria in comparison to the previously described manual parameter variation. In this example the wall thickness of the seat stays serves as tuner parameter  $p$  and a combined optimization criterion is formulated. The main optimization task is to minimize the overshoot in the shock force, referred to in Figure 15 as  $\Delta f$ . Due to mechanical restrictions in the design of the spring damper system the shock travel  $d$  should not exceed

Figure 15: Shock travel  $d$  and overshoot in shock force  $\Delta f$  as optimization criteria

Parameter	Value
Number of criteria evaluations	29
Initial wall thickness $p^0$	3 mm
Range of wall thickness $p$	1 mm – 6 mm
Optimization method	Pattern search
Computation time	1766 s
Best tuner parameter $p^*$	5.43 mm
Overshoot of shock force $\Delta f^*$	23.14726 N
Shock travel $d^*$	47.99986 mm

Table 2: Optimization preferences and results

48 mm. The following formulation summarizes the optimization problem:

$$\min_{1 \leq p \leq 6} \Delta f(p) \quad \text{s.t.} \quad d(p) \leq 48. \quad (5)$$

Table 2 summarizes the results of the optimization run. A solution  $p^*$  is found by a Pattern Search algorithm in less than half of an hour execution time. The solution activates the inequality constraint, i.e.  $d^* \approx 48$  mm and minimizes the overshoot of the shock force.

The shown examples serve mainly for demonstration purpose of the working toolchain and shall illustrate the potential of parameterized design and combined

## 5 Conclusions

An automated model conversion from CATIA to Modelica has been described in this paper. In contrast to existing conversion approaches the paper focuses on the simulation process with Modelica in Dymola. The quick and easy CAD model preparation task can be executed solitary by a simulation expert with basic CATIA experience. The model generation and update toolchain after the model preparation in CATIA is completely controlled out of Dymola. The multibody and design parameters are stored in the model as fixed values or in a separate textual data file. In this way the Modelica models that are derived from CAD are separated from the simulation experiments. Design parameters together with the Optimization Library enable automated parametric design studies. The algorithms and methods in this Library enable the optimization of a part or an assembly in CATIA considering the dynamic behavior of the underlying multibody system.

In the future the focus will be on code enhancement to decrease processing time. Direct communication between Dymola and CATIA via the Active-X-Com interface could improve the model generation process. Further application examples will validate the process quality.

# Modelling elastomer buffers with DyMoRail

Elisabeth Dumont    Werner Maurer  
Institut für Angewandte Mathematik und Physik  
Zürcher Hochschule für Angewandte Wissenschaften  
Technikumstrasse 9, Winterthur, 8401 Switzerland

## Abstract

In this paper a model for elastomer buffers for longitudinal railway vehicle dynamics is presented. This model is part of the more extended DyMoRail library which allows to simulate longitudinal dynamics of entire railway trains. With this library an efficient simulation of complete train compositions in various combinations is possible. The elastomer buffer can be used in combination with other buffer models and couplers in different test scenarios. We present details of our rubber spring model based on the one-dimensional, non-linear rubber spring model proposed by M. Berg [1][2][3]. To illustrate the behavior of the friction force modelled in the latter, it is compared to a diode model for Coulomb friction similar to the one in the Modelica Standard Library. Simulations for 40 J-buffer known as "Miner40" used for freight waggons during shunting at speeds up to 12 km/h are shown. Also shown are simulations of an entire S-Bahn combination with sixteen cars and fifteen elastomer buffers.

*Keywords: mechanics, railway*

## 1 Introduction

The tough competition in the railway industry is forcing operators to continuously set higher quality and comfort standards. Buffers on railway vehicles, as fabricated by Schwab Verkehrstechnik, are no more simple devices but have to be considered Hi-Tech components. They have to be absolutely reliable and present optimal properties to absorb run-up energy from trailing wagons safely. They have to absorb minor impacts, take up slack between locomotive and wagons and bear the load of preceding wagons when pushing. Years ago it was good enough for couplers and buffers to fulfill UIC (International Union of Railways) stan-

dards. But nowadays manufacturers only survive in this competitive market if they are able to offer optimized solutions regarding force, energy absorption, and driving comfort. The manufacturer has to be able to react quickly and flexibly to the challenges of rail operators and rolling stock manufacturers and offer final products and customized solutions with high customer value landlord. Since hardware tests are extremely costly, modeling and simulation step into the optimization process. DyMoRail allows to optimize buffers and couplers in different configurations for safety, energy absorption and costs. Train composition can be chosen by the user.

Figure 1: Drawing of a buffer (Seitenpuffer Kategorie A by Schwab Verkehrstechnik).

Schwab Verkehrstechnik AG and ZHAW carried out a project funded by CTI (Swiss Federal Commission for Technology and Innovation) to develop a tool which allows to simulate longitudinal dynamics of entire railway trains. During the following years a Modelica library has been developed, which is called DyMoRail. The DyMoRail library allows an efficient simulation of complete train compositions in various configurations. The library has been presented at Modelica 2012 [4] and a description of the coupler models can be

### 3 Model

Figure 4: Model for a rubber spring proposed by M. Berg.

For model implementation of the DyMoRail library, the Modelica based simulation software Dy-mola is used. The elastomer model is taken from the non-linear rubber spring model by M. Berg [1][2][3]. The model proposed in these papers is one-dimensional and based on the superposition of three forces (elastic, friction and viscous force) and contains five parameters. For better understanding, a schematic drawing is shown in Figure 4.

In the model by M. Berg, the elastic force is linearly modelled with a stiffness constant  $D$ :

$$F_e = D \cdot x \quad (1)$$

The viscous force is modelled by a linear spring (spring constant  $Dv$ ) in series with a linear viscous damper (damping constant  $k$ ):

$$F_v = Dv \cdot x - kv \quad (2)$$

The friction force  $F_{Coul}$  depends both on the displacement  $x$  and on a reference state ( $x_s, FR_s$ ) in the friction force versus displacement characteristic. Depending on the position relative to this reference state, the friction force is expressed with two parameters maximum force  $FR_{max}$  and constant  $x_2$ . A small value of  $x_2$  gives a steep increase in the friction force and thereby high frictional stiffness. The friction force  $F_{Coul}$  in the model is, depending on how  $x$  is related to the reference displacement  $x_s$ , defined by the equations below.

The reference state is set to  $x_s = 0$  and  $FR_s = 0$ .

$$F_{Coul} = FR_{max} \frac{s_{rel}}{s_{rel} + x_2}$$

For backward movement  $x_s = x_1$  and  $FR_s = FR_1$ :

$$F_{Coul} = FR_1 + (FR_{max} + FR_1) \times \frac{s_{rel} - x_1}{x_2 \left(1 + \frac{FR_1}{FR_{max}}\right) - (s_{rel} - x_1)}$$

For backward movement  $x_s = x_1$  and  $FR_s = FR_1 = FR_{max}$ :

$$F_{Coul} = FR_{max} \left(1 - 2 \frac{s_{rel} - x_1}{2x_2 - (s_{rel} - x_1)}\right)$$

For forward movement  $x_s = x_3$  and  $FR_s = FR_3$ :

$$F_{Coul} = FR_3 + (FR_{max} - FR_3) \times \frac{s_{rel} - x_3}{x_2 \left(1 - \frac{FR_3}{FR_{max}}\right) + (s_{rel} - x_3)}$$

For forward movement  $x_s = x_3$  and  $FR_s = FR_3 = -FR_{max}$ :

$$F_{Coul} = FR_{max} \left(s \frac{s_{rel} - x_3}{2x_2 + (s_{rel} - x_3)} - 1\right)$$

When the buffer is at rest  $x_s = x_5$  and  $FR_s = FR_5$ :

$$F_{Coul} = FR_5 + FR_{max} \frac{s_{rel} - x_5}{x_2 + (s_{rel} - x_5)}$$

When the buffer is at rest mode  $x_s = x_5$  and  $FR_s = FR_5 = \pm FR_{max}$ :

$$F_{Coul} = FR_{max} \left(\pm 1 + \frac{s_{rel} - x_5}{x_2 + (s_{rel} - x_5)}\right)$$

The implementation of these equations in Modelica is as follows

```

dx = dx1 + dx2
dv2 = der(dx2)
k * dv2 = Dv * dx1
Vorzeichen = if dv > 0
then 1
else if dv < 0
then -1
else 0
FCoul = FCouls +
(dx - dxs) * (FCoulmax - Vorzeichen * FCouls)
/(x2 * (1 - Vorzeichen *
FCouls/FCoulmax)
+ Vorzeichen * (dx - dxs))
when change(Vorzeichen) then
dxs = pre(dx)
FCouls = pre(FCoul)
end when
F = D * dx + Dv * dx1 + FCoul
der(W) = P
    
```

where  $dx_1$  is the displacement of spring  $Dv$  and  $dx_2$  is the displacement of the damper  $k$ .

To illustrate the behavior of the M. Berg friction model, it (Figure 5) is compared to a diode model for Coulomb friction, similar to the one of the Modelica Standard Library (Figure 6), as described for example in reference [7]. As can be seen from these graphs, the hysteresis loop of the Modelica Standard Library model has a rectangular form, whereas the M. Berg friction model shows sharp corners at the maximum and minimum displacements with a smooth transition between the upper and lower branch of the hysteresis.

Figure 5: Friction force versus displacement. Simulation of the friction model for a rubber spring proposed by M. Berg.  $F_{max} = 2$  and  $x_2 = 0.002$ .

Figure 6: Friction force versus displacement. Simulation of the friction model for the basic model for Coulomb friction in the Modelica Standard Library.  $F_{max} = 2$  and  $x_2 = 0.002$ .

In the final model for the Miner buffer in the DyMoRail library, the total force:

$$F = F_e + F_v + F_{Coul} \quad (3)$$

is taken to the exponent of an exponential function. This corresponds more to reality, shown by a thorough parameter study.

## 4 Simulation

For their acceptance test, railway companies define several crash scenarios with different crash partners at different speeds.

Figure 7 shows simulations for 40 J-buffer known as "Miner40" at different initial speeds. This type of buffers is exclusively used for freight wagons. The acceptance tests demand reversible shunting at speeds up to 12 km/h. During collisions at low speeds, the energy has to be absorbed by the buffers. Absolutely no damage should occur to the rolling stock. The acceleration must remain below 4.0 g.

Figure 7: Simulation of the buffer model with different initial speeds. Force vs stroke diagram.

The elastomer model works also in combination with other coupler or buffer models in complete train configuration. Figure 8 shows a simulation of three S-Bahn combinations colliding with a single combination at rest during shunting. Each S-Bahn contains four cars and three Miner models, so in total the model contains sixteen cars and fifteen buffer models. In this graph, one can distinguish the different cars colliding one after the other.

## 5 Conclusion

In this paper a model for elastomer buffers for railway vehicle dynamics is presented. This model is part of the more extended DyMoRail library which allows to simulate longitudinal dynamics of entire

Figure 8: Simulation of three S-Bahn combinations colliding with a single combination at rest during shunting.

railway trains. With this library an efficient simulation of complete train compositions in various combinations is possible. The elastomer buffer can be used in combination with other buffer and couplers models. The acceptance test scenarios can be simulated with the help of this model.

## Abstract

Modeling of multibody mechanics plays a central role in the design of mechatronic systems. In technical use-cases, they often contain loose couplings, where contact is possible. We present a ready-to-use contact library in Modelica. It comprises surface definitions for simple contact surfaces, which can be connected with multibodies of the Modelica Standard Library. It implements a force-based approach between single contact points. The contact forces are calculated in configurable non-central contact blocks. Exemplarily, the results of three experiments are shown and compared to benchmark simulations.

*Keywords:* contact library; simple contact surfaces; non-central contact block; contact forces

## 1 Introduction and Motivation

In the design process of mechatronic systems, the designers are facing the challenge of developing and controlling the more and more complex dynamics of the system. Therefore, multi-domain simulation models come to use from the outset of the conceptual design stage. As this also denotes a significant modeling effort, object-oriented modeling languages like Modelica offer the possibility to utilize and/or build up model libraries. The concept of ports makes it possible to combine and simulate components of different domains and origins in one model of the system. We intend to extend the available libraries by providing an idealized contact library that makes it possible to model contact phenomena. In particular, it should be possible to define each component separately in order to be able to reuse and combine approved patterns in new applications (c.f. [1]).

Considering technical use-cases one often finds multibody mechanics that typically comprise mainly fixed (e.g. kinematic chains) and few loose

couplings, where dynamic contact phenomena take place. Nevertheless, modeling contacts is “a key factor and a challenging problem in simulation of multibody systems (MBS), where a balance between performance and accuracy has to be found” [2]. However, to the best of our knowledge, there is currently no ready-to-use Modelica library available to handle contact problems in any level of detail. Otter et al. [3] suggest a force-based extension to the Modelica MultiBody Library to enable central collision handling. Herein, three variants to define contact surfaces are described (parametric surfaces, algebraic constraint surfaces, surfaces of polytopes). In [4] the surfaces of arbitrary bodies in the MBS are discretized by means of polygons. The approach presented in this paper differs from that, as it implements contact modeling by means of non-central contact blocks. It provides combinable, simple contact surfaces, which are described by single contact points.

We observed that in many industrial applications, even if the complete bodies are of complex shape, only a certain part of them contacts with others. The actual contact surfaces are often designed to be simple. Thus, the aim is to enable the designer to perform simulations of such systems including idealized representation of the contacts. Thereby, the analysis of the principle functional capability of the system in the course of the conceptual design is focused. This entails specialized modeling principles concerning the usability and the interpretation of the simulation results, which both should be relatively easy.

## 2 Concept of the Contact Library

Multibody mechanics is usually modeled using rigid bodies, which are described by their mass, located in the center of mass (CM), and their moment of inertia. In order to be able to model elastic, non-stiff collisions one has to weaken the rigid body assumption a little. Furthermore, one has to consider

the shape of the bodies. We address these two issues in the following subsections.

### 2.1 Idealization of the Elastic Foundation Model

References in literature introduce a so called “foundation model” to approximate the complex contact theory of Hertz and others in the context of multibody simulation [4,5,6,7,8]. It is assumed that the contact area is small compared to the dimensions of the contacting bodies (nonconforming contacts). The foundation model comprises a thin elastic or viscoelastic layer between the rigid bodies and neglects shear stress. With these assumptions, which are valid for isotropic and homogenous materials, one is able to describe dynamic as well as static contact incidents. The force-based approach contrasts with idealized impulse-based calculations, which are only applicable for stiff contacts [3].

We use a further idealization (c.f. Figure 1) that is based on single force elements. Assuming that the contact area is not only relatively small but also of an idealized shape, we describe it by means of single contact points. A nonlinear spring-damper element is inserted to calculate the normal force  $F_n$  between these points of the colliding surfaces. This requires the previous identification of possible contact points on the rigid body surfaces and the continuous determination of the normal direction. For these purposes, we provide analytic solutions for simple geometries in our library. The normal force is then used to determine the friction force  $F_t$  between the two bodies in the tangential direction.

Figure 1: Idealization of the elastic layer

### 2.2 Classification of Contacts

As a starting point, we focused on *spherical*, *cylindrical* and *plane* surfaces, either in *rectangular* or *circular* shape. Depending on the shape of the contact area, we use 1 (punctiform), 2 (linear) or 4-5 (planar) points to describe it. The position of the respective number of *potential contact points* is calculated on both of the contact bodies and the collision detection is performed for each pair of

potential contact points. Figure 2 shows the shape of the contact area for all possible combinations, as well as the number of contact points. As the contact region may alter with the moving bodies, the contact points will also move on the defined surface.

	<b>punctiform</b> (1 point)	<b>punctiform</b> (1 point)	<b>punctiform</b> (1 point)
	<b>punctiform</b> (1 point)	<b>punctiform/linear</b> (1/2 points)	<b>linear</b> (2 points)
	<b>punctiform</b> (1 point)	<b>linear</b> (2 points)	<b>planar</b> (4-5 points)

Figure 2: Shapes of the contact area and number of contact points for the different contact pairs<sup>1</sup>.

### 2.3 Definition of Contact Surfaces

To describe the aforementioned, elementary contact surfaces (Figure 2), we provide ready-to-use blocks. The surface blocks represent a thin and massless layer, which can be connected to any kind of rigid body by a *frame* connector (c.f. Figure 3). The dimensions of the surface can be parameterized. In order to be able to use the dimensions in the contact block we introduce a new interface to connect the surface definition with a contact block. This adds a vector to the MultiBody *frame* of the Modelica Standard Library that comprises maximum three terms to describe the surface geometry (e.g. width, length) and the respective direction vectors to get the orientation in the connected *frame*. The latter constitutes the body coordinate system (BCS) of the contact surface.

Figure 3: Example of a multibody model including contact

<sup>1</sup> Spherical, cylindrical and plane surfaces are displayed by the respective icon, which also indicates the maximum number of contact points.

Figure 3 displays an example of the intended use of the contact library. While the shape of the rigid bodies may be arbitrary, the shapes of the surfaces that possibly can collide are defined to be a circular and a rectangular plane. For example, body 1 may represent a bottle with a round and plane base. As this stands on a rectangular desk only these two simple contact surfaces have to be defined. More complex contact surfaces may be assembled from elementary ones, where every pair of surfaces is connected via a contact block. The contact block is adjusted to the respective surface combination by using the *replaceable* method for class parameterization in Modelica.

### 3 Modeling of the Contact Block

The calculation of the appropriate force in the contact block clearly depends on the combination of surfaces. Nevertheless, a comprehensive sequence (c.f. Figure 4) can be established that is implemented in the contact block and performed in each time step. As mentioned before, the *sphere-to-sphere*, *sphere-to-cylinder* and *sphere-to-plane* contact areas are described via a punctiform contact. In these cases, three steps have to be passed to determine the contact force. First, a potential contact point is determined on each of the two contact surfaces. The contact condition for these two points is checked in the next step. If the condition is fulfilled, the two bodies collide and the contact force between the two contact points is calculated. Otherwise, no contact force is applied.

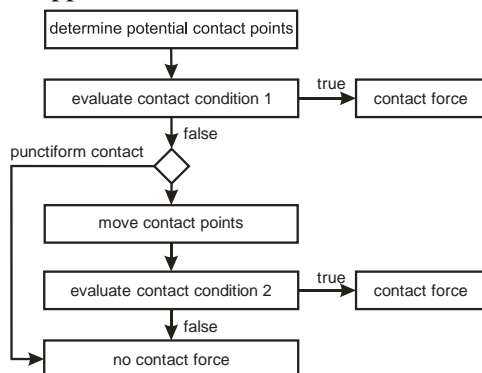

Figure 4: Calculation of the contact force

In the case of linear or plane contact, the contact area may become smaller if only parts of the surfaces collide, whereas the shape stays the same. Thus, additional contact point movement may be necessary. Here, the detection of contact points and the contact condition checking are performed analogously in the first two steps. If the contact condition 1 is not fulfilled, the contact points are

displaced to a new position on the contact surfaces in a way that contact between the new potential contact points might be possible. The latter is checked by evaluating the second contact condition. If a collision occurs, the respective contact force is calculated and applied.

#### 3.1 Contact Detection

The main principle of the implemented contact detection is shown with the help of two examples. The first example comprises a contact between a sphere and a cylinder (c.f. Figure 5). Initially, the bodies are represented by their centroids  $a_1$  and  $a_2$  in the MBS model. Two body-fixed frames BCS1 and BCS2 describe these two points. Furthermore, we assume that the lateral surface of the cylinder and the spherical surface of the ball are defined according to Section 2.3. Consequently, the two frames, the radius  $r$  of the ball and the length  $L$  and the diameter  $D$  of the cylinder, as well as the direction vectors of  $L$  and  $D$  resolved in BCS1, are available in the contact block.

In order to determine the potential contact points, the sphere-centroid  $a_2$  is projected on the longitudinal direction of the cylinder. The latter is represented by the  $x$ -direction of BCS1 by default. The result of the projection is the point  $a'_2$  given in BCS1. However, the absolute position of the point  $a'_2$  is limited to  $\pm L/2$ . This ensures that the point is always located between the two end faces of the cylinder. The local coordinate system LCS1 is defined in  $a'_2$  and has the same orientation as BCS1.

Figure 5: Contact point detection of the *sphere-to-cylinder* contact model

Based on vector  $\overline{a'_2 a_2}$  the direction vector  $\vec{e}_1$  is computed. Then, the orthogonal projection  $\vec{e}_{1ot}$  of the vector  $\vec{e}_1$  is determined in the  $y$ - $z$ -plane of LCS1. We obtain the first potential contact point  $b_1$  by displacing  $a'_2$  along the vector  $\vec{e}_{1ot}$ . As  $b_1$  lies on the cylinder surface, the distance is given by  $D/2$ . In the potential contact point  $b_1$ , the local coordinate system LCS2 is defined. Again, the orientation of it is equivalent to BCS1. With the help of LCS2 the position of the potential contact point  $b_2$  on the ball-

surface can be calculated. Therefore, the vector  $\overline{a_2 b_1}$  and the direction vector  $\vec{e}_2$  are determined. By moving  $a_2$  along  $r\vec{e}_2$  we calculate the position of the second potential contact point  $b_2$  on the spherical surface. The vector  $\vec{e}_2$  also constitutes the normal direction for the force calculation (c.f. Section 3.3) in this case.

After the determination of the potential contact points  $b_1$  and  $b_2$ , the contact condition is evaluated (c.f. Equation (1)). It consists of two terms. On the one hand, it is verified that the distance between the points  $b_2$  and  $a_2'$  is less than radius of the cylinder end face ( $D/2$ ) and greater than the difference between the radius and the maximum penetration  $t$ . The latter results from the assumption of a thin contact layer. This evaluation is performed in LCS1. On the other hand, the interval  $|x_{b_2}|$  between  $b_2$  and  $a_1$  in the longitudinal direction of the cylinder has to be less than or equal to  $L/2$ . This is evaluated in BCS1. If both conditions are fulfilled at the same time, the two bodies intrude and the contact force is applied to the contact points (c.f. Section 3.3).

$$\text{contact} = \left( \frac{D}{2} - t \leq |\overline{a_2' b_2}| \leq \frac{D}{2} \right) \cap \left( |\vec{e}_{x_{BCS1}} \cdot \overline{a_1 b_2}| = |x_{b_2}| \leq \frac{L}{2} \right) \quad (1)$$

The second example is the collision between a cylinder and a circular plane (see Figure 6), which denotes a linear shape of the contact area. As regards the circular plane, the geometry is sufficiently described by the radius  $R$ . Again, body-fixed coordinate systems (BCS1 and BCS2) are defined in the centroids  $a_1$  of the cylinder and  $a_2$  of the plane. The  $y$ -direction of BCS2 represents the vertical direction of the plane and the normal direction for force calculation. According to Figure 2 the contact area has a linear shape. Thus, two potential contact points have to be determined on the surface of the cylinder. These do not necessarily touch the plane at the same time.

To detect the contact points on the surface of the cylinder, the centers  $a_{1l}$  and  $a_{1r}$  of the two end faces are observed. The local coordinate systems LCS1 and LCS2 in these points are oriented like BCS2. In preparation for the potential contact point  $b_{11}$ , the unit vector  $\vec{e}_L$  of the  $x$ -direction in BCS1 and the orthogonal projection  $\vec{e}_{Lp}$  on the  $x$ - $z$ -plane of BCS2 are determined. Then, we implemented the following rotation sequence to get local coordinate systems that are orientated as needed. As regards  $a_{1l}$ , the local coordinate system LCS1 is rotated about the  $y$ -axis (LCS'1) and the  $x$ -axis (LCS''1) thereafter. The rotation angle  $\alpha$  is determined by the scalar product of  $\vec{e}_{Lp}$  and the unit vector of the  $x$ -direction of the

BCS2. Whereas  $\beta$  is specified by the angle between the vectors  $\vec{e}_L$  and  $\vec{e}_{Lp}$ . The contact point  $b_{11}$  is then given by  $(0, -D/2, 0)$  in the obtained system LCS''1. With the same principle, one can also determine the point  $b_{12}$ . In addition, the contact points  $b_{21}$  and  $b_{22}$  on the surface of the circular plane can be located by projecting  $b_{11}$  and  $b_{12}$  onto the plate (BCS2).

Figure 6: Contact point detection of the circle-to-cylinder contact model

Based on these preliminary, potential contact points the contact condition 1 is evaluated. It consists of three parts. As an example, the condition related to  $b_{11}$  is given in Equation (2). The variables  $x_{b_{11}}$ ,  $y_{b_{11}}$  and  $z_{b_{11}}$  are the components of  $b_{11}$  in the corresponding direction given in BCS2. To detect a collision, the absolute position in the  $x$ - and  $z$ -direction must not be greater than the radius of the plane, and the penetration depth must not exceed the maximum value of  $t$  in the negative  $y$ -direction.

$$\text{contact1} = \underbrace{(|x_{b_{11}}| \leq R)}_i \cap \underbrace{(-t \leq y_{b_{11}} \leq 0)}_{ii} \cap \underbrace{(|z_{b_{11}}| \leq R)}_{iii} \quad (2)$$

### 3.2 Contact Point Movement

However, contact between the cylinder and the circular plane might be possible, even if the contact condition 1 is not fulfilled. Figure 7 shows a configuration where the term  $i$  in Equation (2) is false. In this case, the preliminary contact point  $b_{11}$  should be displaced along the contact surface. We use the law of cosines to calculate the position of this new point  $b'_{11}$ . Considering the displayed triangle (Figure 7), we get the displacement  $b$  by the following equations.

$$R^2 = a^2 + b^2 - 2ab \cdot \cos \gamma \quad (3)$$

$$a = |\overline{b_{11} a_2}|$$

$$\gamma = \angle(\overline{b_{11} a_2}, \overline{b_{11} b_{12}})$$

Figure 7: Contact point movement in the *circle-to-cylinder* contact model

The vector  $\overline{b_{11}b_{12}}$  can be replaced by the length direction of the cylinder, which is available from the contact interface (c.f. Section 2.3). Thus, the new contact point  $b'_{11}$  is determined and the analogous contact condition 2 is checked.

$$\text{contact2} = (|x_{b'_{11}}| \leq R) \cap (-t \leq y_{b'_{11}} \leq 0) \cap (|z_{b'_{11}}| \leq R) \quad (4)$$

Since every linear contact region denotes a possible one-directional displacement of preliminary contact points, the contact detection in these cases is very similar. In contrast, planar contact regions lead to two directions of motion. Exemplarily, the contact point movement in the case of two rectangular planes is described in the following.

The initial situation of the example is shown in Figure 8. Again, the body-fixed coordinate systems BCS1 and BCS2 are defined in the two centers  $a_1$  and  $a_2$ . The geometry information of each plane contains the length  $L$  and the width  $W$ . The potential contact points are placed in the four corners of the planes. The contact condition in Equation (5) is used for the potential contact point  $b_{11}$ .

$$\text{contact1} = \underbrace{(|x_{b_{11}}| \leq \frac{L_2}{2})}_i \cap \underbrace{(-t \leq y_{b_{11}} \leq 0)}_{ii} \cap \underbrace{(|z_{b_{11}}| \leq \frac{W_2}{2})}_{iii} \quad (5)$$

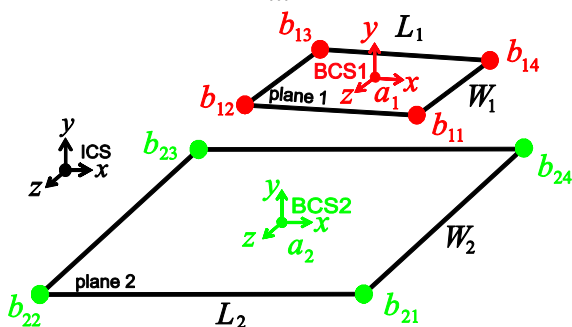

Figure 8: Initial contact points and coordinate systems of the *rectangle-to-rectangle* contact model

If the contact condition in Equation (5) cannot be fully met, the corresponding point is displaced along

the two adjacent edges of the rectangular plane and two new points are obtained. However, it must be ensured that the displacement cannot exceed the length of the respective edge. Figure 9 exemplarily shows a configuration, where one of the initial contact points of plane 1 is outside plane 2. The condition  $i$  in Equation (5) is violated, which means that the contact point exceeds plane 2 in  $x$ -direction of BCS2. The height  $h_{ol}$  of the displayed triangle constitutes the distance between  $b_{11}$  and the nearest edge on plane 2. It is calculated by the following equation.

$$h_{ol} = |x_{b_{11}}| - \frac{L_2}{2} \quad (6)$$

The relationship between the displacement of  $b_{11}$  and the distance  $h_{ol}$  can then be expressed with the help of the angle  $\varphi$ .

$$V_{lw} = \min\left(\frac{h_{ol}}{|\sin \varphi|}, W_1\right)$$

$$V_{ll} = \min\left(\frac{h_{ol}}{|\cos \varphi|}, L_1\right) \quad (7)$$

From these equations the two new potential contact points  $b_{11l}$  and  $b_{11w}$  are obtained by circumventing singularity problems in case of  $\varphi = 0$  or  $\varphi = \pi/2$ . Again, the second collision detection is evaluated to check whether contact forces have to be applied or not. As a result, it is possible that a maximum of five points can represent planar contact areas.

When implementing the contact point movement in Modelica, we tried to minimize the number of DAEs and events. Therefore, for example the *prismatic* block of the Modelica Standard Library has been modified in order to be adaptable to the respective direction. It is furthermore possible to disable the inserted filtering of the contact point displacement. Because it is usually continuously differentiable, this denotes an effective possibility to reduce the simulation time very often (see Section 4).

Figure 9: Contact point movement of the *rectangle-to-rectangle* contact model

### 3.3 Contact Forces

The three-dimensional contact force is applied, if the contact condition holds for one contact point. It

consists of both the normal force and the tangential friction force. The respective directions can be obtained by means of the local coordinate systems in the contact points. As aforementioned, the continuous surface layer is replaced by a nonlinear spring-damper element. Consequently, the normal force  $F_n$  is determined by means of the penetration  $p$  in normal direction, and the penetration velocity  $\dot{p}$ . A continuous contact force model with hysteresis damping according to [9] is implemented (Equation (8)). Nevertheless, selecting  $n = 1$ ,  $m = 0$  one can get the linear Kelvin-Voigt model, where the coefficients  $c$  and  $d$  are the spring and damping constants. Choosing  $n = m$  a formulation according to [10] is obtained.

$$F_n = cp^n + dp^m\dot{p} \quad (8)$$

In order to calculate the friction forces without further discontinuous events, which would decrease the simulation speed and impede controller design, we use the continuously differentiable friction model of Makkar et al. [11]. They introduced the following function of the relative velocity  $v_{rel}$  to approximate the friction coefficient  $\mu$  of the characteristic Stribeck curve.

$$\mu(v_{rel}) = \gamma_1(\tanh(\gamma_2 v_{rel}) - \tanh(\gamma_3 v_{rel})) + \gamma_4 \tanh(\gamma_5 v_{rel}) + \gamma_6 v_{rel} \quad (9)$$

Thus, no ideal static friction can be obtained, because the actual force to be applied in the ideal static state is independent of the relative velocity  $v_{rel}$  of the two contact points. Static friction is rather represented by sliding with very small relative velocities. However, this in fact matches the actual characteristics of many tribological systems [12]. To set the unknown, non-physical constants  $\gamma_i$  ( $i = 1 \dots 6$ ) we use five parameters, which are shown in Figure 10. The parameters  $\mu_s$  and  $\mu_k$  denote the coefficients of static and kinetic friction. The limit velocities  $v_{\varepsilon 1}$  and  $v_{\varepsilon 2}$  define the beginning of mixed and viscous friction. The latter is described by the proportionality factor  $k_v$ .

Figure 10: Approximation of the Stribeck friction curve

As an example, the following force vector (resolved in the LCS) is applied to the contact points of plane 1 of the *rectangle-to-rectangle* contact, if the contact condition is fulfilled.

$$F_{contact} = \begin{pmatrix} \mu_x \cdot F_n \\ F_n \\ \mu_z \cdot F_n \end{pmatrix} \quad (10)$$

## 4 Simulation Results

In this section, we will show some of the obtained results. We present three experiments, which were performed in Dymola using the DASSL solver. The results are compared to a benchmark simulation in the commercial MBS software RecurDyn. Herein, a powerful recursive algorithm to model contact problems is implemented, which is based on contact forces as well [13]. Despite the comprehensive and complex *solid-to-solid* contact that can be used for arbitrary CAD-geometries, RecurDyn offers the possibility to utilize idealized contact definitions for simple surfaces. In each of the three experiments, all parameters<sup>2</sup>, including the contact force calculation as well as the solver settings, are attuned to fit each other exactly. The direction of gravity is the negative  $y$ -direction of the ICS. When selecting the presented experiments, we refer to the aforementioned surface configurations (c.f. Section 3).

*Experiment 1* comprises a sphere ( $r = 0.015$ ,  $m = 0.11$ ) falling onto a cylindrical contact surface. The initial position of the sphere centroid is  $(0, 0.05, 0.002)$ . It is not coupled, whereas the position of the cylinder is fixed in the ICS. The latter has a diameter of  $D = 0.015$  and a length of  $L = 0.05$ . In this configuration two collisions occur. After the second contact with the cylinder surface, the sphere falls down beside the cylinder. Figure 11 shows the  $y$ -position of the centroid of the sphere. One can see that the calculated trajectories of the different tools are comparable. In this case, the effect of the nonlinear damping seems to be slightly higher in Dymola than in RecurDyn. Nevertheless, the peaks in the normal forces nearly coincide at approximately 21 N and 9 N (not shown).

In *Experiment 2*, a cylindrical body ( $d = 0.015$ ,  $l = 0.03$ ,  $m = 0.04$ ) falls on a circular plane ( $d = 0.08$ ) and then rolls down. The plane is fixed in the ICS, but rotated by  $5^\circ$  around the  $x$ -axis. The initial position of the cylinder is  $(0, 0.02, 0)$ . As the cylinder reaches the end of the plane, the preliminary contact points are displaced along the length

<sup>2</sup> All units are specified according to the International System of Units (SI)

direction. In Figure 12 some results are displayed exemplarily. We again observe that the positions of the centroid largely comply. The initial angular velocity (around the length direction) of the cylinder after the hit is slightly smaller in RecurDyn than in Dymola, while the acceleration is equivalent. The RecurDyn model (solid-to-solid contact) shows some implausible behavior right before the end of the plane is reached. Unless no external force is applied, deceleration can be monitored here. For these two reasons, the cylinder stays about 10ms longer on top of the plane.

Figure 11: Sphere falling on a fixed cylinder; parameters:  $c = 1e^5$ ,  $d = 10$ ,  $n = 1.5$ ,  $m = 1.5$ ,  $t = 5e^{-3}$ ,  $\mu_s = 0.03$ ,  $\mu_k = 0.02$ ,  $v_{\varepsilon 1} = 0.01$ ,  $v_{\varepsilon 2} = 0.1$ ,  $k_v = 0$

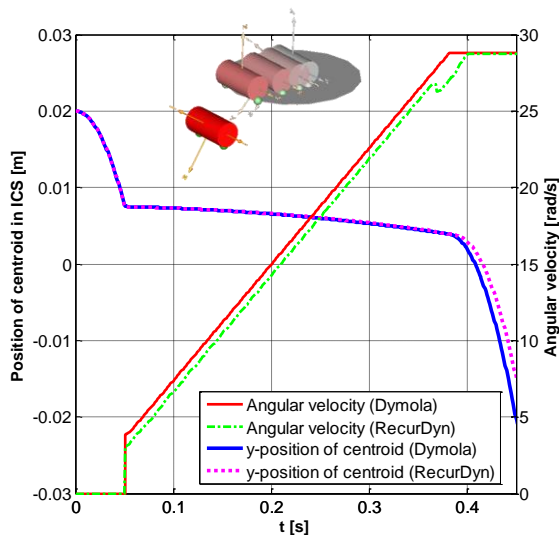

Figure 12: Cylinder on a circular plane; parameters:  $c = 5e^3$ ,  $d = 5e^2$ ,  $n = 1$ ,  $m = 0$ ,  $t = 3e^{-3}$ ,  $\mu_{s,k} = 0.12$ ,  $v_{\varepsilon 1,2} = 0.01$ ,  $k_v = 0$

*Experiment 3* contains a cuboid body ( $l = 0.07$ ,  $w = 0.1$ ,  $h = 0.05$ ,  $m = 2.75$ ) falling and afterwards sliding on a rectangular plane. The plane

( $l = 0.2$ ,  $w = 0.25$ ) is again fixed in the ICS and rotated by  $15^\circ$  around the z-axis. What can be seen in the plots (Figure 13) is that we get very similar movement of the box, despite an observed higher velocity in RecurDyn. In our opinion, the small divergence we obtain may be due to three reasons. (1) Again, the effect of the damping is slightly higher in Dymola, which leads to more sliding and therefore more decelerating friction forces. (2) The approximation of the Stribeck curve varies, which may lead to differences. (3) The handling of forces at the edge of the plane may be different (compare to Experiment 2).

In the case of our contact model the contact points are moved as displayed in Figure 14 (see Figure 8 also). As  $b_{13}$  constitutes the first edge of the cube to reach the end of the plane, it is the first contact point to be split up and moved in the length and width direction. The movement is limited to the respective dimensions of the cube.

Figure 13: Box falling and sliding on a plane; parameters:  $c = 1e^7$ ,  $d = 1e^7$ ,  $n = 1.1$ ,  $m = 1$ ,  $t = 5e^{-3}$ ,  $\mu_k = 0.08$ ,  $\mu_s = 0.12$ ,  $v_{\varepsilon 1} = 1e^{-4}$ ,  $v_{\varepsilon 2} = 1e^{-2}$ ,  $k_v = 0$

To evaluate the efficiency of the contact library in the context that was outlined in the beginning, we also investigated the ‘‘CPU-time for integration’’. Table 1 compares this characteristic property of the aforementioned models (simulated time  $t = 1s$ ). The results depict the experiences we made in various tests and further experiments. While in general, the integration times are comparable, they strongly depend on the number of contact points in Dymola. One can observe a strong increase, especially when movement of contact points occurs and the calculated displacement is filtered. On the other hand, modeling a rolling body sometimes leads to problems in RecurDyn, which is reflected in the CPU-time (see also Figure 12).

Figure 14: Contact point movement resolved in the local coordinate systems

Table 1: CPU-time for integration<sup>3</sup>

	Dymola	RecurDyn
Experiment 1	0.37s	0.20s (sphere-to-cylinder) 0.50s (solid-to-solid)
Experiment 2	3.52s (filter 10kHz) 0.61s (filter disabled)	4.98s (solid-to-solid)
Experiment 3	5.86s (filter 10kHz) 5.63s (filter disabled)	0.59s (surface-to-surface) 1.90s (solid-to-solid)

## 5 Conclusion and Future Work

In conclusion, we state that our idealized contact library provides a powerful and easy to use opportunity to model contact phenomena of simple contact geometries. Results of various experiments were compared and verified by means of analogous simulations in RecurDyn. The chosen architecture with the implemented contact interface and the configurable contact block matches the idea of reusing composable models. It is therefore especially useful in the conceptual design of mechatronic systems.

In the future, we want to provide more contact surfaces. In addition, we will investigate a possibility to save simulation time by disabling the contact calculation when they are not needed. Despite the validation with RecurDyn, comprehensive measurements are necessary. The major drawback of the force-based approaches is that the spring/damper parameters cannot be obtained directly from the given material properties. These parameters also depend on the surface combination and are usually determined experimentally. To tackle this, we plan to

<sup>3</sup> The simulations were performed on an Intel Core2Duo CPU with 2.53GHz and 4GB RAM

provide ready-to-use parameter sets for often-used combinations. After making our library publicly available, we also hope to identify further opportunities for improvement with the help of the Modelica community.

## Abstract

The OneWind<sup>®</sup> Modelica Library<sup>1</sup> [15] for coupled wind turbine loads calculation developed at Fraunhofer IWES uses a structural element based on a modal reduction method to model the motion and deformation of flexible wind turbine rotor blades and tower. The degrees of freedom (DOF) are rigid body motions and modal DOF. The `ModalElement` model allows the simulation of coupling effects like bend-twist coupling in wind turbine rotor blades and the structural behavior is dependent on the selected eigenmodes. This paper gives an overview about the Modelica implementation of the theory of modal elements, the advantages over other methods (finite-elements), how the `ModalElement` model is included into the OneWind<sup>®</sup> Modelica Library, and how it is used for load calculation.

*Keywords: modal, blade, OneWind, OneModelica, load calculation, wind turbine loads, coupled wind turbine simulation*

## 1 Introduction and Motivation

In wind turbine simulations, flexible multibody dynamics is widely used to describe the large motion and flexible deformation of blades. A flexible multibody system is based on the floating Frame of reference formulation. In a standard flexible multibody method, a finite element discretization is often combined with the multibody formulation to describe the beam flexibility. In the finite element method, the flexible beam is discretized into several beam elements. Each element is described with local shape functions weighted with nodal displacements. The numerical accuracy of the finite element method is dependent on the number of elements. A large number of elements demand quite a

lot computational costs, which are usually not suitable for wind turbine simulation.

A modal reduction approach can dramatically reduce the number of DOF of the beam by transforming nodal coordinates to modal coordinates. This approach is based on the assumption that the displacement of the beam can be expressed as the superposition of a series of eigenmodes weighted with modal coordinates.

The objective is to achieve the same accuracy as the finite element method with less computational time. This is a requirement for a wind turbine load calculation with a large number of load cases which are necessary for fatigue analysis. Therefore, the modal reduction method is used to create a structural element in the Modelica programming language which can represent the motion and deformation of flexible components of a wind turbine. With the OneWind<sup>®</sup> Modelica Library, a package of necessary Modelica models for aero-servo-elastic wind turbine simulations is finally available.

The paper is structured as follows: Section 2 describes the theoretical approach of flexible multibody and concludes with the equation of motion in modal coordinates. Section 3 shows the implementation of the flexible multibody with modal reduction in Modelica. In Section 4, an overview of the OneWind<sup>®</sup> Modelica Library with `ModalElement` model for rotor blades and tower is given. Moreover, the internal layout of wind turbine components is shown with a focus on interaction between models. Section 5 shows results of wind turbine deflection with the `ModalElement` model for flexible tower. Lastly, Section 6 concludes the presented work and gives an outlook for further applications of the `ModalElement` model.

<sup>1</sup>Version 1.0 for onshore wind turbine load calculation was released and is now available under dual license model. For further information contact: [info@onewind.de](mailto:info@onewind.de)

## 2 Flexible multibody with modal reduction

The ModalElement model is developed based on multibody dynamics and a modal reduction approach. The multibody system is based on the floating reference Frame. The floating reference Frame indicates that the deformation of the body can be formulated with respect to the corresponding body coordinate system, which moves together with the body. The absolute motion of an arbitrary point  $P$  on the body is defined by

$$r_P = R + A(\bar{u}_0 + \bar{u}_f), \quad (1)$$

where  $R$  represents the location of the origin of the body reference,  $A$  is a transformation matrix,  $\bar{u}_0$  is the local position vector in undeformed state, and  $\bar{u}_f$  is the deformation vector.

The representation of a deformable body in the world Frame requires  $6 + N$  DOF, which includes 6 rigid translational and rotational DOF and  $N$  flexible DOF

$$q = [q_r \quad q_f]^T = [R \quad \theta \quad q_f]^T, \quad (2)$$

where  $\theta$  are the orientation angles of the reference Frame and  $q_f$  is the  $N$ -dimensional vector of flexible DOF. In the Modelica model,  $q_f$  is formulated based on the finite element method and thus,  $q_f$  represents the nodal displacements in the reference Frame.

Using the principle of virtual work [14], the equations of motion for a flexible body in a multibody system can be described as

$$\begin{bmatrix} m_{RR} & m_{R\theta} & m_{Rf} \\ m_{\theta R} & m_{\theta\theta} & m_{\theta f} \\ m_{fR} & m_{f\theta} & m_{ff} \end{bmatrix} \begin{bmatrix} \ddot{R} \\ \ddot{\theta} \\ \dot{q}_f \end{bmatrix} + \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & K_{ff} \end{bmatrix} \begin{bmatrix} R \\ \theta \\ q_f \end{bmatrix} + \begin{bmatrix} C_R^T \\ C_\theta^T \\ C_f^T \end{bmatrix} \lambda = \begin{bmatrix} Q_{eR} \\ Q_{e\theta} \\ Q_{ef} \end{bmatrix} + \begin{bmatrix} Q_{vR} \\ Q_{v\theta} \\ Q_{vf} \end{bmatrix}. \quad (3)$$

A modal approach is implemented in the Modelica model to reduce the size of the system. In the modal approach, the specified displacement fields are formulated with the eigenvectors of a series of eigenmodes. The generalized displacement expression can be written as

$$q_f = \sum_{k=1}^n \phi_k Y_k, \quad (4)$$

where  $\phi_k$  is the eigenvector in the  $k^{th}$  mode and  $Y_k$  is the generalized modal coordinate in the  $k^{th}$  mode. The modal coordinate is time dependent, which is solved together with the multibody system. The eigenvector

is calculated in the preprocessing with OneModelica (see Section 4.6).

Equation (4) can be rewritten in the matrix form as

$$q_f = \phi Y, \quad (5)$$

where  $Y$  are the modal coordinates and  $\phi$  is the eigenvector matrix given by

$$\phi = [\phi_1 \quad \phi_2 \quad \dots \quad \phi_n]. \quad (6)$$

This procedure is the modal displacement superposition method. The number  $n$  represents the number of DOF in modal analysis. According to the characteristics of modal analysis, the first several modes dominate the contribution to the displacement field. A proper selection of these modes leads to a good approximation of displacements with a small number of DOF. For example, if  $m$  eigenmodes are selected,  $q_f$  can be described approximately by

$$q_f \approx \phi_m Y_m. \quad (7)$$

Using the eigenvector matrix as the modal transformation matrix, Equation (3) can be written in terms of modal coordinates as

$$\begin{bmatrix} m_{RR} & m_{R\theta} & m_{Rf}\phi_m \\ m_{\theta R} & m_{\theta\theta} & m_{\theta f}\phi_m \\ \phi_m^T m_{fR} & \phi_m^T m_{f\theta} & \phi_m^T m_{ff}\phi_m \end{bmatrix} \begin{bmatrix} \ddot{R} \\ \ddot{\theta} \\ \dot{Y}_m \end{bmatrix} + \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & \phi_m^T K_{ff} \phi_m \end{bmatrix} \begin{bmatrix} R \\ \theta \\ Y_m \end{bmatrix} + \begin{bmatrix} C_R^T \\ C_\theta^T \\ C_f^T \phi_m \end{bmatrix} \lambda = \begin{bmatrix} Q_{eR} \\ Q_{e\theta} \\ \phi_m^T Q_{ef} \end{bmatrix} + \begin{bmatrix} Q_{vR} \\ Q_{v\theta} \\ \phi_m^T Q_{vf} \end{bmatrix}, \quad (8)$$

where all matrices related to flexible DOF are modal reduced if the number of modal coordinates  $Y_m$  is less than the number of nodal coordinates  $q_f$ .

## 3 Implementation in Modelica

A flexible multibody model with modal reduction has been implemented by using the Modelica language. This model is named ModalElement (see Figure 1) in the OneWind<sup>®</sup> Modelica Library. Frame\_a and Frame\_b are the interfaces which are used to connect to other structural components. Frame\_c is the interface which is used to connect external loads.

The modal shape matrix, the modal reduced stiffness matrix, and the modal reduced mass matrix are

Figure 1: ModalElement icon

calculated in Java in a preprocessing step due to problems with calculating large matrices in Modelica (the details are described in Section 4.6).

The input modal reduced representations of the model are as follows:

```
parameter Real phi[divisions*6,nModes]
=modalElementData.phiMatrix;
parameter Real modalReducedStiffnessMatrix[nModes,nModes]=modalElementData.modalReducedStiffnessMatrix;
parameter Real modalReducedMassMatrix[nModes,nModes]=modalElementData.modalReducedMassMatrix;
```

Listing 1: Modal reduced representations

Dynamic equations (see Equation (8)) of ModalElement with damping are implemented in Modelica language as follows:

```
M*ddQ + D*dQ[7:6+nModes] + K*Q[7:6+nModes]
+ CqT[1:6+nModes,:]*lambda = Qe + Qv;
```

Listing 2: Dynamics equations

### 3.1 Boundary conditions

To solve a finite element problem, suitable boundary conditions are defined in the finite element system. In a pure finite element system, boundary conditions are usually enforced externally. However, in our flexible multibody formulation, boundary conditions are enforced internally in the model. This is because the floating Frame only exchanges the location of the origin of the body reference, the orientation of the body

reference, and the forces with other components. The deformation displacements of the flexible multibody model are not accessible externally.

The boundary condition for ModalElement is the “clamped-free” boundary condition. In this model all six flexible DOF are fixed at the root of the beam. Both displacements and rotations are equal to zero as

$$q_{f1} = q_{f2} = q_{f3} = q_{f4} = q_{f5} = q_{f6} = 0. \quad (9)$$

### 3.2 Animation

Animation is an important feature in wind turbine simulation. The immediate visual feedback about the dynamic behavior of the wind turbine helps the user with troubleshoot during a simulation. The 3D animation of ModalElement is realized by using the Surface function in Dymola with the following code:

```
model ModalElementSurface
extends Modelica.Mechanics.MultiBody.Visualizers.Advanced.Surface(redeclare function surfaceCharacteristic=OneWind.BeamElement.FlexibleMultibody.BeamVisualizer.BeamVisualizer (
    radius=radius,
    extra=1,
    r=r_i,
    qf=qf,
    angle=angle,
    der_angle=der_angle,
    scalingFactor=scalingFactor));
parameter Integer nl "number of visualization points along length";
parameter Real scalingFactor "scaling factor to visualize deformation";
input Modelica.SIunits.Position r_i[nl,3] "initial Position of visualization points";
input Modelica.SIunits.Distance qff[nl,3] "displacements of visualization points";
input Modelica.SIunits.Angle angle[nl,3] "angle at visualization points";
input Modelica.SIunits.AngularVelocity der_angle[nl,3] "angular velocity at visualization points";
end ModalElementSurface;
```

Listing 3: 3D ModalElement animation

## 4 OneWind<sup>®</sup> Modelica Library for coupled flexible wind turbine simulation

The OneWind<sup>®</sup> Modelica Library is based on the MultiBody Library from the Modelica Standard Library and contains all models for aero-servo-elastic load simulation. The models are grouped according to wind turbine components as seen in Figure 2 for an

Figure 2: Onshore wind turbine with corresponding component instances and interaction

onshore wind turbine. This Figure shows the model instances and corresponding interaction for the main wind turbine components: the rotor (with the sub-components of blade and hub), the tower, the nacelle (with the sub-components of drivetrain and generator), operating control, and the wind. The corresponding Modelica model for the main wind turbine components is written as:

```

model WindTurbine
  extends OneWind.OnshoreWindTurbine
  (
    //=== rotor ===
    redeclare OneWind.RotorModal rotor
    //=== tower ===
    ,redeclare OneWind.TowerModal tower
    //=== nacelle ===
    ,redeclare OneWind.NacelleRigid nacelle
    //=== operating control ===
    ,redeclare OneWind.Control operatingControl
    //=== wind ===
    ,redeclare OneWind.WindTurbulent wind
  );
end WindTurbine;

```

Listing 4: Modelica representation of Figure 2

To simulate at different levels of detail, several models for almost every wind turbine component are available. To exchange component models, the Modelica concept of replacing classes in the modifier with redeclare (with corresponding replaceable), as seen in Listing 3 and Listing 4, is used. The model OnshoreWindTurbine contains the declaration of instances of necessary wind turbine component models with all connections. These models are

exchanged in WindTurbine while extending from the OnshoreWindTurbine model. To ensure subtype compatibility, models that represent one turbine component extend the same partial model, which contain a replaceable, basic parameter record definition, and the external interface (Figure 3).

Figure 3: Inheritance concept for subtype compatibility

#### 4.1 Rotor model

The rotor model is the most important component of the wind turbine since it transforms wind velocity through aerodynamic lift to torque, which drives the electrical generator.

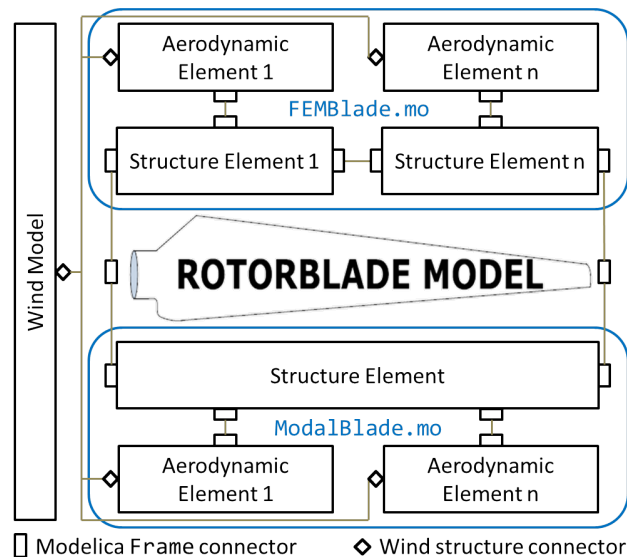

Figure 4: Different layout between the modal and finite element model and interaction between the structure model and the aerodynamic model in the rotor blade model

The rotor blade model consists of two main components which are connected via the Frame connector: the aerodynamic load element and the structure ele-

ment. In Figure 4, the connector scheme and the interaction between the structure model and the aerodynamic model is shown. The rotor blade models differ in regards to their structural part. The `ModalBlade` model consists of only one structure element, the `ModalElement` model, whereas the `FEMBlade` modal consists of  $n$  structure elements (in case of the NREL 5-MW reference wind turbine [7],  $n$  is 17 per blade and 11 for the tower). The structure elements are internally connected to the blade root, the blade tip, and to the aerodynamic load element through the use of the `Frame` connector. All rotor blade models extend a `PartialBlade` model, where the aerodynamic load element model is defined as well as the external interface root `Frame`, tip `Frame`, and the specific connector `StructureWind`, which is used to connect the wind velocity and position to the aerodynamic load element.

#### 4.1.1 Wind models

Deterministic and stochastic wind models are available. Deterministic wind uses several gust models. The stochastic wind data is read from binary or ASCII file in TurbSim [8] format.

All wind models consider the effect of the tower on wind velocity: in case of upwind, the potential flow method is applied and in case of downwind, an empirical model is used. Furthermore, exponential or logarithmic wind shear and vertical and horizontal inclination angle are accounted. The wind velocity is given as an input to the `StructureWind` connector.

All available wind models fulfill requirements defined in IEC 61400-3 [5].

#### 4.1.2 Aerodynamic models

Inside the aerodynamic load element, the `StructureWind` connector delivers the wind velocity which is used to calculate aerodynamic forces and moments. The aerodynamic load calculation uses either the blade element momentum theory (BEM, described in [11], [2], and extended in [1], [3]) or the general dynamic wake (GDW, described in [4], [16]) method. The BEM is implemented as an iterative algorithm while the GDW is a set of differential equations. For the BEM, corrections for the dynamic wake and the dynamic stall can be used. Dynamic stall correction is also available for GDW. The aerodynamic forces and moments are given as an input to aero load `Frame` connector.

#### 4.1.3 Blade models

Blade models differ in regards to their representation of flexible body motion. The `ModalBlade` model uses modal degrees of freedom, the `FEMBlade` model based on the Bernoulli beam element formulation uses 6 degrees of freedom at each node, and the `RigidBlade` model has no flexibility at all (only rigid body motion). The flexible blades consider centrifugal stiffening and pre-twist. All formulations are linear which are the standard in wind turbine load calculations. Non-linear formulations for large deflections but small deformations are under development.

Aerodynamic loads from the aero load `Frame` connector act as external forces and moments and lead to the rotation of the blades. The resulting forces and moments are transferred to the blade root `Frame` connector. Aero-Structure-Coupling enables the simulation of the coupling between the rotor blade deflection and the aerodynamic load calculation.

#### 4.2 Tower models

As for blade models, rigid and flexible models are available for the tower. The structure is basically the same: on the outside, the tower consists of a bottom `Frame`, a tip `Frame`, and load `Frame` connectors along its vertical length. Internally, the tower consists of the structure elements for load and deflection calculation and load elements for the calculation of the aerodynamic drag force from the wind. The connections are realized via `Frame` connectors (except for wind which uses a specific connector similar to the rotor model).

#### 4.3 Control system

The operating control system is implemented as discrete algorithms based on [7] and consists of a PI-pitch algorithm to control the power production above rated rotor rotation speed and a generator-torque controller which requests the counter torque from the electrical generator due to rotor torque. A single pole, low pass speed filter with cut-off frequency of 0.25 Hz transfers the continuous generator rotation speed signal to a discrete signal for control logic. For communication of control signals between sensors inside the wind turbine components and operating control, the `SignalBus` and the `SignalSubBus` connectors are used to build a hierarchic network of expandable connectors (as described in [9]).

#### 4.4 Offshore wind turbine components

Several physical models in the Modelica language for the dynamics of offshore wind turbines and the modeling of water and waves are under development. Fraunhofer IWES is a participant of IEA Wind and the Cooperative Agreement<sup>2</sup> with OC3 [17] and OC4 [10] projects to compare offshore wind turbine simulation codes, where the developed models for offshore wind turbine simulation are verified (see [18]).

#### 4.5 Interfaces between component models

The OneWind<sup>®</sup> Modelica Library basically uses three types of interfaces:

- Modelica Frame connector,
- Modelica FFlange connector,
- Component specific connector.

The Frame connector is utilized whenever loads are exchanged between different models and so does the aerodynamic load element calculate forces and moments from wind velocity using an aerodynamic theory. The transfer between aerodynamic load element and rotor blade is done via a Frame connector.

The FFlange connector is used for a limited degree of freedom representation of the drivetrain dynamics and transfers the torque and angle from the rotor to the electrical generator.

Additionally, user-defined connectors are used to transfer specific information between models that are not covered by the Frame or FFlange connector. Figure 4 exemplarily shows a user defined connector that transfers the wind velocity and position along the structure components to the corresponding aerodynamic load element.

#### 4.6 OneWind<sup>®</sup> Modelica Library with OneModelica

The Modelica IDE OneModelica [12], which is based on the Eclipse RCP framework, is being developed at Fraunhofer IWES. Figure 5 illustrates the workflow of the Modelica model development with OneModelica.

Modelica models can be developed by reusing models from libraries like the Modelica Standard Library and the OneWind<sup>®</sup> Modelica Library. Both libraries are integrated into OneModelica by default. Additionally, OneModelica also provides functionality for the generation of turbulent wind (according to Kaimal [6]). Input files for Modelica models are generated in

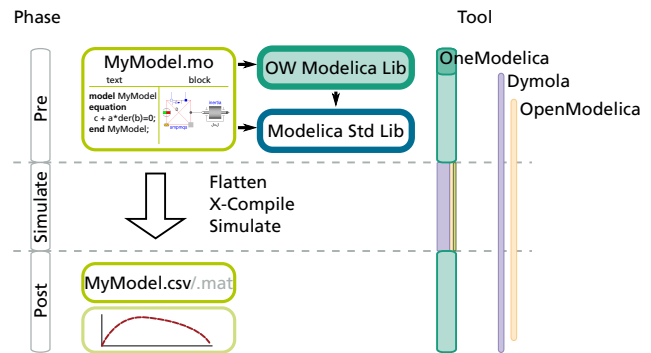

Figure 5: Modelica workflow with OneModelica

binary or ASCII format. The transformation of structure components into model reduced representations has been implemented in Java. This was necessary due to problems with large matrices when calculating the eigenfrequencies directly in Modelica.

In OneModelica, input models for the transformation are automatically recognized and a marker is added to the model files. Input models need to be of type record and must extend the record ModalInput which is included in the OneWind<sup>®</sup> Modelica Library. By right-clicking on the model file, the user can open the transformation dialog and provide a path and file name for the generated modal representation.

The record ModalInput defines distributed structural properties. At the user defined record level, parameters have to be redefined and the needed information for the FEM structure model have to be provided. In this way, the usage of the same data for modal and finite element model is ensured. The parameters are then extracted from the Modelica file and used by the transformation code developed with Java. The generated Modelica record with modal data contains the modal reduced mass and the stiffness matrix as well as the eigenforms and can be used with modal components. Changes in the structure model can easily be transferred to the modal component by the regeneration of the modal record.

The same workflow is used for the generation of turbulent wind data. A template record must be extended and parameterized. The generated wind file can then be used by a Modelica wind field generator that is included in the OneWind<sup>®</sup> Modelica Library. The user can re-use the generator and provide a path to the generated wind file.

Besides the described functionality, OneModelica supports several Modelica simulation tools for doing the flattening, compiling, and simulation and several simulations can be run in parallel. After a simula-

<sup>2</sup>[http://www.ieawind.org/about\\_co-operative\\_agree.html](http://www.ieawind.org/about_co-operative_agree.html)

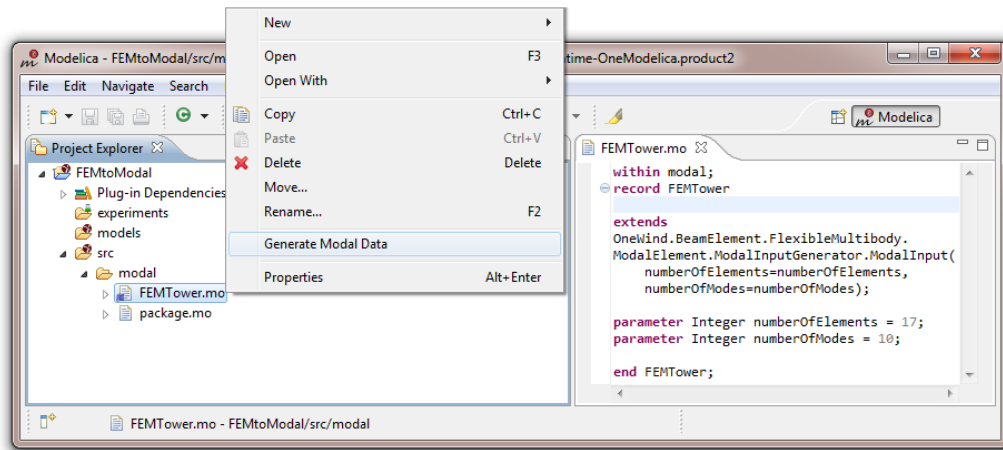

Figure 6: Transforming structure models to modal format

tion, the results are transferred back to OneModelica for post processing. Simulation settings and results are stored. The latest enhancement in OneModelica is an integrated framework for the automatic Modelica model testing [13].

## 5 Simulation Results

In the following section, simulation results with flexible wind turbine components are presented. All mentioned results were computed in Dymola<sup>3</sup>.

Figure 7 compares the deflection obtained with the ModalTower model and the finite element based TubularTowerModel model at the tower top Frame connector in the x- (downwind) and y-direction (side-to-side). The tower model is parametrized according to the NREL 5-MW reference wind turbine with the addition of a constant three dimensional force at the tower top. Both flexible models oscillate at the same frequency at each respective direction. The ModalTower model results strongly depend on the number of modes. The selected modes from the modal reduction must be able to represent the motion, which are enforced to the structure by external loading. Table 1 shows the error for a selection of eigenmodes (for a detailed view on convergence of error up to 30 Modes, see Figure 8). The reference is always the finite element model. Since the first eigenmode is only a 1-directional bending mode, it can only represent the bending in x-direction. Using more than 6 modes causes the error to drop below 1% in both directions. This means that 6 flexible (modal) DOF are enough

to represent the deflection of the ModalTower with almost the same accuracy as with TubularTowerModel. A reduced number of DOF will result in less computational time, especially with coupled wind turbine simulation.

To compare CPU-time, the load simulation of an aero-servo-elastic wind turbine is utilized. The model is parametrized according to the NREL 5-MW reference wind turbine. For the tower, the ModalTower model with six eigenmodes or the finite element based TubularTowerModel model is used. Integration algorithms are DASSL and Euler mixed<sup>4</sup>. For ModalElement based models, it is possible to choose Rkfix4<sup>5</sup>, which is not possible for the finite element model where no solution is found. Table 2 contains the results. As mentioned before, a reduced number in flexible DOF result in a reduction of computational time. The increase in simulation performance depends on the integration algorithm and lies between 300% and 550% for Euler mixed and DASSL. With Rkfix4, the simulation reaches real-time abilities.

## 6 Conclusion

This paper describes the approach and the implementation of a flexible structure element based on a modal reduction method in the Modelica programming language and its integration into the OneWind<sup>®</sup> Modelica Library for aero-servo-elastic load simulations of wind turbines.

The ModalElement model delivers comparable structural behavior as the finite element model. The

models oscillate with the same frequency. The error in deflection calculation drops below 1% beginning from the use of 6 eigenmodes. At this configuration, the simulation results are almost the same as with the finite element model and are available at a fraction of the finite element model computational time (see Table 2). Therefore, the ModalElement model is applicable for the load simulations of a flexible wind turbine.

The next step will be the application of the ModalElement model on substructure components for offshore wind turbine simulations and the integration to the OneWind<sup>®</sup> Modelica Library together with models for water and waves. Further development of the OneWind<sup>®</sup> Modelica Library aims to add:

- A structure element model for large deflections and large rotations,
- A state-machine based supervisory control,
- An interface for Bladed-style DLL for the controller,
- Real-time capability for a coupled flexible wind turbine simulation.

## Abstract

In this paper an approach for handling collision within the Modelica MultiBody library is presented. Therefore, a short overview about collision consideration for multibody simulation is given. Different methods for calculating the contact reactions are discussed and their potentials for implementation in a free Modelica library are deliberated. Furthermore the implementation of this collision library, using a penalty-based collision approach and the *Bullet Physics Library* for collision detection is described. The application is demonstrated in examples and limitations are brought up. Although some drawbacks restrict usability, the library can be used to increase the level of detail for multibody simulation models.

*Keywords:* contact; collision detection; collision library

## 1 Introduction

### 1.1 Motivation

Many physical systems cannot be simulated in a feasible manner without the description of collision interaction. Not only the typical applications, like wheel-road-contact, newton's cradle or a bouncing ball need collision consideration, but especially real-life models require contact handling. For example, simulation of typical working processes for construction machines, with lifting rocks can benefit from this. But also machine elements like mechanical springs require collision handling for simulations including dynamic loads.

For the Modelica Library *Modelica.Mechanics.MultiBody* (*M.MB*) several collision handling considerations have been made, with two to be shortly mentioned. In [1] Otter et al. introduced an extension to the *M.MB* library with capabilities of handling collisions. Collision detection using different approaches of surface representation were

shown. Engelson [2] described a way of contact implementation using impulse-based and penalty-based methods. However, those approaches have never been available in public.

To offer collision handling to general public, *CollisionLib* – the library presented here – will be freely available. Although the functionality of this very first version has only been tested in Dymola, support for OpenModelica and other Modelica environments are planned for the future.

### 1.2 Outline

In the following section general information about collision handling is given. The main steps for treating contacts are considered and several methods for handling collisions are described. These methods are compared with respect to their capabilities of straightforward implementation in Modelica.

The next chapter addresses *CollisionLib* - a library for collision handling within Modelica. A summary about requirements and intentions is given and, moreover, the implementation of collision detection and collision response is described.

Examples and limitations of applications are shown in section 4 and the paper is closed with an outlook about further development.

## 2 Collision handling approaches

### 2.1 Main aspects of collision handling

When handling collision interaction in multibody simulations two main steps have to be considered.

(1) **Collision detection** needs to be performed for every possible contact pair of bodies. By testing each combination the effort  $e_T$  is  $O(n^2)$ , see (1), where  $n$  is the total number of bodies.

$$e_T = \frac{n \cdot (n - 1)}{2} = \frac{n^2 - n}{2} \quad (1)$$

It follows from the foregoing that collision detection might have an impact on simulation time.

In order to accelerate this process different two step methods have been developed. Firstly, in the so called broadphase, a rough estimation which bodies might collide is made. Hence, all body combinations that cannot interact for obvious reasons are rejected. Those couples, that might collide, are tested with a proper distance algorithm, e.g. GJK [11], in the second step, called narrowphase.

By doing so, the overall effort can be reduced considerably. In [3] Baraff describes a broadphase method with  $O(n)$ . The total resultant effort  $e_T$  then is  $O(n+k)$ , with  $k$  being the number of body pairs requiring proper examination.

In addition to finding colliding body pairs, the corresponding contact normal and tangent vectors have to be determined for each of these pairs. For some approaches even more data has to be provided.

**(2) Collision reactions** have to be computed according to the chosen collision approach. Since collision handling has a long history, going back to Newton, Poisson, Coulomb and their laws and hypotheses, many different approaches for calculating collision responses are available. However, regarding to Mirtich [4] the state-of-the-art methods can be classified into three categories.

**(a) The Penalty-based approach** is the only one of these three allowing intersection among the bodies. The basic idea is that between the colliding bodies a spring, spring-damper or some other force element is present, which generates separating forces. The forces are related to the penetration of the bodies. This rather simple approach has some disadvantages. Finding right contact parameters is an open problem. Moreover, this parameters cannot be adopted from one simulation to others. Also collision forces have to be big in order to avoid deep intersection between the bodies. This leads to stiff DAE systems which are hard to solve, require small time steps and thus may lead to long simulation times.

**(b) Analytical solutions** prohibit intersection among the colliding partners. The constraints between the involved bodies are conveyed into a linear complementary problem (LCP), see [5] or [6]. Without consideration of friction the LCP formulation will always lead to contact forces, creating realistic movements of the bodies. However, these contact forces do

physically not need to present the right solution since the LCP might find unlimited numbers of solutions. In Figure 1 three possible solutions for the symmetric table under weight force  $w$  are presented with only (c) showing correct behavior. If friction is included

Figure 1: Possible solutions for the a standing table simulation using the LCP approach [4]

into the collision consideration the analytical approach might lead to no or no unique solution. In addition, solving an LCP can become difficult and system information is required, e.g. mass matrix and Jacobian matrix.

**(c) Impulse-based methods** are the third group of approaches for handling collision reactions. All kinds of constraints are neglected and no constraint forces are calculated. Instead all movements are handled using impulses and correcting impulses. Basics of this rather young idea of simulating movements are described in [7], [4]. The impulse-based methods, like the analytical approaches, prohibit intersection between the bodies. But, in contrast to the solutions of the analytical approach, the contact reactions are always calculated physically correct. Of course, also the impulse-based methods have some drawbacks. Stationary contact, like resting bodies on the ground, need to be solved by a high frequent number of small impulses. Interaction between multiple bodies, like a stack of boxes, can cause problems and corrupt results, cf. [4]. The biggest problem, when working with impulse based methods is, that a special form for the equations of motion is needed and special routines for solving those are required.

## 2.2 Implementation in Modelica

Because impulse based methods do not use constraint forces, an implementation in Modelica appears expensive – especially since correction impulses need to be calculated in one simulation step and have to be applied in the previous one. Also the interaction with other physical domains seems difficult.

The analytical approach is more applicable since constraint forces are calculated. However, solving the LCP can be difficult and requires knowledge of the mechanical system, like mass matrix of the mechanical system, etc.. Since Modelica is a multi-domain modeling language collecting the equations from all domains, a straightforward implementation in Modelica is, regarding to the author, not possible.

Hence, for this implementation a penalty method is chosen. For the first part of the collision handling, collisions have to be identified, as described above. Different free collision detection software packages, e.g. *Bullet* or *ODE*, are available, calculating the needed data for a penalty approach. Therefore, integration can be done directly without rewriting any contact routine, etc.. However, drawbacks of the penalty based methods may not be ignored and limitations must be accepted.

### 3 CollisionLib - a contact library for the multibody environment in Modelica

#### 3.1 General aspects

CollisionLib is a library that extends the *Mechanics.MultiBody*-library (*M.MB*) by collision consideration. This expansion implies that existing models do not need to be rebuilt. Instead, the mechanical components are connected to special collision objects, as seen in figure 2.

Figure 2: Setup of a mechanical System including collision handling

#### 3.2 Collision detection within Modelica

For solving the issue of collision detection *Bullet Physics Library* (*Bullet*) [8], an external C++-library, is used. It is a free package for simulating mechanical

systems, originating from entertainment industry with focus on video games and movies. Since *Bullet* uses a modular conception, see Figure 3, it is possible to take its collision detection only and drop the simulation routines.

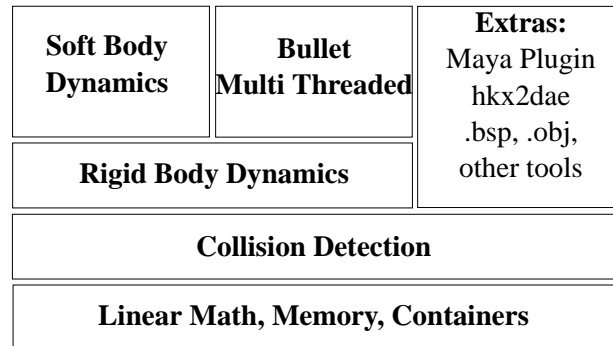

Figure 3: The modular concept of the *Bullet Physics Library* [9]

In order to calculate distance between two bodies, their geometry and their position as well as their orientation must be defined. Within the *M.MB* bodies are represented by their mass and inertia and therefore no additional information is present. However, *Bullet* contains a database with the basic geometries – sphere, box, cone, cylinder and capsule –, able to create a representation, if the right information is passed to it. For complex structures surface data, using a polygon mesh, need to be passed. In collaboration of *Bullet* and Modelica this implies that for basic bodies only some identifier and dimensions have to be supplied. The use of complex, mesh based geometries are currently not included, but planned for future versions.

Due to the fact, that all bodies of the *M.MB* are rigid, meaning that their inertia respectively shape will not change by cause of loads, the geometry information is only passed at initialization of the simulation.

In contrast to shape, the pose of each body needs to be updated every simulation step. This is done by transferring position and rotation matrix to *Bullet* each step.

With all the information described above *Bullet* can perform the check for collisions. From the several available broadphase algorithms within the C++- library an approach using axis aligned boundary box trees (AABB-trees) is used. Detailed information about AABB-trees can be found for example in [12]. For narrowphase intersection tests *Bullet* provides different algorithms for primitive shapes, triangle meshes, etc..

The coupling between Modelica and *Bullet* is done

by expanding the Modelica class *externalObject* into a class called *CollisionWorld* and developing a *Bullet* simulation runtime. Attentive readers might have noticed that *Bullet* is a C++-library and therefore cannot directly be connected to Modelica. To attach the *Bullet Physics Library* to Modelica an additional C-interface is needed. At instantiation of class *CollisionWorld* within a Modelica model, geometry information is passed to the interface. This interface itself, creates an instance of the *Bullet* simulation runtime, passing the position and rotation matrix, and returning a reference to Modelica. This procedure is visualized in Figure 4.

Figure 4: Coupling between Modelica and *Bullet* at system initialization

During each simulation step, the pose of the bodies needs to be updated and collision detection must be performed within the *Bullet* runtime. In Modelica, the function *updatePosition*, of type *externalC*, passes the reference to the *bullet* environment and the pose of the bodies back to the C-interface. This results in an updated *Bullet* simulation, giving back the number of contact body pairs (NoC). Using a second *externalC*-function, named *getCollisionData*, the collision data (coll. data) is given back to Modelica. The complete data flow between Modelica, C-interface and *Bullet* is shown in Figure 5.

Figure 5: Data flow during simulation

### 3.3 Collision normal force

As specified before, a penalty based approach for calculation collision reactions is used. The approach included in the *CollisionLib* calculates reaction forces using deepest point penetration. This means the two deepest points between the intersection bodies are calculated and the normal vector based on this two is

given by *Bullet*. Another possible penalty method for calculating response, could use consideration of intersecting volume. However, this is not possible using *Bullet*.

There are many different approaches calculating contact normal forces taking geometry, material properties, velocities, mass, etc. into account. A survey about some ideas is given by Machado et al. in [10]. In order to embrace the dimension of methods user-defined collision response laws can easily be implemented.

The basic normal force calculation, available in this library, uses a parallel set of non-linear spring and linear damper. The non-linear spring has its origin in the Hertzian contact theory but is here extended using energy dissipation.

$$F_N = F_c + F_d \tag{2}$$

The part  $F_c$  represents contact force due to the spring and  $F_d$  is the force due to the damper.

$$F_c = K \cdot \delta^n \tag{3}$$

The parameter  $K$  delineates the contact stiffness while the exponent  $n$  describes the non-linear force behavior due to penetration  $\delta$ .

For the damping force some limitations apply. Its magnitude can never exceed the spring part, preventing sticking between the two bodies. Therefore a dummy item  $F_{d2}$  is introduced

$$F_{d2} = D \cdot \dot{\delta} \tag{4}$$

$$F_d = \begin{cases} F_c & \text{if } F_{d2} > F_c \\ -F_c & \text{if } F_{d2} < -F_c \\ F_{d2} & \text{else} \end{cases} \tag{5}$$

The factor  $D$  describes the contact damping and  $\dot{\delta}$  denotes the relative velocity of the contact points.

All parameters ( $K$ ,  $n$ ,  $D$ ) depend on geometry and material of the colliding bodies. For special combinations of bodies different analytical and empirical approaches have been published. The parameters can also be derived by Finite-Element-Analysis or practical test execution. However there are no generalities available.

As mentioned before the contact parameters are individual for each contact. Nevertheless the parameters are globally set for all contacts in the first place. But of course the contact parameters can be individually assigned for each pair of bodies.

### 3.4 Friction force calculation

In order to calculate friction forces it is necessary to determine two tangent vectors ( $\mathbf{tv}_1$ ,  $\mathbf{tv}_2$ ) from the contact normal vector  $\mathbf{nv}$ . Since the two tangent vectors and the normal vector have to be orthogonal to each other two components of one tangent vector can be chosen freely. In *CollisionLib* this is done by the following scheme:

- Determination of the biggest component of the normal vector  $\mathbf{nv}$
- Assignment of value 1 to the two components of the first tangent vector  $\mathbf{tv}_1$ , respectively to the two smaller components of  $\mathbf{nv}$
- Calculation of the last component of  $\mathbf{tv}_1$  using dot product ( $\mathbf{nv} \cdot \mathbf{tv}_1 = 0$ )
- $\mathbf{tv}_2$  is calculated via cross product ( $\mathbf{nv} \times \mathbf{tv}_1$ )
- Normalization of both tangent vectors

With this tangent vectors the tangential plane of the contact is determined, in which the friction force vector is located. In order to identify its direction the projection of the relative velocity vector  $\mathbf{v}_{rel}$  into the tangential plane is required. The vector  $\mathbf{v}_{rel}$  is calculated from the contact pair of deepest penetrating points between the two bodies  $\mathbf{K}_a$  and  $\mathbf{K}_b$  as described from (6) to (8). All calculations are performed with respect to the initial frame  $\{\mathbf{O}^I, \mathbf{e}^I\}$  and refer to Figure 6. To keep calculations as short as possible only the quantities of *bodyB* are derived. The values of *bodyA* are calculated analogical.

First of all, the vector from the body fixed frame  $\{\mathbf{O}^B, \mathbf{e}^B\}$  to the contact point  $\mathbf{K}_b$  is calculated.

$$\mathbf{r}_b = \mathbf{r}_{Kb} - \mathbf{r}_{b0} \quad (6)$$

Using this vector the velocity of the contact point can be obtained.

$$\mathbf{v}_{Kb} = \frac{d\mathbf{r}_{Kb}}{dt} = \dot{\mathbf{r}}_{b0} + \boldsymbol{\omega}_b \times \mathbf{r}_b \quad (7)$$

After determination of  $\mathbf{v}_{Kb}$  the relative velocity is computed:

$$\mathbf{v}_{rel} = \mathbf{v}_{Kb} - \mathbf{v}_{Ka} \quad (8)$$

Figure 6: Calculation of the relative velocity during contact

By projection this vector into the tangent plane ( $\mathbf{v}_{relP}$ ) the opposite direction of the friction force vector is derived.

$$\mathbf{v}_{relP} = (\mathbf{tv}_1^T \cdot \mathbf{v}_{rel}) \cdot \mathbf{tv}_1 + (\mathbf{tv}_2^T \cdot \mathbf{v}_{rel}) \cdot \mathbf{tv}_2 \quad (9)$$

The magnitude of  $\mathbf{v}_{relP}$  is compared to a limiting velocity  $v_G$  at which the coefficient of static friction  $\mu_H$  is no longer used and sliding friction  $\mu_G$  is applied.

$$\mu = \begin{cases} \mu_H & \text{if } |\mathbf{v}_{relP}| < v_G \\ \mu_G & \text{if } |\mathbf{v}_{relP}| \geq v_G \end{cases} \quad (10)$$

Along with the magnitude of the contact normal force  $F_N$  the magnitude of the Friction force  $F_{Fmag}$  is calculated.

$$F_{Fmag} = \mu \cdot F_N \quad (11)$$

However, since the contact normal forces can be enormous a user-defined quantity  $F_{Fmax}$  is introduced, allowing to reduce the maximum assignable friction force if wanted, see (12).

$$F_{Fmag} = \min(F_{Fmax}, \mu \cdot F_N) \quad (12)$$

Using the negative normalized vector of the projected relative velocity the friction force vector can be computed.

$$\mathbf{F}_F = -F_{Fmag} \cdot \frac{\mathbf{v}_{relP}}{|\mathbf{v}_{relP}|} \quad (13)$$

By default the coefficients of friction are equal for all bodies. However, since different body pairs might interact the user can specify frictional coefficient for each contact pair individually.

## 4 Application of the Contact Library

### 4.1 General information about application

In order to enable collision handling in the *M.MB* library the components *CollisionWorld* and *CollisionBody* are needed. *CollisionBody* has a multibody connector frame that needs to be connected to a body respectively another multibody frame, see Figure 7.

Figure 7: The model *BouncingBall* with and without collision consideration

Within the parameters of this component the user can specify the type of the collision shape and its geometrical parameters, see Figure 8.

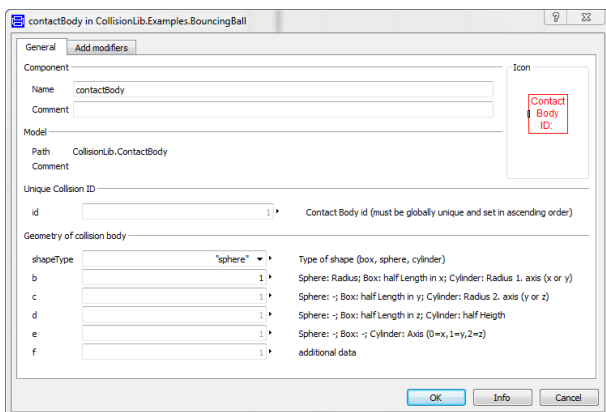

Figure 8: Parameters of the component *contactBody*

Each instance of *CollisionBody* needs a unique ID in ascending order starting at 1 (1,2,3,...). For the

*CollisionWorld* the highest ID has to be set as parameter in order to achieve "automatic" connections to the instances of *CollisionBody*. These connections are build using a *inner-outer-coupling*, meaning that an array of frame connectors is created for *CollisionWorld* with size of the passed parameter (maximum ID) and the *CollisionBody* is connected to the corresponding frame, based on the ID. Information about the shape is send from each instance of *CollisionBody* to the *CollisionWorld* via a user-defined connector. This is also done using *inner-outer-coupling*.

The problem concerning unique IDs has been discussed by Otter et al. in [1] before. However, planned changes in the Modelica language have not been implemented since then.

One of the bigger problems when handling contacts is the so called ghosting. This means, that one object moves through another object during one time step. This problem can only be solved by reducing the maximum solver step size. Alternatively within the *CollisionWorld* sampling can be activated, i.e. a collision check has to be performed during each sample. However, collision forces are also only calculated during each sample. This can result in wrong behavior, since the forces are constant between the samples.

The last big drawback when using the library *CollisionLib* are problems with collision detection for not strictly convex bodies. The GJK algorithm used by Bullet for many distance calculations, derives exactly one pair of deepest penetrating points, from the infinite number of pairs. This results in more or less unreal behavior, as pointed out in Figure 9. This issue

(a) configuration between cylinder and grounded box during contact with contact point pair (black)  
 (b) configuration after separation due to contact forces in the contact point pair

Figure 9: Wrong contact reactions due to an incongruous collision point pair

can be fixed by changing from deepest point penetration to intersection volume. However, a solution using the *Bullet Physics Library* is not known.

For some reason a user might want to ignore collision between a specific set of bodies. This feature is implemented by adding contact pairs (IDs) into a table within the component *CollisionWorld*.

### 4.2 Application 1: The pool table

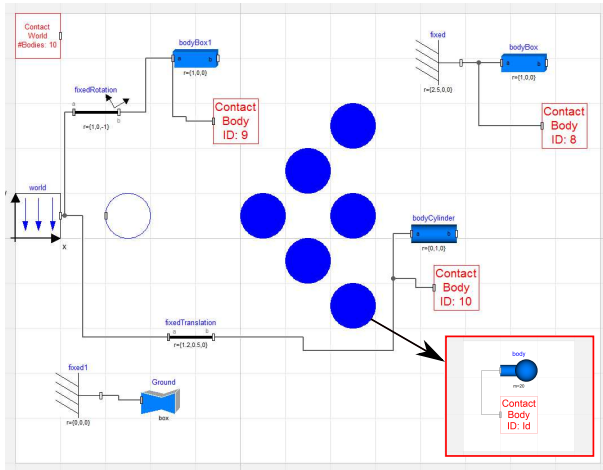

Figure 10: Setup of the model "billiard balls"

In Figure 10 a setup containing some "billiard balls" and other obstacles can be seen. While the obstacles are attached to the ground, the individual balls are free. Gravity of the system is set to zero. The white ball crashes into the group of balls, causing multiple collisions within the group of balls and the obstacles. In Figure 11 the system at time  $t = 0\text{ s}$ ,  $t = 0.25\text{ s}$  and  $t = 1\text{ s}$  is shown.

Note that the conservation of momentum is not fulfilled in the system. This Error occurs due to the chosen penalty approach.

The computation time for this rather simple model is lower than the time simulated, which means for small models real-time simulation is possible.

### 4.3 Application 2: dynamically loaded compressing spring

Apart from made-up models, the *CollisionLib* library has been used for the simulation of compressing springs. If simulating springs in high dynamic systems, like hydraulic valves, they can no longer be treated by the relation  $F = c \cdot \Delta x$ . Effects like coils hitting other coils or coils lifting of the spring cups need

(a) The system at time  $t = 0\text{ s}$

(b) The system after multiple collisions at time  $t = 0.25\text{ s}$

(c) The system after multiple collisions at time  $t = 1\text{ s}$

Figure 11: The model "billiard ball" with multiple collision partners

to be considered. Using collisions this consequences can be handled.

In picture 12 the multibody representation of the spring is shown. It consists of multiple rigid bodies that are connected by spring-damper-elements. There are no joints connecting the rigid spring elements or the single elements to the spring cap.

Due to a force of  $200\text{ N}$  acting for  $0.01\text{ s}$  on the upper spring cap, the spring is compressed and the coils interact among one another. At time step  $t = 0.03\text{ s}$  the spring has almost reached its block length and starts to expand shortly after. At  $t = 0.07\text{ s}$  the elements moved beyond their starting position during expansion of the

spring, see Figure 13.

Figure 12: setup of a compressing spring model using the *CollisionLib* ( $t = 0$  s)

(a) The spring at  $t = 0.03$  s      (b) The spring at  $t = 0.07$  s

Figure 13: States of the spring during simulation

Highly detailed modeling of systems, like the spring with a lot of self-interactions, can benefit from collision handling. However, simulation times can become very large. The spring model shown here takes seven hours for the complete simulation. Simulation time will be a subject of further investigation.

## 5 Outlook

In this paper the development of an add-on library to the *M.MB* for consideration of collision handling was given. The present version can be used to improve

simulation, as shown in 4.3. However, there are some greater drawbacks that hinder the full potential of contacts in this early version of *CollisionLib*. Development in order to provide a fully functional collision library continues:

- Support for OpenModelica
- Enable calculation of more than one contact point pair within a contact.
- Finding a suitable solution for the ghosting effect (dynamically change of solver step size)
- Support of mesh representation as geometry information

## 6 Annotation

Help and cooperation to promote this project are very welcome. Feel free to send your ideas and offers to [Andreas.Hofmann7@boschrexroth.de](mailto:Andreas.Hofmann7@boschrexroth.de)

## Abstract

The short term thermal production planning problem is solved in two steps by integrating physical plant models into the standard approach. The first step aims at solving the discrete variables from the unit commitment sub-problem (UCP) using standard mixed integer linear models and optimization techniques. The second step focuses on the economic dispatch sub-problem (EDP) described by high-fidelity, continuous time, physics-based Modelica models together with nonlinear optimization techniques from the JModelica.org platform. The output of the second step includes optimized power flows but also highly relevant variables such as supply temperature, supply flow rate, turbine by-pass valve in the cogeneration plant. The optimization is formulated as a maximization of the benefit from heat and electricity sell over a finite time-horizon.

The proposed method is validated in several test cases using experimental data from a plant in Nyköping. The optimizations demonstrate the feasibility and the high economic potential of the proposed approach when comparing with measurement data and the standard optimization techniques. The optimized planning schedules result in a balance between produced and consumed heat, priority to low-cost boilers and maximization plant revenue. Compared to measurement data, the optimizations result in a significantly lower supply temperature, a more extensive usage of the external cooler for higher efficiency and higher electricity production, fewer starts of units as well as an appropriate use of the accumulator tank.

The high-level description of optimization problems using JModelica.org provides useful means to speci-

fy flexible optimization problems including constraints on arbitrary process variables such as heat load of the production units, supply temperature and flow rate, pressures.

## 1 Introduction

### 1.1 Background

#### 1.1.1 Production planning

Production planning in district heating systems aims at finding a cost optimal scheduling of the heat and power production plants, which satisfies both the network load demand and operational constraints. Scheduling refers to the status of the production unit (on-off, a discrete variable), and the produced power (a continuous variable). The resulting optimization problem that involves both discrete and continuous variables is referred to as mixed integer non-linear problem (MINLP), for which no robust algorithm is available. It is therefore necessary to make reasonable assumptions on both the modeling and the computation approaches to get a tractable optimization problem. The problem can be described as being composed of two sub-problems:

- The Unit Commitment Problem (UCP), in which decisions are taken on whether a plant should be running or not. The main difficulty lies in the combinatorial nature of the problem.
- The Economic Dispatch Problem (EDP) in which the load decisions for all active plants are taken. The main difficulty lies in the nonlinearity of the plant.

A good survey of the available approaches for short-term production planning is given in [15].

As an input to the production planning problem, a predicted heat load over the entire optimization horizon should be provided. This is often generated by a load prediction model that typically includes a description of the district heating network and the effect of outdoor temperature. Here it is assumed that a perfect load prediction is available over the entire optimization horizon.

### 1.1.2 Common approach

The standard formulation of the thermal production planning problems relies on a simplified representation of the model equations. The plant models are typically linearized and the resulting problem becomes a Mixed Integer Linear Program (MILP). The continuous decision variables of the optimization problem are the energy flows whereas the influence of the supply temperature and mass flow are usually not modeled. This represents a limitation since e.g., supply temperature affects many critical parameters such as the amount of energy that can be stored in the network or the accumulator, the heat loss in the network and the electric efficiency of the co-generation plants. To maintain a low model complexity, it is also common to describe all processes by static relationships except for the storage dynamics (heat and fuels) and eventually the transport delays in the distribution network. The linearization process, which is a necessary and critical part of the MILP approach, is consequently a trade-off between model accuracy and tractable model complexity.

## 1.2 Proposed approach

The proposed approach is based on the natural separation of the discrete problem (UCP) from the continuous one (EDP).

- UCP. The entire optimization problem is formulated using simple piecewise linear models and solved using a MILP solver. The main result of this stage is the status of every plant (on/off) over the optimization horizon.
- EDP. The desired load is dispatched between the running production plants to meet all plant operational and safety constraints. The status (on/off) of the plants and the start values of continuous control signals are given by the solution of the UCP.

The aim of the second step is to optimize the non-linear plant model based on physical laws without

any major simplification. The plants are described by mass and energy balances, in terms of enthalpy, mass flow rate and pressure. Dynamics can be included without restrictions to match the real dynamic behavior of the plants. The output of this second step includes optimized power flows, but also highly relevant variables that affect the production economy such as supply temperature, supply flow rate or turbine by-pass valve in the co-generation plant. This model complexity yields however a non-linear dynamic optimization problem and requires another type of solver than MILP solvers, see [1] for an overview of the available strategies. One reliable and efficient method to solve dynamic optimization problems that is based on non-linear programming solvers is the so-called collocation method. Control signals to be optimized and model equations are parameterized by a smaller number of variables, reducing considerably the complexity of the non-linear optimization problem. The original continuous-time optimization problem is transformed into a (discrete-time) Non-linear Programming (NLP) problem that can be efficiently solved using commercial or open-source solvers. The authors have applied the collocation method for dynamic optimization of a Carbon Capture plant, see [2]. Other successful applications of this optimization technique have been reported in the literature, see [3] for a list of applications where IPOPT (Interior Point Optimizer), an open-source NLP solver, was used. To the authors' knowledge, limited work on applying large-scale NLP methods for solving the economic dispatch problem has been performed.

## 2 Optimization tools and languages

Two environments were used to define and solve the production planning problem:

- Dymola [9] was the chosen platform to derive, calibrate and simulate the physical Modelica [10] models defining the economic dispatch sub-problem
- Python was the chosen platform to solve both optimization problems and to do the post-processing

The unit commitment problem (UCP) was formulated in Python using the package PuLP [4] that is a light weight package that allows modelers to easily express mathematical programming problems, including mixed integer linear programs. It uses a high level modeling language and has been built to interface with commercial and open-source solvers. In the present work the solver CBC has been used, see [5].

The economic dispatch problem was solved from Python using the JModelica.org platform [16] as follows:

- The optimization problem was formulated in the Modelica and Optimica languages
- An FMU-simulation was carried out to generate a guess trajectory for the initialization of the nonlinear optimization
- The nonlinear optimization problem was solved using a collocation method available in JModelica.org

Applying nonlinear dynamic optimization techniques to solve the economic dispatch problem requires some considerations on initial trajectories, smooth media model functions, smoothing of mathematical functions such as absolute value, square root, min and max as well as scaling of optimization variables yielding a numerically sound behavior.

### 3 Plant models

#### 3.1 Idbäcken plant

The Vattenfall AB owned district heating plant Idbäcken, providing heat to customers in Nyköping, Sweden, served as reference plant. It contains in total seven different heat production units, one accumulator and one co-generation plant, see Figure 1. The Idbäcken plant has been the topic of interest in other research projects, see for instance [6] [7] and [8].

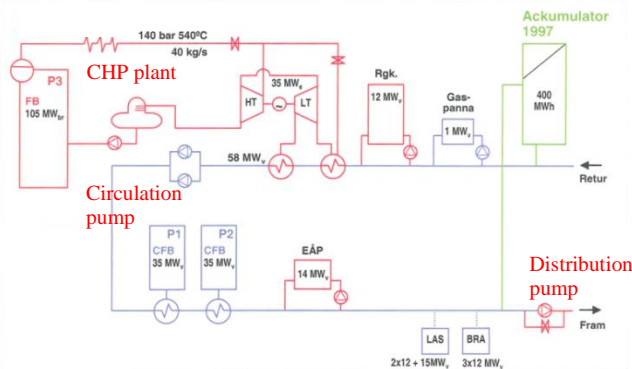

Figure 1. Schematic diagram of the Idbäcken plant with 7 heat production units, the accumulator and the co-generation plant

The main unit of Nyköping is the Combined Heat and Power plant (CHP) with a total heat capacity of 105 MW. The plant turbines can at most produce 35 MW of electricity, and the condensers can approximately transfer 75 MW of heat to the district heat water. The flue gas of P3 is used in a flue gas con-

denser of maximum 12 MW to pre-heat district heat return water before entering the CHP plant.

Two circulating fluidized bed units, P1 and P2, of each 35 MW used only for heat production may be used when heat demand is high. Additionally, there is an electric boiler of 14 MW and two oil based heat production units at the hospital and the residential area Brandkärr with 2×12 and 3×12 MW production capacity, respectively.

There is also an accumulator tank of hot water and an external cooler Beriden (not shown in figure) that can be used to decrease the return temperature and therefore increase both the load and the efficiency of the co-generation plant for a higher electricity production.

#### 3.2 Models for UCP

The unit commitment problem is formulated in Python using the PuLP modeling language.

##### 3.2.1 Heat production units

The discrete time plant model, i.e., the UCP model, is very coarse compared to the EDP model. All heat producing units  $i$ , except for the CHP plant, are modeled only by the produced heat  $Q_i$  and its minimum and maximum capacity. The influence of plant actuators such as pumps, valves or the influence of physical variables such as temperature, pressure and mass flows are not captured. The fuel consumption  $U_i$  of a pure heat unit is calculated using the efficiency parameters  $\eta_i$  as

$$U_i = \frac{Q_i}{\eta_i}$$

and for the CHP plant it is calculated as

$$U_3 = \frac{Q_{P3} + P_{el}}{\eta_3}.$$

For the CHP plant also the ratio between produced electricity and heat is interesting, defining the  $\alpha$  value as,

$$\alpha = \frac{P_{el}}{Q_{P3}}$$

The accumulator energy  $E_{acc}$  is given by a simple integrator equation and is not temperature dependent:

$$E_{acc}[t] = E_{acc}[t - 1] - hQ_{acc}[t - 1]$$

where  $Q_{acc}[t]$  is the energy flow from the accumulator,  $h$  is the sample time and  $t$  is the time index.

### 3.2.2 Co-generation plant P3

The produced heat  $Q_{P3}$  and electric power  $P_{el}$  are influenced by the boiler load, the position of the turbine by-pass valve as well as the flow and temperature of the district water. It is by far too complex to describe this relationship by simple (piecewise) linear functions. By using a physics based Modelica plant model and varying the four main variables, a feasible region in the  $Q_{P3}$ - $P_{el}$ -plane has been created to describe the behavior of the cogeneration plant. The resulting feasible region was described by four inequalities of the form

$$a_i P_{el} + b_i Q_{P3} + c_i \geq 0$$

where the points  $a_i$ ,  $b_i$  and  $c_i$  are scalar coefficients.

The UCP optimization should optimize  $Q_{P3}$  and  $P_{el}$  with the constraint that they should be in the feasible region described by the inequalities.

### 3.3 Models for EDP

The models used to formulate the economic dispatch problem are implemented in Modelica.

#### 3.3.1 Medium model

Two different types of media models are used in the model package:

1. Simple water media – a water media with constant specific heat capacity and density, used to describe the water in the district heating network.
2. Advanced water media – a water media with polynomial functions approximating IF97 reference functions, used to describe liquid and vapor water in the cogeneration plant, see [17] for more details.

#### 3.3.2 Cogeneration plant

The co-generation (heat and electricity production) unit P3, shown in Figure 2, is described by the following models

- One high pressure turbine and two low pressure turbines, all with bleed streams
- Two condensers
- By-pass valve for by-passing steam directly to the condensers
- A lumped bleed streams to describe the flow to the de-aerator and the high-pressure pre-heater
- Control volumes

The characteristics that are important to capture with respect to the optimization is the influence of the turbine by-pass valve, the district heat network flow and temperature and the boiler load on the produced heat and electricity. It is not necessary to describe e.g., the furnace, instead, focus has been directed towards the vapor cycle. The main modeling simplifications on the vapor cycle is that it is not closed, which results in the following assumptions:

- The vapor characteristics (pressure and enthalpy) at the boiler outlet are constant and the boiler load linearly affects the boiler mass flow rate.
- The feed water heaters that are downstream of the condensers are not modeled. All the bleed streams that normally go to the non-modeled pre-heaters are represented by a single stream connected to a constant pressure source.
- The condensate leaving the condenser is assumed to be at saturation pressure.

Figure 2. Dymola model of the cogeneration plant P3 with connections to the district water.

#### 3.3.3 Fluid component models

##### 3.3.3.1 Turbine

Physics-based model defined by an isentropic efficiency to calculate the outlet enthalpy and turbine work. The mechanical power generated from the steam is calculated using a mechanical efficiency and the pressure drop is related to the flow rate using Stodola's law. The electric power is calculated from the mechanical power using an efficiency parameter (generator losses).

### 3.3.3.2 Condenser

The heat flow rate transferred to the district water is driven by the temperature difference between the incoming water and the saturation temperature in the condenser. This heat flow rate is further used to compute the condensation rate that drives the bleeding flow from the turbine.

### 3.3.3.3 Control Volume

The control volume is a straightforward implementation of dynamic mass and energy balances expressed using pressure and enthalpy as states. Temperature is computed using pressure and enthalpy. The model requires partial derivatives of density with respect to enthalpy and pressure.

### 3.3.3.4 Valve and pressure loss

The mass flow through the valve is computed using the pressure difference, the valve opening and data from a nominal point. A standard quadratic equation relates mass flow and pressure drop.

### 3.3.3.5 Circulating Fluidized Beds, P1 and P2

The model is not physics-based and heat transferred to the water is calculated by first-order filtering of the load and using parameters for efficiency and maximum heat transfer.

### 3.3.3.6 Electric Boiler and Oil Driven Boilers

The model is not physics-based and heat transferred to the water is calculated by the load and using parameters for efficiency and maximum heat transfer.

### 3.3.3.7 Accumulator

The accumulator is modeled using a finite-volume approximation that neglects buoyancy effects, i.e. no mixing is assumed when the accumulator is not charging or discharging. The accumulator is charged and discharged from the top and bottom. Return water enters from the bottom. Heat loss has been neglected.

### 3.3.3.8 External cooler

The cooler is modeled as a lumped epsilon-NTU heat exchanger where heat transfer is driven by the difference between the inlet temperatures. It is assumed that the minimal heat capacity flow is always on the district side flow.

### 3.3.3.9 Transport Pipe

It is a finite volume implementation of a pipe with control volumes in series. The nominal number of discretization segments is 4 and the pipe diameter and length are parameters.

### 3.3.3.10 Flue Gas Condenser

The model is not physics-based and is an ideal heat source which produces constant heat as long as P3 is running.

### 3.3.3.11 Pump

The pumps are ideally modeled, delivering a specific mass flow rate depending linearly on the control input, i.e., pump speed.

### 3.3.3.12 Splitter/Valve

The splitter/valve is ideally modeled and splits the incoming flow into two flows which sizes depend on the control signal to the splitter.

### 3.3.3.13 Customer

The customer is modelled with a fixed outlet temperature and the heat absorbed is calculated by the temperature difference between in- and outlet and the flow that is merely propagated through from in- to outlet.

## 4 Problem formulation

### 4.1 Degrees of Freedom

The discrete time optimization (UCP) includes the power heat flows, the electricity production rate as well as the status (on/off) of every unit as optimiza-

tion variables. The status of each unit is fixed in the continuous optimization.

The continuous time optimization problem contains 11 degrees of freedom, namely:

- $U_i(t)$  fuel load of production unit  $i$ ,  $1 \leq i \leq 6$
- $U_{BP}(t)$ , turbine by-pass valve position
- $U_{CP}(t)$ , Speed of circulation pump
- $U_{DP}(t)$ , Speed of distribution pump
- $U_{split}(t)$ , ratio between flows going to customer and by-passing customer respectively
- $U_{cooler}(t)$ , ratio between flows going to external cooler (Beriden) and by-passing it

In the optimizations however, the decision variables used by the optimization routine will be the derivatives of the above inputs. Thus, an equation on the form

$$U_j(t) = \int_t \dot{U}_j(t) dt$$

is introduced for each input. This extension makes it easy to set minimum and maximum constraints on the input signal derivatives in the optimizations. In Modelica code, for a general input  $u$  with minimum and maximum values  $u_{min}$  and  $u_{max}$  and minimum and maximum derivative values  $\dot{u}_{min}$  and  $\dot{u}_{max}$ , an example is the following:

```
model inputExample
  parameter Real u_min = -1;
  parameter Real u_max = 1;
  parameter Real u_der_min = -1;
  parameter Real u_der_max = 1;
  input Real u_der(min = u_der_min,
max = u_der_max);
  Real u(min = u_min, max = u_max);
equation
  der(u) = u_der;
end inputExample.
```

Another possibility is to utilize the constraint-section in the optimization model.

## 4.2 Cost function

The goal of the optimization, both in the UCP and EDP, is to produce enough heat to follow the customer heat load over time and at the same time do it as economically beneficial as possible. The EDP problem considers fuel costs  $U_i(t)p_i$  and incomes from selling heat  $P_{el}(t)p_{el}$  and electricity  $Q(t)p_Q$  to describe the plant economy. Note that operational costs for e.g., pumps are not considered. The cost for

starting a production unit  $start_i[t]s_i$  is only included in the objective function of the UCP sub-problem. Hence, the revenue at a time instant can thus be formulated as

$$R(t) = P_{el}(t)p_{el} + Q(t)p_Q - \sum_i U_i(t)p_i - start_i(t)s_i,$$

A minor cost on the input derivatives must be used for regularity reasons. This cost at a certain time instant is formulated as

$$\dot{W}(t) = \sum_{\substack{j=All\ model \\ inputs}} q_{\dot{U}_j} \dot{U}_j(t).$$

where  $q_{\dot{U}_j}$  is the weight for derivative  $\dot{U}_j$ .

The cost function to be minimized, considering the cumulative revenue over the optimization horizon, can thus be formulated as

$$J = \int_{t_0}^{t_f} (\dot{W}(t) - R(t)) dt$$

where the optimization interval is  $[t_0, t_f]$  and 24 h long. This is as long as the optimization horizon in the UCP and also as the prediction time series provided by the heat load prediction model. Without the extra term of the input derivatives, this cost function is the continuous time counter part of the cost function in the UCP except for the start-up costs.

## 4.3 Constraints

### 4.3.1 Common constraints for EDP/UCP

For fulfillment of the heat demand from the customers, the following constraint is used in both EDP and UCP:

$$-Q_{dev.max} \leq Q(t) - Q_d(t) \leq Q_{dev.max}$$

where  $Q$  is the heat delivered to the customers,  $Q_d$  the desired heat load from the prediction model. The maximum deviation  $Q_{dev.max}$  is set to 1 MW. The supply temperature is not a direct function of the outdoor temperature, which is common practice. Instead, the supply temperature depends on the supply flow and heat demand, where the latter is a prediction depending on predicted outdoor temperature. A lower bound on the supply temperature has also been introduced and this could be replaced by a lower bound on the temperature at the customer substation if the district heating network is modelled.

An accumulator energy end-point constraint is introduced in both EDP and UCP to avoid that the accumulator gets empty at the end of the optimization interval:

$$E_{acc}(t_f) \geq E_{acc}(t_0)$$

The input derivatives, i.e., the decision variables for the optimizer, are given minimum and maximum values. A maximum change of  $\pm 2\%/min.$  has been set for all input derivatives relative to the maximum value of the input to the model. These limits can be set both from a physical perspective but also from a numerical perspective such that highly changing control signals are avoided. In the optimization results presented in this report, the derivative constraints are far from being active.

#### 4.3.2 UCP specific constraints

The start and stop of large solid fuel boilers is time-consuming and it is therefore critical to model the delay between the start/stop decision and the time the boiler is running at minimum/zero load. All units that are starting or stopping are required to follow a pre-defined trajectory  $Q_{i,start}[t]$  or  $Q_{i,stop}[t]$ , respectively. The constraints are formulated as

$$\begin{aligned} Q_i[t] &= Q_{i,start}[t], \\ t &\in [t_{start}, t_{start} + t_{startdelay}] \\ Q_i[t] &= Q_{i,stop}[t], \\ t &\in [t_{stop}, t_{stop} + t_{stopdelay}] \end{aligned}$$

where  $t_{startdelay}$  and  $t_{stopdelay}$  are the lengths of start and stop sequences in time. The details on how the timing variables  $start_i[t]$ ,  $stop_i[t]$ ,  $starting_i[t]$  and  $stopping_i[t]$  relate to the starting and stopping sequence equations above can be found in [11].

The accumulator storage capacity and heat flow are constrained with minimum and maximum values as

$$\begin{aligned} E_{acc,min} &\leq E_{acc}[t] \leq E_{acc,max} \\ Q_{acc,min} &\leq Q_{acc}[t] \leq Q_{acc,max} \end{aligned}$$

#### 4.3.3 EDP specific constraint

Normally, the supply temperature is chosen as a function of the outdoor temperature. In the continuous optimization, the supply temperature is optimized and allowed to vary between  $74.5^\circ\text{C}$  and  $110^\circ\text{C}$ . Also the flow to the customers, essentially the distribution pump flow, is given minimum and maximum values. These are  $0 \text{ kg/s}$  and  $550 \text{ kg/s}$ .

## 5 Optimization example

Different test cases based on measurement data from Idbäcken plant were considered to evaluate the production planning strategy. All optimizations, both UCP and EDP, are performed using an optimization horizon of 24 h. The UCP sampling time is 0.5 h while the number of elements in the collocation scheme is 72, i.e., the length of each element is 20 minutes. One test case with two load peaks is presented in the paper.

### 5.1 Initialization

All dynamic models were initialized using experimental data of the real plant. The variables of the UCP model that require initialization are the status of each unit, the heat and electricity production of the co-generation plant as well as the accumulator energy. The physical model of the plant used to formulate the EDP sub-problem contains much more states to be initialized. The start values were either directly taken from the measurement data or computed using an FMU simulation of the plant.

### 5.2 Computational statistics

In all optimization cases, the UCP optimization formulation results in a MILP of approximately 4000 decision variables and 7000 constraints. The sampling time considered is 30 minutes and the optimization horizon is 24 h. With the CBC MILP solver, see [5], the solution time is less than 25 s for all optimization cases.

The resulting NLP, after discretization of the EDP optimization problem using 72 elements each of a length 20 minutes, is solved using IPOPT v3.10.0 running with the linear solver MA27, see [12] and [13]. The NLP contains approximately 130 000 variables for each of the considered optimization cases, which can be considered a small to medium sized problem for IPOPT. Much larger problems have been solved using the JModelica.org framework and IPOPT, see [14] and references therein. The solution time is approximately 2-5 minutes and depends on e.g., initial guesses number of decision variables and number of active constraints.

### 5.3 Specific test case

#### 5.3.1 Experimental data

In this test case, the co-generation plant P3 is the only running unit at the beginning of the considered

time interval. The heat load profile showed in the figure below displays two peaks that require the start of additional units. To meet that increasing customer demand, the heat production in the cogeneration plant was first prioritized by fully opening the bypass valve before both P1 and P2 were started, see dotted curves in Figures 4 and 5.

Figure 3. Profile of the customer heat load: measurement, polynomial approximation, MILP and NLP solutions.

### 5.3.2 Optimization results

The solution of the unit commitment problem is characterized by the start of P2 at the first sample to meet the increasing customer demand. The start of P1 does not seem to be necessary. As the first peak of the customer heat demand comes before P2 is fully available, the accumulator is used and its energy level is significantly decreased during the first half of the optimization interval. P2 stays at its minimum capacity during the first 12h, a stop and re-start would be a more expensive alternative. During the second half of the optimization, P2 is used to load the accumulator and provide heat to the network. The optimization leads to a constant and maximum heat electricity production as it is economically beneficial. The turbine by-pass valve is therefore kept closed during the entire optimization interval. The variation in the customer load is met by changing the load in P2 and by using the accumulator. Figure 6 shows one typical advantage of applying nonlinear optimization for the economic dispatch: the supply temperature and flow are optimized to maximize the benefits. Note that none of these variables are in the UCP formulation as the UCP only contains heat and energy variables. For minimal fuel consumption, the supply temperature is kept low, about 5 degrees lower than in measurement data, the flow rate to the

network is instead increased to meet the heat power demand. Note that the distribution pump operates close to its maximal capacity except when the accumulator needs to be charged. Accumulator loading requires indeed a difference in the flows delivered by the circulation and the distribution pumps. At  $t=70h$ , the circulation pump operates at its maximum and the distribution pump is therefore forced to be decreased for accumulator loading.

### 5.4 Conclusion from other test cases

The production planning strategy has been successfully tested and compared with experimental data in 6 different cases, see [18] for more details. The following conclusions can be drawn:

- It is fully possible to integrate nonlinear optimization techniques from JModelica.org into the standard production planning approach for more accurate and more informative production plans.
- One of the main advantage of combining physical modeling and nonlinear optimization techniques is the optimized supply temperature and mass flow rate as well as a more accurate description of the accumulator.
- In the considered network, the optimization showed a high potential income related to the use of the external cooler that reduces the return temperature for a higher electric efficiency and a higher electricity production. This only occurs at low customer loads, i.e., when P3 is not required to run on full load. If customer load is high, then P3 should already be running at full load and the electricity production maximized.
- Handling of constraints on physical variables such as temperature, pump capacity and also constraints related to the way the accumulator is connected, improves substantially the quality of the optimization results.
- Supply temperature can be decreased by approximately  $4^{\circ}C$  compared to experimental data. With a perfect load prediction, the savings compared to measurement data is about 8%, which is related to the extensive use of the external cooler.

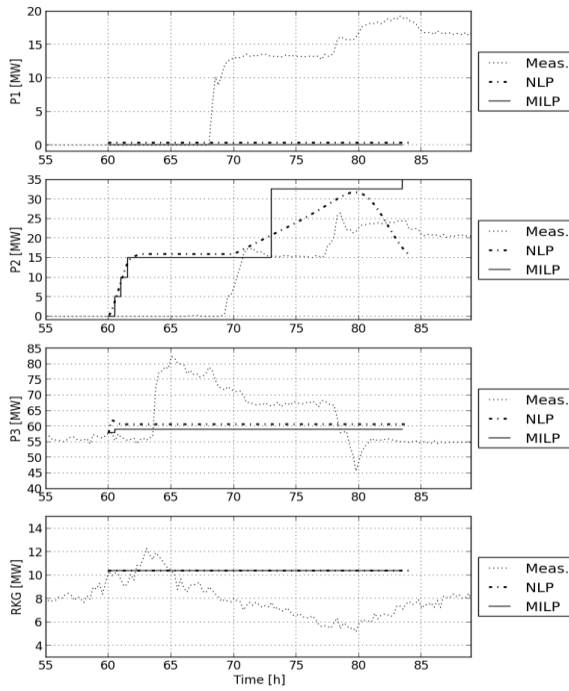

Figure 4. Heat production of the main units: measurement (dotted), MILP (solid) and NLP (dashed).

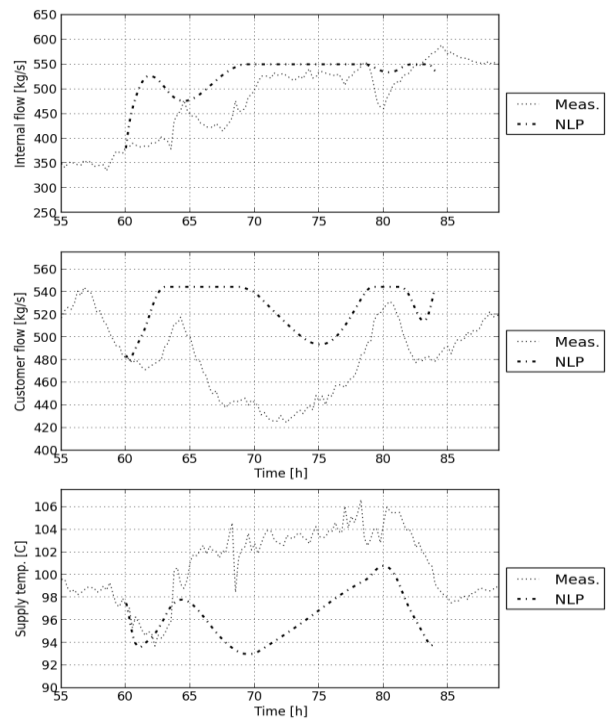

Figure 6. Circulation flow, flow to network and supply temperature. Measurement (dotted) and NLP (dashed).

Figure 5. Heat, electricity production rates and alpha-value of the cogeneration plant P3.

Figure 7. Accumulator energy and temperatures.

## 6 Conclusions

A method that substantially improves the standard approach for short-term production planning has been proposed in the paper. It is based on the use of physical plant models and nonlinear optimization techniques from JModelica.org to solve the economic dispatch sub-problem. The strategy has been validated using experimental data from a plant in Nyköping.

ping Sweden. Compared to measurement data, the method results in a significantly lower supply temperature, a more extensive usage of the external cooler for higher efficiency and higher electricity production. The flexible optimization platform JModelica.org makes it possible to optimize the plant economy and introduce constraints on critical variables such as temperature, pressure or flow.

# Modelling the system dynamics of islanding asynchronous generators

Håkon Molland Edvardson  
Oslo, Norway  
haakky1@gmail.com

Dietmar Winkler  
Telemark University College, Norway  
dietmar.winkler@hit.no

## Abstract

Asynchronous generators are often used for small hydro power stations with an installed power capacity of under  $1\text{ MW}$ . The reason for this is their robustness and low cost. In order to be able to produce active electrical power with an asynchronous generator one needs to provide enough excitation by means of reactive power provided by either the electrical grid or additional capacitors.

But in asynchronous generators we can also find the phenomenon of self-excitation which allows the asynchronous generator to operate as a standalone unit. Investigation of the self-excitation process shows that significant over-voltages can occur if a generator with sufficient capacitors is suddenly disconnected from the utility grid. The precondition for a successive voltage build-up is that the generator is left with enough capacitive power and a low load after the disconnection.

The *Lønnestad* radial in *Seljord, Norway*, is a distribution radial with both asynchronous and synchronous generators connected. In order to investigate the system dynamics in the radial after it is disconnected from the rest of the  $22\text{ kV}$  distribution grid, the radial was modelled and simulated using *Modelica* as modelling language.

**Keywords:** *modelica, asynchronous generators, self-excitation, islanding, electric power library*

## 1 Introduction

The main share of the electricity produced in Norway is based on utilisation of the nation's large potential of hydro power. Today are nearly all the large waterfalls profitable for hydro power production already utilised, or protected against encroachment on nature. Due to this, there has for the last decades been an expansion in the number of small hydro power stations below  $10\text{ MW}$ . This is often minor

projects where the power station is located near a small waterfall owned by a local landowner.

These small hydro power stations are often connected to already existing distribution grids, due to the geographical location and installed capacity of these stations. This is often grids constructed for low capacities with purpose to distribute the electricity out to the local consumers. Connection of power stations in these types of grids will therefore often change the situation of power flow in the grid, and lead to challenges regarding voltage stability and requirements for faults detection.

## 2 Theory

The system that will be described in this paper consists of a electrical distribution radial to which one synchronous generator and several asynchronous generators are connected. This theory section will only cover the most important aspects of the complex power systems.

### 2.1 Asynchronous generators

In the industry the asynchronous machine, or induction machine, is used in a wide variety of applications with purpose of converting electrical power to mechanical work. The asynchronous machine is very economical, reliable, and easy to control, which are some of the reasons for its popularity. There are two main types of asynchronous machines based on the rotor construction; squirrel cage type, and wound rotor type. The simplicity and low cost, and the fact that they can be driven as a generator as well as a motor, makes these machines very beneficial for wind power generation and small hydro power stations up to  $1\text{ MW}$ .

Unlike in wind power applications, the wound generator is seldom used in small hydro power stations. The reason for this is that generators used in small hydro power stations generally is operated on the

principle of self-excitation without any rotor excitation. For such applications, generators with the squirrel cage rotors can with advantage be used instead of generators with wound rotor, since the squirrel cage machine has lower cost.

### 2.1.1 The phenomena of self-excitation

Unlike the synchronous generator which gets its magnetisation from an internal magnetising source, and can be controlled to operate at a given frequency, the induction generator has no independent control over the air-gap field. The induction generator needs lagging reactive power to produce the main air-gap and winding leakage flux [1]. This phenomenon is referred to as self-excitation since the generator achieves its magnetising from a grid, or capacitors which are connected to the stator terminals. The phenomena permit utilisation of an induction generator as a standalone unit without a voltage source connected. Due to this the induction generator is often referred to as a *SEIG* (Self-Excited Induction Generator).

The phenomenon of self-excitation has been known for a long time, and a great deal of research has been done in the field of describing the phenomena and its transient behaviour. Various types of models have been proposed, but the main part of them is rather complicated models expressed by the Park's transform[2].

**Initiation of the self-excitation process** Self-excitation of a standalone generator may take place if a sufficient amount of capacitors is connected to the generator. In order to initiate the self-excitation process, the residual flux in the rotor iron has to be high enough. The residual flux will induce a voltage in the stator when the generator is accelerated to a certain speed. By connecting capacitors to the terminals of the generator, the induced stator voltage will cause a flow of current from the stator [3].

For a given capacitor, an SEIG running at no load requires only a minimum speed for the self-excitation to initiate [4].

**Voltage build-up in the generator** Once the process of self-excitation is initiated, the generator voltage builds up. The voltage build up can more easily be understood by looking at the phasor diagram in Figure 1.

Figure 1: Phasor diagram before and after the self-excitation is initiated [3]

In this figure it can be observed that a current,  $I_c$ , starts to flow from the capacitors once the self-excitation is initiated. This current generates a flux,  $\Psi_{gen}$ , into the generator, with the same direction as the residual flux,  $\Psi_{res}$ . Therefore, the current,  $I_{gen}$ , circulating in the stator reinforces the total flux,  $\Psi_{total}$ . This reinforced total flux causes an even higher stator voltage leading to successive increase in current and flux [3].

Figure 2 shows the generator magnetising characteristic and capacitance for three different frequencies, where the machine magnetising characteristic is simplified by linear segments with a knee point.

For a given capacitance and generator saturation characteristic, the intersection of the capacitance line and the *V-I-curve* of the generator moves as the frequency increases. The voltage build-up comes to halt when the non-linear magnetisation curve for the generator intersects the capacitor voltage curve [1]. This point is the steady state operating point for an induction generator running at no-load with capacitors connected. The no-load steady state operating point is determined by the non-linear magnetisation curve of the generator, the value of the capacitors, and the speed of the generator.

Figure 2 shows that by increasing the frequency, the generator curve is moved upwards, while the slope of the capacitor curve decreases, which results in an increase of steady state operation voltage. This states that connection of capacitors supplying a no-loaded induction generator with a larger reactive power than needed may cause over-voltage at the generator terminals [3].

The intersection point between the saturation characteristic and the capacitor line can be defined in terms of the electrical frequency [1]:

Figure 2: V-I curves for induction generator and capacitor at different frequencies [11]

$$V(\omega) = \frac{\omega A}{1 - \omega^2 L_d C} \quad (1)$$

$$I(\omega) = \frac{\omega^2 A C}{1 - \omega^2 L_d C} \quad (2)$$

Where  $L_d$  is the non-linear magnetisation inductance defined as  $d\Psi/dI$  on the saturated portion of the no-load  $\Psi - I$  curve for the generator, and  $A$  is the interception of the dynamic inductance line with the ordinate, defined as  $\Psi(I) = A + L_d I$ .

In order to achieve a steady state operation point at any frequency, the capacitance must satisfy the following expression:

$$\frac{L_a}{\omega^2 L_d} > C > \frac{1}{\omega^2 L_a}$$

Where  $L_a$  is the inductance defined by the air-gap line of the generator. [1]

## 2.2 Synchronous generators

Three phase synchronous generators are the primary source for all the electric energy produced in a power system. One of the reasons is that the synchronous generator gives the opportunity to decide whether it is desirable to produce or consume reactive power, which gives us the ability to regulate the voltage and power flow in an interconnected grid [5].

The rotor contains a field winding which is supplied by a DC source. This voltage results in a field current,  $I_x$ , which produce the rotor field in the air-gap between the rotor and stator. Controlling the rotor current and hence the rotor produced field, makes

it possible to regulate the induced emf and the reactive power of the generator.

## 2.3 Transmission lines

Small hydro power stations are often connected to a local distribution grid. This grid is usually owned by the local utility company, and is normally operated at a voltage level between 11 kV and 22 kV.

A distribution grid is normally composed of a combination of overhead lines and underground cables. The overhead lines are used for long distances and rural areas, while underground cables are used in urban areas and for underwater crossings. An underground cable is 10 to 15 times more expensive than an overhead line, and it is therefore only used in situations where overhead lines are unsuitable.

From a mathematical point of view, an underground cable can be modelled in exactly the same way as an overhead line. Here, the values of the electrical parameters are the only difference between them. In a cable, the shunt capacitance is strongly dependent on whether the three-phase conductors are screened or not, and on whether the three conductors constitute separate three-phase cables or one common cable [6].

The typical per unit length series inductance,  $L$ , of a cable is about half the inductance of a similar rated overhead line. On the other hand, the per unit length charging current is about 30 times more than for a similar rated overhead line. For a critically long cable, the charging current can be equal to the maximum current of the cable, there will then be no capacity left for transmission of power.

## 3 Over-voltage phenomena in Grunnåi

On the 27<sup>th</sup> July in 2011, several unwanted events took place in Grunnåi power station. By looking at the damages it could be seen that significant over-voltages had occurred in the 22 kV busbars of the power station.

### 3.1 Damages from the events

On the end termination of one of the incoming supply cables, a phase to ground fault had occurred. Two pictures of the end termination and its damage are shown in Figure 3. From the figure it can be seen

that there has been heat generation in the end termination.

Figure 3: Phase to ground fault on end termination of supply cable

A breakdown of a surge arrester had also occurred under the events. Figure 4 shows the surge arresters with the broken one to the left. By looking at the broken surge arrester and the signs of heat, it is natural to assume that the amount of energy dissipated in the surge arrester was higher than its energy handling capability.

Figure 4: Broken surge arrester to the far-left

Signs of high temperatures and arcs were also seen other places in the rack of the 22 kV busbar, which could be signs of a possible short-circuit due to a high voltage.

Damages did also occur in other places of the radial this day, which indicates that the phenomenon did not only take place locally in *Grunnåi*.

### 3.2 The sequence of events

By looking into the logs of the protection relays in *Grunnåi* and *Seljord* sub-station, it was discovered that several functionalities in each of the protection relays had started to account for triggering. Unfortunately the clocks in the protection relays were not synchronised, so it is impossible to determine which protection relay triggered first.

It is most likely to think that the whole sequence started with a breakdown in the end termination of the incoming cable in *Grunnåi*. The breakdown was most likely caused by a weakness in the end termination due an installation failure. This error may have caused a bad connection or a weakness in the insulation which led to heat generation and degradation of the insulation over longer period of time.

The presumed sequence of events was:

1. Earth circuit fault in *Grunnåi* due to a breakdown in the end termination of a incoming supply cables.
2. The protection relay in the *Seljord* sub-station detected the phase to ground fault and disconnected the *Lønnestad* radial from the rest of the grid in *Seljord* momentarily after the fault was detected.
3. The disconnection resulted in heavy imbalance of active power and reactive power in the now islanded radial.
4. The frequency in the grid increased rapidly since *Grunnåi* did not correct for the overproduction in the island.
5. The generator circuit breaker disconnected *Grunnåi* from the grid, due to triggering of the over-frequency relay (51 Hz and 0.1 seconds). This left the asynchronous generators in *Sagbekken 1* and *Sagbekken 2 and 3* alone in the island.
6. Sufficient amount of reactive power in the grid to initiate self-excitation. The self-excitation led to a successive voltage build-up, which resulted in significant over-voltages in the grid.
7. The high voltage led to a large voltage drop across the surge arresters in *Grunnåi*. The amount of energy dissipated in the surge arrester was higher than its energy handling capability. This caused one of the surge arresters to breakdown.
8. The high voltage exceeded the dielectric strength of air inside the rack of the busbars. The air became ionised and arcing occurred inside the rack. This arcing led to low impedance in the grid, and the process of self-excitation came to halt.

This is the presumed sequence of events, based on the damages and grid configuration. Following chapter presents simulations from the *Lønnestad* radial where different scenarios are carried out.

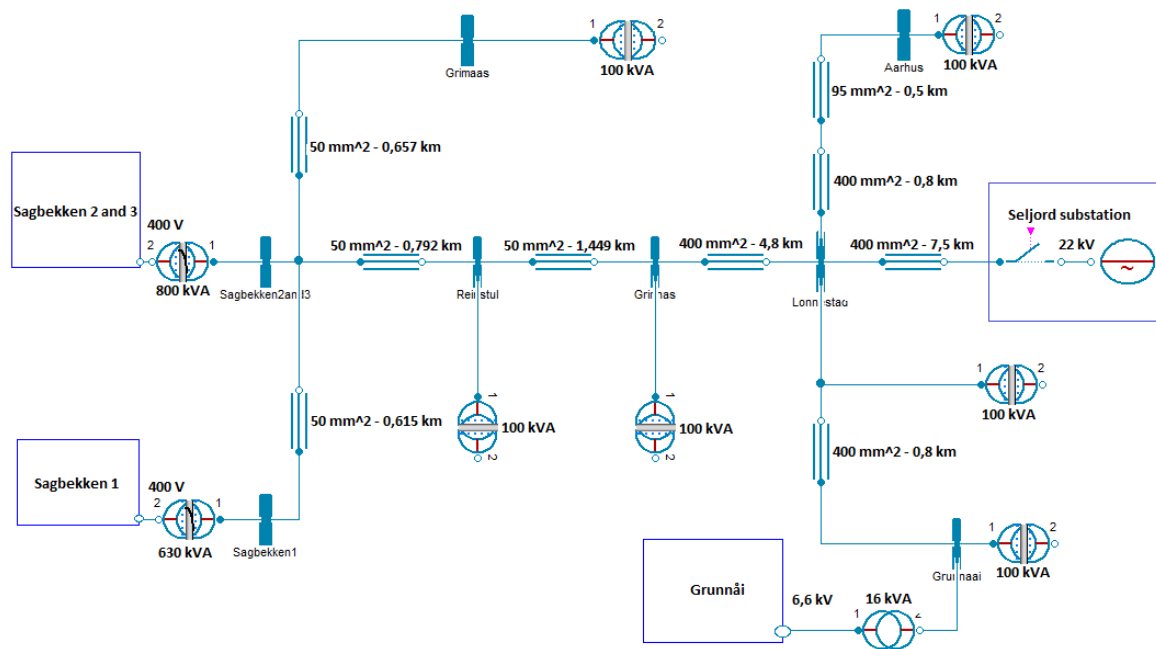

Figure 5: Overview of the Lønnestad radial

## 4 Description of the grid

For investigation of the over-voltage phenomena in *Grunnåi* power station, only the *Lønnestad* radial is of interest. This is the 22 kV radial where the *Grunnåi* power station and *Sagbekken* power stations are connected. The radial is mainly built up with cables, where the total length of 22 kV cables is 17.9 km. An overview of the *Lønnestad* radial is shown in Figure 5. The total power consumption in the radial will vary throughout the day, but is assumed to be 250 kW with a power factor equal to 0.96 during the working hours.

### 4.1 *Grunnåi* power station

*Grunnåi* hydro power station is the largest power station in the *Lønnestad* radial with a synchronous generator of 15.06 MW. The turbine is governed with an infinite droop control, which means that the power station runs at a constant power set-point independently of the electrical frequency in the grid. Figure 6 shows a picture of the synchronous generator inside the power station.

### 4.2 *Sagbekken* power stations

*Sagbekken 1* and *Sagbekken 2 and 3* are two micro power stations that utilise the water from the same river. Both of the power stations are equipped

Figure 6: *Grunnåi* power station with its generator

with asynchronous generators with squirrel cage rotor, where *Sagbekken 1* has three units with a total installed capacity of 400 kW, and *Sagbekken 2 and 3* has four units with a total installed capacity of 475 kW.

Each of the power stations is equipped with protection relays that operate a common generator circuit breaker in each station. Figure 7 shows the four generator units in *Sagbekken 2 and 3*.

Figure 7: The four generator units in *Sagbekken 2 and 3*

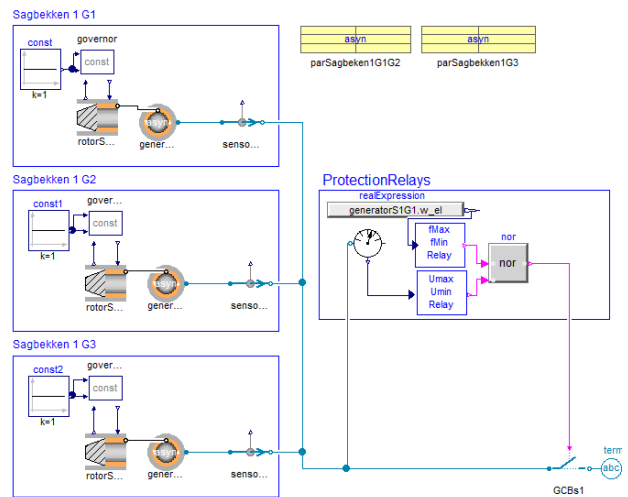

Figure 8: Sub-model *Sagbekken 1*

## 5 Power system simulations

The power system of the *Lønnestad* radial was modelled and simulated using Modelica [7] as modelling language and Dymola[8] as simulation tool. Several models of the power system were created to simulate different scenarios. A small project library was built for the power system, containing the different power system models, main components, and subsystems developed for the models.

The power systems model developed for the *Lønnestad* radial are based on the Electric Power Library[9] which is a commercial library developed by the Swedish company Modelon[10]. The library gives the opportunity to model, simulate, and analyse electric power systems, including AC three phase systems, AC one phase systems, and DC systems. The models can be used for both steady state and transient mode for simulation and initialisation.

Some components like the protection relays and RMS voltage sensors were not available in the Electric Power Library and were therefore created using the Modelica Standard Library [11].

The following sections will give you a brief introduction to the models used and the investigated effects. A more complete and thorough documentation is also available in [12].

### 5.1 Simulation models

Each of the power-station models consist of model for the generator-turbine unit and a protection relay unit. Figure 8 shows an example how the different power stations are build up in principle.

### 5.2 Investigation of the self-excitation process

To be able to investigate the process of self-excitation with different grid configurations, the model in Figure 9 was created.

Figure 9: Model used for investigation of the self-excitation process

The model consists of a 100 kW asynchronous production unit and an equivalent distribution line which is connected to an infinite grid. The investigation was carried out as sensitivity analysis where different loads and capacitors were compared in order to determine their impact on the system. At  $t = 1 \text{ second}$  the circuit breaker was opened, which brought the power plant into islanded grid operation with a given capacitive power and resistive load connected.

### 5.2.1 Self-excited induction generator without capacitors

Figure 10 shows how the SEIG behaves when it is suddenly brought into islanded operation without capacitors connected to the generator terminals. Before disconnection it can be observed that the generator operates in steady state where it produces  $98.4kW$  with active power, and consumes  $67.1kvar$  with reactive power. As the induction machine no longer is able to produce the main air-gap and winding leakage flux after the disconnection, it can be seen how the voltage reaches zero when the machine de-excites. Due to the constant mechanical torque,  $T_m$ , on the rotor, it can be seen in Figure 10 how the angular velocity,  $\omega_r$ , increases when the electrical torque,  $T_e$ , disappears:

$$\frac{d\omega_r}{dt} = \frac{T_m - T_e}{J}$$

Figure 10: SEIG with no capacitor, disconnection at  $t = 1s$

### 5.2.2 Self-excited induction generator with capacitors

The unloaded SEIG's behaviour with different capacitors after a disconnection is shown in Figure 11. From the figure it can be seen that the SEIG needs at least  $10kvar$  of capacitive power in shunt with the generator to initiate a successful voltage build-up after a disconnection. The figure also shows that

a further increase of the capacitive power results in shorter time from the disconnection to the voltage build-up and a lower peak voltage. This is because larger capacitors provide the minimum amount of reactive power required for self-excitation at a lower angular velocity than smaller ones.

Figure 11: SEIG voltage with different capacitors, disconnection at  $t = 1s$

### 5.2.3 Self-excited induction generator with capacitors and load

To simulate a resistive load's impact on the SEIG, a sensitivity analysis was performed with different resistive loads. For all the different loading scenarios, a  $30kvar$  capacitor bank was connected in shunt with the generator terminals.

By comparing the  $10kW$  simulation in Figure 12 with the similar no-load simulation in Figure 11, it can be observed that the load has a considerable influence on the new operating point. The  $10kW$  load reduces the maximum over-voltage of the  $100kW$  generator from  $10kV$  to  $1.4kV$ .

For the simulation with the  $90kW$  load, it can be observed that the load is too large to initiate the voltage build-up immediately after the disconnection. As the rotor accelerates, it can be seen that the self-excitation is initiated after  $t = 2.5seconds$  when

the angular velocity is large enough for the capacitors.

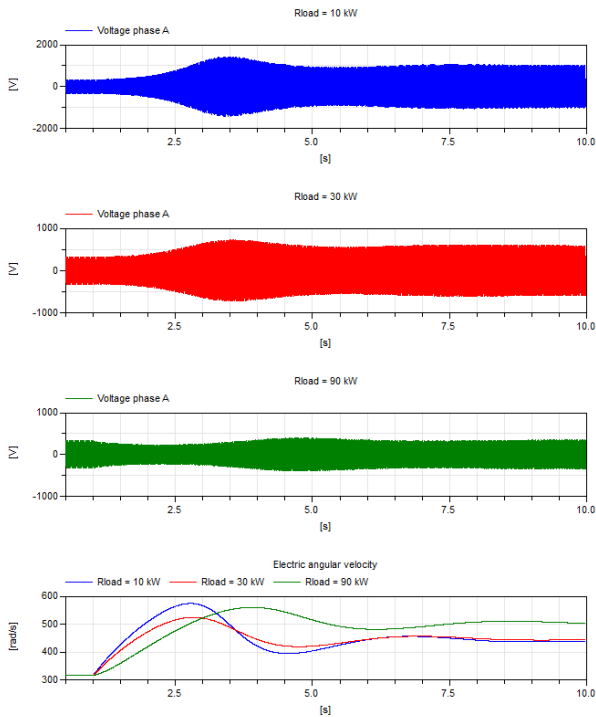

Figure 12: SEIG with 30kvar capacitors and different loads, disconnection at  $t = 1$  s

### 5.3 Simulation with phase to ground fault at Grunnåi

In order to investigate the over-voltage that occurred at the 22 kV busbar in Grunnåi on the 27<sup>th</sup> July 2011, the simulation model in Figure 13 was created. At  $t = 1$  second a phase to ground fault occurs at phase A. Simultaneously as the phase to ground fault occurs, the circuit breaker in Seljord substation disconnects the Lønnestad radial from the rest of the grid due to momentary triggering settings in the protection relay.

Figure 14 shows how the voltages changes when the phase to ground fault occurs at phase A, causing the system to go from a balanced system to an unbalanced system. By looking at the figure it can be clearly seen that the radial has enough capacitive power and low enough load to initiate self-excitation process in the Sagbekken power stations once the Grunnåi power station is disconnected.

Figure 15 shows that it took 1.5 seconds from the phase to ground fault occurring at the Grunnåi power station before all the generators in the radial were dis-

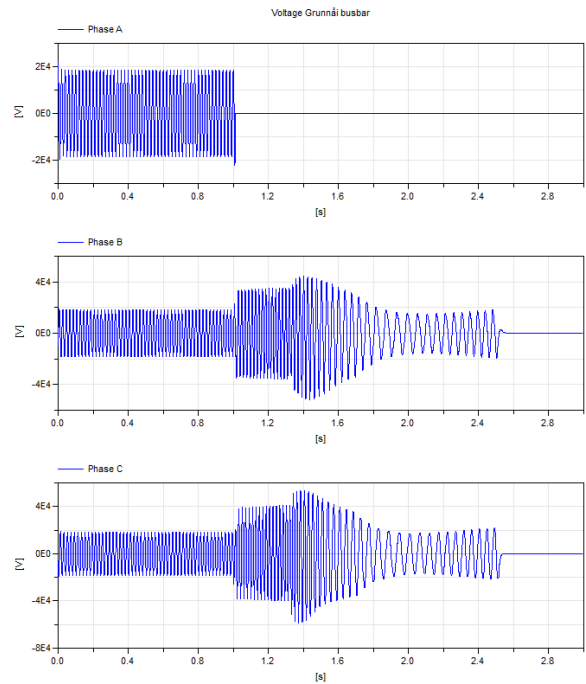

Figure 14: Voltage at Grunnåi busbar, phase to ground fault at  $T = 1$  s

Figure 15: Disconnection times, phase to ground fault at  $T = 1$  s

connected. During this time the over-voltage reached its maximum value of 53.36 kV and was continuously over 30 kV for 0.7 seconds at phase C.

## 6 Discussion

The investigation of the self-excitation process shows how the dynamics of the generator changes when different capacitors and loads are connected to the generator terminals. For a generator running at no load with capacitors connected to the terminals, there exists a minimum speed for self-excitation to occur. If the capacitors do not provide sufficient excitation to initiate the self-excitation at the given speed, the loss of the utility grid causes a sudden in-

Figure 13: Model of *Lønnestad* radial with phase to ground fault

crease in the slope of the equivalent capacitor line seen by the generator [1]. This change may cause a complete or partial loss of the generator excitation. Due to this, the generator fails to produce an electromagnetic torque large enough to overcome the mechanical torque, which results in acceleration of the rotor.

Unless the residual flux is lost, the self-excitation can be initiated when the angular velocity has increased such that the reactive power from the capacitors is sufficient. Once the process of self-excitation is initiated, the terminal voltage starts to build up. The generator reaches its new stable operating point when the dynamic magnetisation line of the generator intersects the linear capacitor line.

For asynchronous generators connected to a utility grid with much reactive power in form of capacitors or cables, it is crucial with quick detection and low trigger time for over-frequencies to avoid unwanted over-voltages.

The simulations shows that the reactive power in the grid is great enough initiate self-excitation that results in harmful over-voltages, independently of whether the load is connected or not. It is seen that the voltage build-up happens quickly. It takes below 0.4 seconds from the radial is brought into islanded operation to the voltage reaches its peak value.

Significant over-voltages can also occur when a

phase to ground fault arise at *Grunnåi* busbar. Regardless of whether *Grunnåi* power station is connected or a phase to ground fault arise, the self-excitation of the *Sagbekken* stations will result in harmful over-voltages. For all the simulations, the magnitude and length of the over-voltages are greater than the thermal stability limit of the surge arresters in *Grunnåi* power station.

Correct parameters for the protection relays are essential for providing sufficient protection of the grid. This is also the easiest way to protect the *Lønnestad* radial against harmful over-voltages. Simulations show that the peak value of the angular velocity can vary dependent on the load scenario. Correct parameters for detection of over-voltages are therefore most important for the protection relays.

## 7 Conclusion

This paper investigates the system dynamics in the *Lønnestad* radial when it is brought into islanded operation. Modelling and simulation of the transient behaviour of an asynchronous generator is a fairly complex task that requires good knowledge of electric machinery and dynamic systems. Due to this, there is often a lack of knowledge in small utility companies when it comes to the asynchronous gen-

erator.

The asynchronous generator has the opportunity to operate as a standalone unit if the amount of reactive power in the cables or capacitors is sufficient. For the *Lønnestad* radial, it was proven that the amount of reactive power in the grid is large enough to initiate self-excitation of all the seven asynchronous generators in the radial.

The self-excitation leads to fast voltage build-ups that results in a harmful over-voltage in the distribution grid. For the simulations with load connected, it was observed that the over-voltage in the distribution grid reached its maximum voltage of circa 50 kV, only 0.4 seconds after the radial was brought into islanded operation.

This is a type of over-voltage that requires a great deal of knowledge regarding self-excitation to ensure good protection of the grid. Normal protection methods as surge arresters will not be adequate, since these are designed to protect against surge voltages, and not transient over-voltages with several seconds duration. Simulations performed in this paper show that it is crucial with correct protection parameters in the *Sagbekken* stations to protect equipment in the *Lønnestad* radial against over-voltages caused by the generators. To avoid unwanted voltage build-ups, correct parameters for over-voltage detection is the most important protection. It is recommended to have momentarily disconnection when the voltage exceeds a given value.

## 8 Acknowledgements

The work was carried out as part of the Master thesis of Håkon Molland Edvardsen [12] in cooperation with Skagerak Energi, Porsgrunn, Norway and under supervision of Dietmar Winkler.

## Abstract

In this paper, a Hybrid Energy System (HES) configuration is modeled in Modelica. Hybrid Energy Systems (HES) have as their defining characteristic the use of one or more energy inputs, combined with the potential for multiple energy outputs. Compared to traditional energy systems, HES provide additional operational flexibility so that high variability in both energy production and consumption levels can be absorbed more effectively. This is particularly important when including renewable energy sources, whose output levels are inherently variable, determined by nature.

The specific HES configuration modeled in this paper include two energy inputs: a nuclear plant, and a series of wind turbines. In addition, the system produces two energy outputs: electricity and synthetic fuel. The models are verified through simulations of the individual components, and the system as a whole. The simulations are performed for a range of component sizes, operating conditions, and control schemes.

*Keywords: hybrid energy system; Modelica; multiple-input; multiple-output; renewable power; optimization*

## 1 Introduction

Over the many years during which the current energy ecosystem was designed and has evolved, technological and social growth occurred slowly and environmental impact was not a primary concern. However in the current context of global climate change and economic volatility, the old energy system is far from optimal. Renewable energy sources promise an alternative that is both low cost and environmentally friendly. However, renewables also pose a challenge: they introduce significant variability in their output.

The output variability and uncontrollability of renewables require grid operators to maintain a larger spinning reserve. If a large plant is asked to reduce generation as the result of using lower-cost solar or wind, the plant has to ramp down and eventually ramp up again. This is harmful, as the cyclical loading reduces the life of the plant, or requires costly maintenance.

In addition to output variability, another concern when designing a power plant is the potential change in the cost of inputs as well as the price of outputs. In a conventional plant, there is only one input and one output. A consequence of this one-to-one energy mapping is that the plant has little control over its profitability when a price change occurs. An increase in the cost of the input, or decrease in the price of the output will most likely cause a decrease in profit. There is a clear tradeoff between using the low cost renewables and the higher level of control that conventional plants offer.

One approach for managing such tradeoffs is the development of Hybrid Energy Systems (HES). HES consider multiple energy inputs and outputs in one system. A Multiple Input Single Output (MISO) HES uses two or more energy inputs, such as nuclear and wind, and produces a single output, most often electricity. A Multiple Input Multiple Output (MIMO) system includes multiple inputs and produces multiple outputs, such as producing both electricity and synthetic fuel. Since they are capable of dynamically utilizing diverse inputs and outputs with different costs, MIMO HES provide a flexible and robust alternative for the energy ecosystem.

There are distinct advantages to having multiple energy inputs and outputs. Consider the HES architecture shown in Figure 1. This MIMO HES uses a renewable energy source (e.g., wind or solar), a non-renewable energy source (e.g., nuclear), and a carbon source to provide both electricity and chemical products. The HES whose models are presented in this

paper use the architecture illustrated in Figure 1. One proposed mode of operation when generation from renewables is high is to direct steam from the non-renewable source to the chemical plant, which requires high-temperature steam to produce synthetic fuel. The amount of steam diverted to the chemical plant can be dynamically varied so that the HES can load-follow, i.e., it can quickly react to changes in the availability of renewables or the demand from the grid. The price of electricity may change dramatically, not only during different seasons, but also during the course of a day. It is even possible that the price of electricity becomes negative, and plants must pay to dispose of the electricity they produce. Producing for a short period at negative prices may sometimes be acceptable because the cost of ramping down and ramping back up is greater than the expected loss from paying to push the electricity onto the grid [5]. Plants or MISO systems that only produce one output have little flexibility as they cannot produce another product. MIMO systems however, are more flexible. If the price for one of its outputs drops significantly, the system can produce other outputs that are still highly priced. This increased diversity allows for plant owners to generate greater and more consistent profits. Since the MIMO system does not need to cycle the non-renewable source as frequently, its performance, reliability, and capacity factor are expected to be larger than for other systems. This in turn results in an opportunity for increased renewable penetration as well as profitability for plant owners.

Although MIMO systems provide many benefits, there are also some disadvantages. Due to the increased complexity of these plants, their design,

analysis, and control becomes more challenging. A second disadvantage concerns the lifespan of key components, such as heat exchangers, which may suffer from additional wear due to thermal cycling. Another concern for HES is that they have to deal with dynamic conditions that cannot be well represented in a static model. In addition, dynamic simulation is critical to controller design and optimization. To support dynamic modeling, models are implemented using the Modelica language, and simulated using Dymola [9].

In the remainder of this paper, other HES models from the literature are first reviewed. Then, models are presented for the thermo-fluid systems, electrical system, and chemical system of the HES architecture shown in Figure 1. Simulations of these models are then reported and interpreted. In addition, lessons learned throughout the model creation process are presented. Finally, concepts for future work are described.

## 2 Related Work

Modeling and optimization of HES is not entirely new. There are multiple examples of research being made in this area [13-15]. [15] is an example of a hybrid wind-solar energy system for small scale applications. The hybrid system does not connect with the electrical grid and therefore avoids any complications associated with having to do so, such as maintaining the same phase angle and voltage. This is another area where HES can be applied; however the systems designed for off-grid use do not help alleviate the non-renewable production of electricity that

Figure 1: The architecture for an Advanced Hybrid Energy System (MIMO) [6, 7]

dominates the electrical grid. There are examples of on-grid applications, such as [13].

In [13], the task of handling renewable generation for the purpose of connecting to the electrical grid is addressed. This system however, focuses on the control and optimization of a wind power generation plant, as compared to HES. In this case, the plant is optimized to account for dynamic changes that can occur in wind. Even so, this does not eliminate the plants dependency on there being a sufficient amount of wind to power the electrical grid. The issue of connecting a HES to the grid is discussed in [14].

In the case of [14], the HES consists of a photovoltaic, diesel, battery combination. This is used for the purpose of supplying electricity to rural Saudi Arabia. In this application, software called the Hybrid Optimization Model for Electric Renewables (HOMER) was used to evaluate and optimize the HES [12]. HOMER allows for the design of HES architectures, in a high level view. It can be used to evaluate the basic structure of HES, but does not deal with the dynamic events occurring within a system. In addition, HOMER handles loads such as electricity and thermal, abstracting the smaller components that would actually be involved in the design of a large scale plant.

There appears to be a gap in terms of designing a full scale HES plant for the purpose of connecting to the electrical grid. The previous examples show that there is potential for economic and environmental improvements from creating HES configurations, either new or from converting old plants.

### 3 Models

The modeling of the HES described above was divided into five main sections. The five sections are: the nuclear reactor, two steam cycles, a chemical plant, and the electrical component. These subsystems are shown in Figure 2, which shows the individual models connected to illustrate the final structure of the HES model. The nuclear reactor supplies the primary heat generation that is utilized in the first steam cycle. The steam cycles consist of one segment that extracts work from the heated steam for the purpose of generating electricity, and the other superheats steam for the chemical plant. The chemical plant takes hot steam and natural gas to produce synthetic fuel. The electrical section contains the renewable source, in this case wind turbines, with a battery and connects with the electricity generated elsewhere to power the electrical grid. The models

used are from the Modelica basic library as well as the ThermoPower library, which is used for modeling of the thermo-fluid components [1].

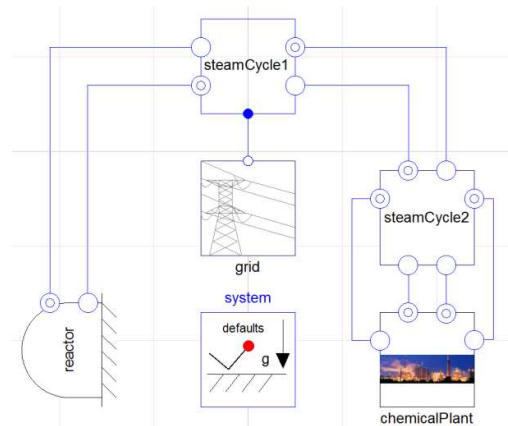

Figure 2: Top-level model for the HES

#### 3.1 Nuclear Reactor

The nuclear reactor's purpose is to supply heat to the steam cycle. This is the largest energy input to the HES. The model for the reactor is shown in Figure 3. The model is simplified as the primary concerns are with the dynamics of the interconnected system involving the electrical and chemical components. The reactor uses a heat source that ramps from a nominal starting power to its full load. This represents a plant powering up from reduced load. This allows for a system that uses the reactor to warm up to steady state operating conditions, as compared to trying to start all of the equipment at full load. This heat transfer is applied to a pipe with water flowing through it to represent a main heat exchanger.

Figure 3: The model for the reactor.

#### 3.2 Steam Cycle

The steam cycle models are responsible for capturing the transfer and distribution of energy of the thermo-

fluid portion of the HES. This is broken into two segments: one whose primary purpose is the production of electricity, and the second being the superheating of steam to the chemical plant. The distinction of primary purpose is necessary due to the fact that both segments produce electricity and heat water.

The portion of the steam cycle primarily responsible for generating electricity is shown in Figure 4. There are some critical observations to note about this model. Since the HES can vary the amount of steam being utilized to produce electricity, if just one turbine were to be used there would be times where it would not be fully utilized. For this reason, multiple turbines are present for use in a cascading fashion, as in, at low power requirements, only the “60% Turbine” may be used. As the electrical demand in-

creases, the “30% Turbine” and eventually the “15% Turbine” will also be added. Other than this, the model represents a Rankine cycle with safety components as well as a boiler to distribute steam to the chemical plant. When the power demanded from the turbines is lowered by the addition of renewable power, the flow rates through the turbines will decrease. This will cause a corresponding increase in pressure as the same amount of heat is being added to the cycle, regardless of the turbine output. To regulate this pressure, a pressure relief valve is present, but instead of venting this excess energy, the excess steam is used to heat condensate water coming from the chemical plant, thus providing it with steam. A temperature control valve is also included to more precisely control the temperature of the colder water entering the nuclear reactor.

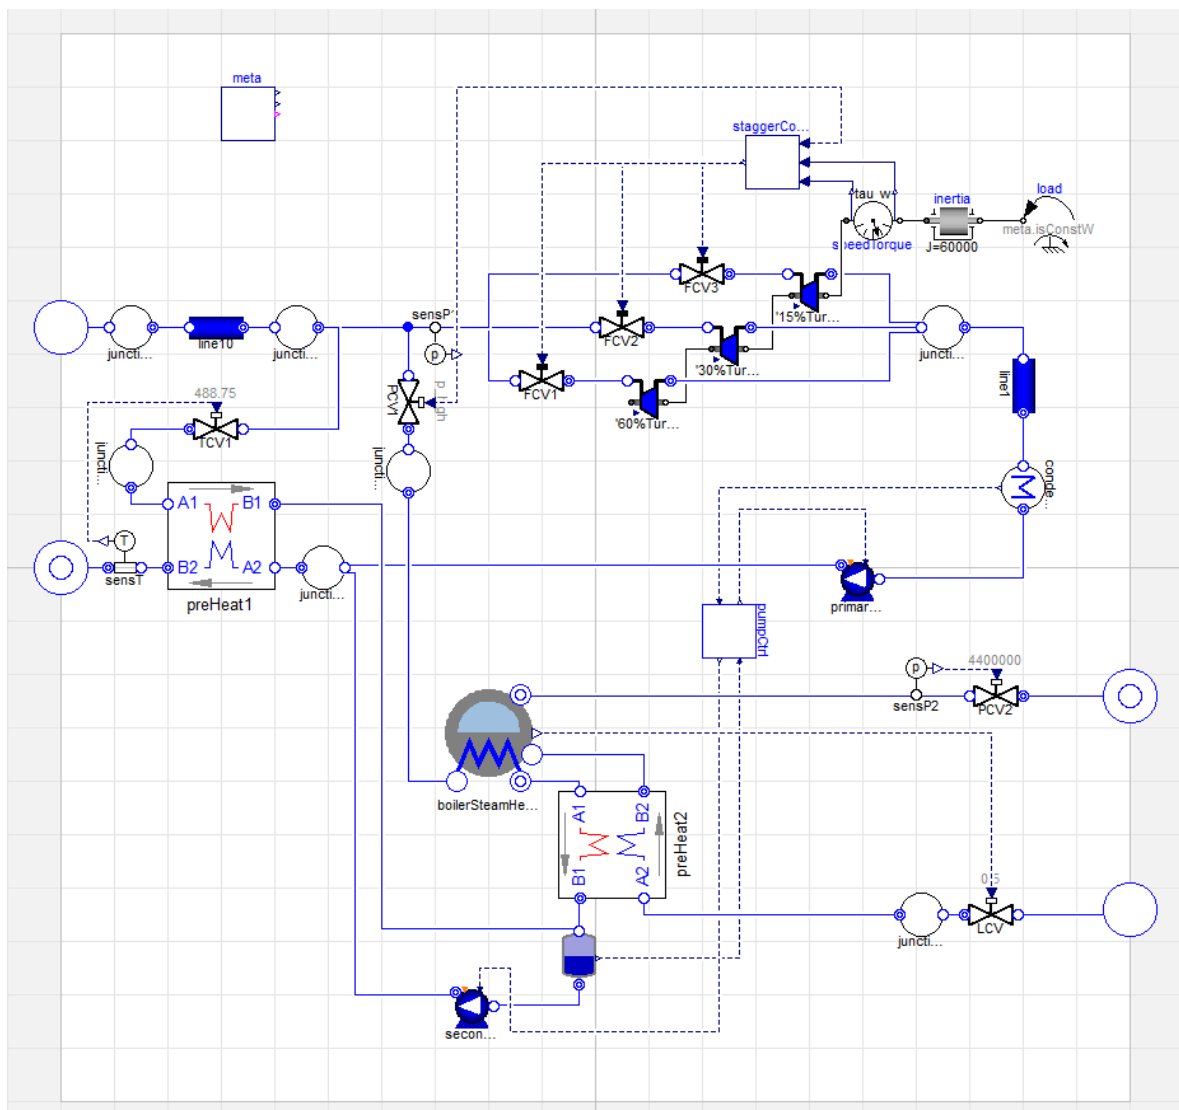

Figure 4: The model for the steam cycle whose primary function is to produce electricity.

The model for the heat exchanger is a simplified one that is capable of simulating phase changes in the system. Other heat exchangers had been tested, such as those from the ThermoPower library and the Modelica standard library, however they did not fit the needs of this application [1, 9]. The complication in using these models is that they were not designed to allow the fluid to undergo a complete phase change. The cooling of steam to water results in significant changes in the fluid properties, such as density. This causes simulation stiffness. Often, at least one of the heat exchangers is not always in use, it is possible for the contents of that heat exchanger to cool to the saturated liquid vapor temperature, and causes corresponding stiffness.

To resolve this, a model was created that utilizes pipes with no volume. Since there is no volume, the large changes in fluid properties that occur throughout the heat exchanger are largely ignored, and only the inlet/outlet conditions of the fluid determine the

heat transfer.

To capture as much detail as reasonable, the heat transfer,  $Q$ , and efficiency of the heat exchanger,  $\eta$ , are calculated in equations (1), (2), (3), and (4) [2, 10]:

$$Q = \Delta h_{Hot} w_{Hot} = -\Delta h_{Cold} w_{Cold} \quad (1)$$

$$\eta = \frac{T_{ColdInlet} - T_{ColdOutlet}}{T_{ColdInlet} - T_{HotInlet}} \quad (2)$$

$$\alpha = k \left( \frac{1}{\dot{m}_{Hot} C_p_{Hot}} + \frac{1}{\dot{m}_{Cold} C_p_{Cold}} \right) \quad (3)$$

$$\frac{T_{HotOutlet} - T_{ColdOutlet}}{T_{HotInlet} - T_{ColdInlet}} = e^{\alpha} \quad (4)$$

where  $\Delta h$  is the change in enthalpy,  $\dot{m}$  is the mass flow rate, and  $C_p$  is the specific heat of the fluid.  $k$  is the assumed heat transfer coefficient. This ignores some of the effects that are present during a phase change in a heat exchanger, however, this occurs

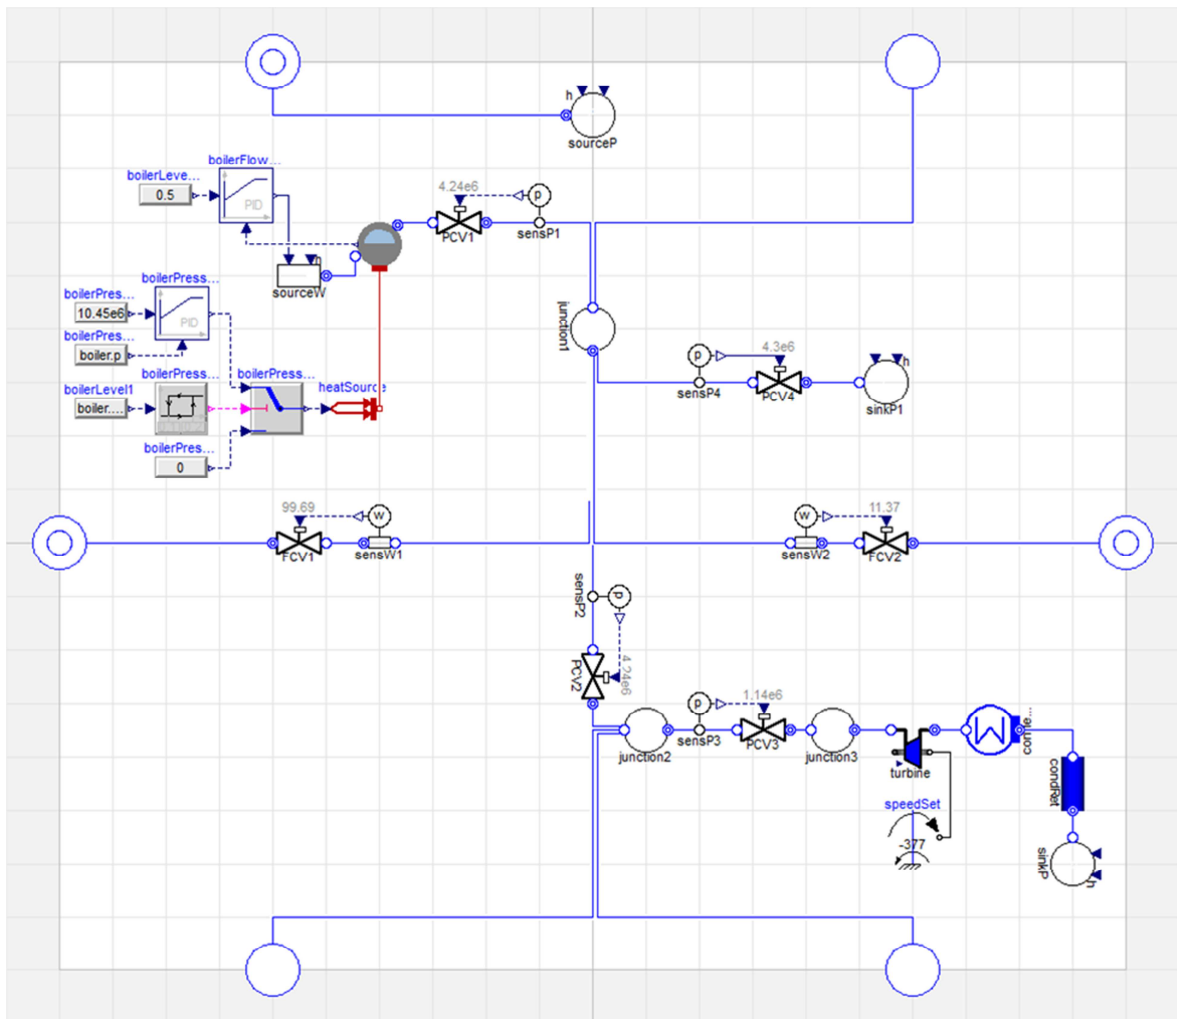

Figure 5: The model for the steam cycle that is primarily responsible for superheating steam to the chemical plant.

under conditions where capturing that change is considered insignificant. A phase change can occur when the flow rate of the hot side is small relative to the cold side. This can occur in the second heat exchanger in Figure 4, labeled preHeat2. It is expected that this condition will not change the results drastically, and the dynamics of the heat exchanger when it is not transferring large amounts of heat are not a concern currently.

Figure 5 presents the other side of the steam cycle, the one responsible for superheating steam to the chemical plant. The purpose of this model is to take steam generated from the model in Figure 4, superheat it, and then transport it to the chemical plant. There are locations where the condensate water addition and removal are represented by sources and sinks of water. This is done for simplicity instead of closing the loop of flowing water. The dynamics of the condensate water used in this system are not considered a significant concern. In addition, the justification for this is that the condensate water is merely being pumped around the system, and the power required to pump liquid water is small relative to the power produced by most Rankine cycles [10].

In the event that there is an insufficient amount of steam being transferred to the model in Figure 5, this system also has auxiliary heat production generate the necessary additional steam. Furthermore, the steam that returns from the chemical plant, in addition to excess steam produced, if any, is put through a turbine to capture energy that would have been

wasted otherwise.

### 3.3 Chemical Plant

The model of the chemical plant is shown in Figure 6. The chemical plant model utilizes a methanol medium, and most of the sub-models perform their functions mathematically, via transfer functions, instead of using the energy based components of the water system. This is done to simplify the overall analysis, as the intricacies of transforming natural gas to gasoline and liquefied petroleum gas (LPG) are not of interest.

### 3.4 Electrical

The electrical model is the location where the renewable source and the electrical grid, which receives power from the HES, are included. The renewable generation for the HES under consideration is a series of wind turbines. The model uses representative data for wind speed for a location in Idaho from the Western Wind dataset, which was made available from NREL (National Renewable Energy Laboratory) [6, 11]. This data assumes a height of one-hundred meters and has wind data for every ten minute period. The year period of 2006 is used for simulations. This wind speed,  $v$ , is then mapped to rotational power,  $P$ , by equation (5) [13]:

$$P = \frac{1}{2} \rho A v^3 C_p \tag{5}$$

where  $\rho$  is the air density,  $A$  is the cross sectional

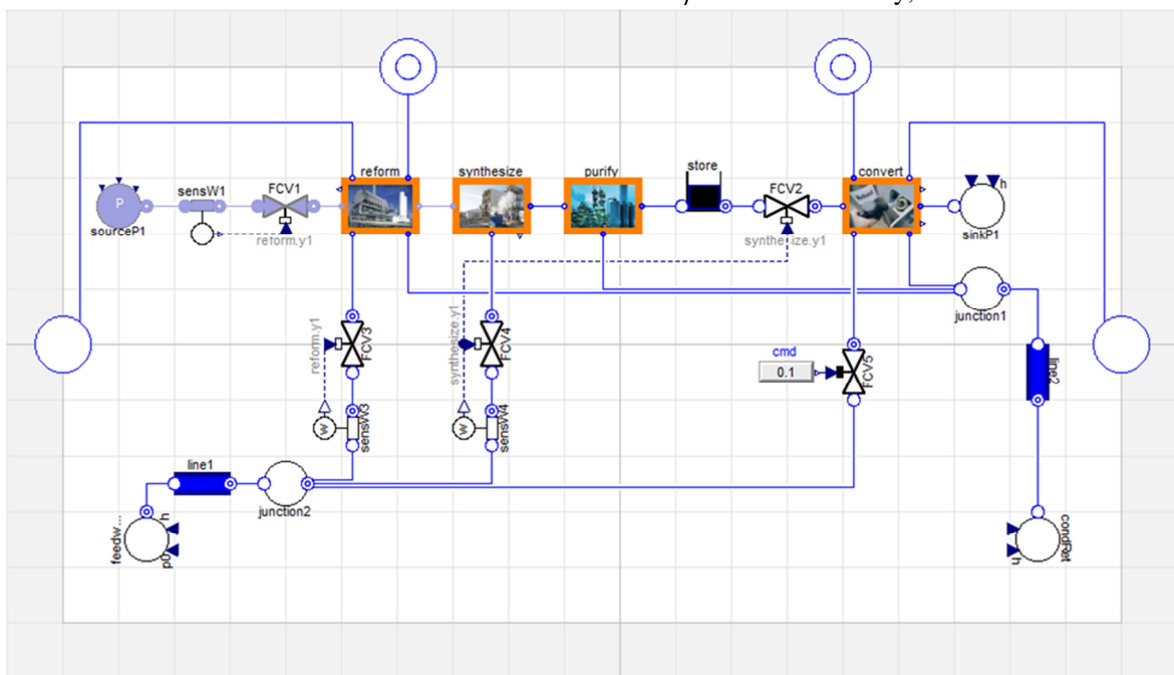

Figure 6: The model for the chemical plant.

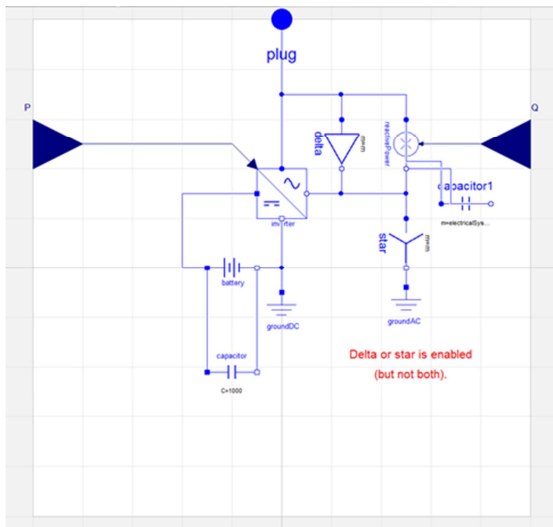

Figure 7: The model for a battery.

area of the blades, and  $C_p$  is the power coefficient. This rotational power is applied to an electrical generator, which outputs three-phase AC. It is worth noting that the models that utilize three-phase AC are done so in dq0-reference frame to improve simulation time.

In addition to the wind turbines, another notable component is the electrical battery. The model for

the batteries is shown in Figure 7. The AC signal interacts with an inverter, which converts AC to DC and DC to AC depending on whether the battery is charging or discharging. The battery itself is a resistor-capacitor unit arranged in series and parallel until the necessary voltage and capacity is reached, also known as the Thevenin Battery Model [3, 8]. The overall electrical model is shown in Figure 8. The plug represents input electrical power generated elsewhere. The two batteries in Figure 8 are controlled by a grid supervisor, which dictates the real and reactive power demanded.

The electrical grid is the location where all of the electrical signals come together to power a model of the U.S. electrical grid. The outputs of the turbines from the steam cycle, as well as output from the wind turbines, each with their own battery to handle transients, are connected to the U.S. grid via a circuit breaker. This circuit breaker connects the HES to the electrical grid when it is closed. In addition, lines and substations are included to represent how the electricity would travel to the grid and include relevant losses from transmission. The lines contain inductor-resistor circuits. Thus, the losses in the resistors, as well as the dynamics from the inductors are taken into account.

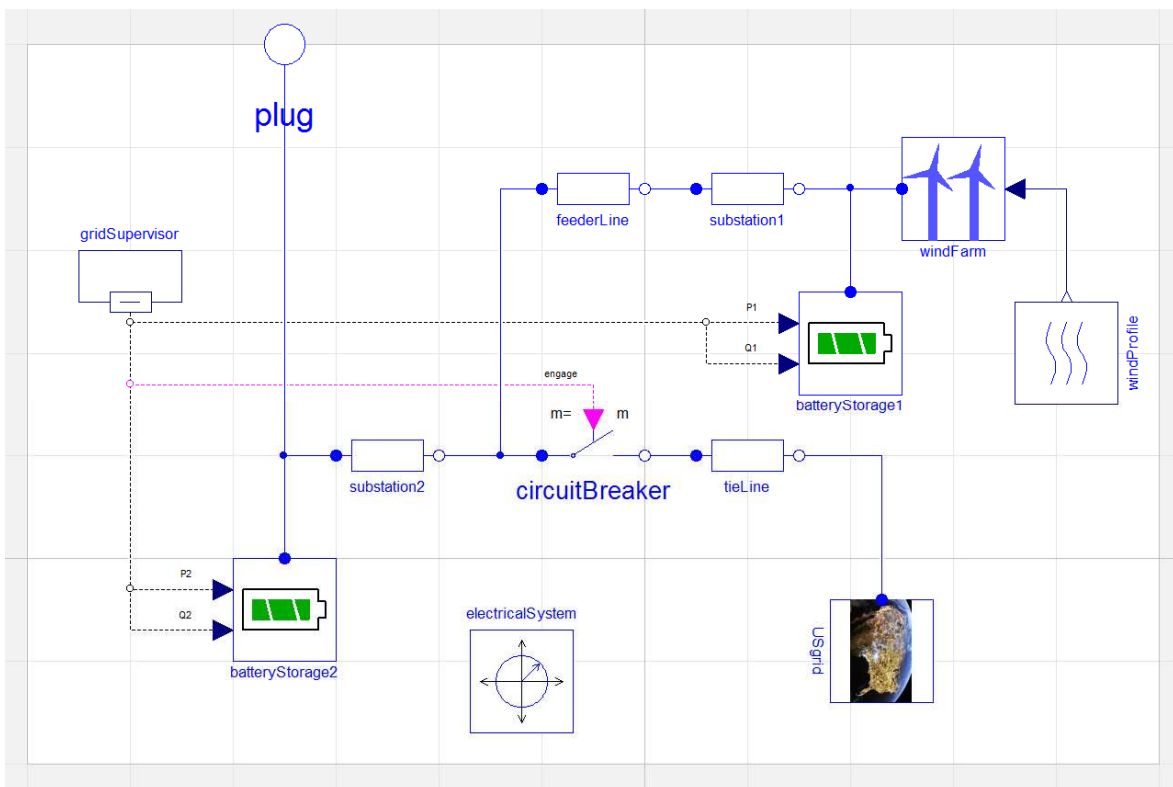

Figure 8: The electrical model, which includes the wind turbines, batteries, and the grid.

## 4 Simulation Results

To verify that the models created represent the system of interest, simulations are conducted. The results of these simulations are analyzed to ensure that the models behave as expected. Before combining the models and simulating the full system, individual components were tested first.

One of the first lessons learned came from the simulations of the first steam cycle. By closing the fluid loop, the simulations immediately became sensitive to various parameter values. Changes in the sizes of components in the loop cause the system to react in the form of large transients that dominate the startup period. These transients cause the simulation to be stiff and result in the simulation time increasing significantly. Attention to initial parameter values is paramount to meaningful results for this situation. This is one reason why the reactor is ramped up to load, as compared to starting at max load.

As mentioned previously, the other heat exchanger's that are considered initially resulted in simulation problems for the first steam cycle. The low flow rate of steam causes the steam to condense to liquid water, which results in a large increase of density, drastically increasing the simulation time. The change in density causes the simulation to both progress slowly, and result in the model not behaving as intended. One result of the large increase in density is that objects with a finite volume began decreasing their pressure rapidly. In some cases, this low pressure causes some components to operate in backflow. For the separator in Figure 4, this result does not make sense. A mixture of liquid water flowing from the top port into a heat exchanger is not realistic or indicative of what would normally be expected for a separator. The phase change also causes problems with the medium model used for water. The changing phase results in the properties, in addition to the density of the water, to change drastically. Since a phase change occurs, the medium model needs to be capable of varying properties, but should do so in a smooth manner so as to avoid stiffness issues.

To explore the interactions between the thermo-fluid systems, a simulation is conducted consisting of only the nuclear reactor, the steam cycles, and the chemical plant, represented in Figure 9. In order to capture the effect of the wind power, the load required from the turbines is reduced as if the wind turbines were connected. Assuming that the overall power that would go to the grid is set to be constant, as the wind turbines produce more power, the turbines accordingly reduce their electrical production.

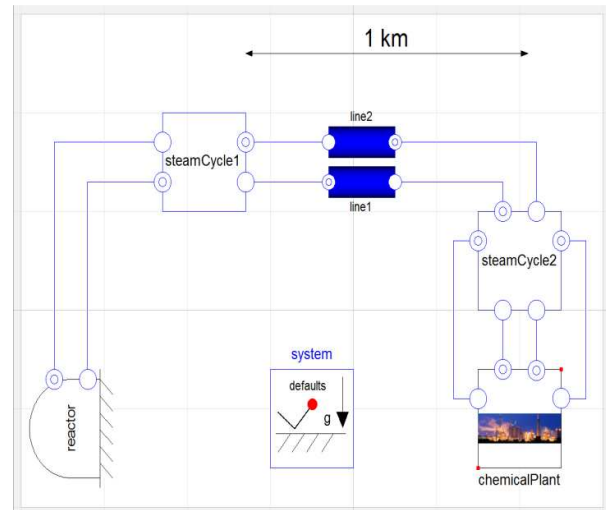

Figure 9: The model containing the reactor, the steam cycles, and chemical plant.

Conversely, as the wind turbines produce less power, more electricity is requested from the turbines.

The simulation is conducted using nominal parameter values that will cause all of the turbines to be used for at least a short period of time. Of particular interest are the flow rates of the steam through the turbines, preheater, and the secondary boiler. The results for this are shown in Figure 10. This simulation in Dymola takes approximately 45 seconds to simulate almost 14 hours of HES operation.

Figure 10 shows the result of the simulation. These results are reasonable for the conditions being simulated. Initially the system is allowed to ramp up and so no power is requested, hence causing large amounts of steam to divert toward the secondary boiler, denoted in pink. As power is requested, the flow rate of steam going to the secondary boiler decreases with a corresponding increase in flow rate through the 60% turbine, denoted in blue on the left. It quickly reaches its operating flow rate and the 30% turbine begins turning on, denoted in red. Around four hours, even the 15% turbine is at its operating flow rate. The wind turbines, based on the wind speed, begin producing significant power at four and a half hours, reducing the load requested from the turbines, and causing the 15% and 30% turbines to turn off as more steam goes toward the secondary boiler, as expected.

The simulation also catches a significant transient move close to twelve hours into the simulation. This is likely related to the low power being demanded from the turbines, with significant quantities of steam being sent to the secondary boiler. The temperature of the condensate water that would inlet to the reactor drops, causing the preheater to turn on.

The cause of the temperature drop may be related to the temperatures in the second heat exchanger that connects to the secondary boiler.

Figure 10: The results of simulation for the flow rates of the turbines, secondary boiler, and preheater1 above. Below shows the power demanded from the turbines.

## 5 Summary and Future Work

In summary, models for a HES that utilizes a non-renewable source (nuclear), a renewable source (wind), and a chemical plant are presented. This work shows that Modelica can be effectively used to model large complex systems, and still allow simulations of dynamic conditions. In addition to modeling

the system, Modelica offers a significant advantage for evaluating control algorithms, which will likely influence the success of HES. The application of this model to determining the optimal design and control schemes will be the target of future work.

Ultimately, the economic and environmental benefits of the proposed MIMO HES described above are to be estimated in order to be optimized. The controllers and other variables, such as the quantity of wind turbines, will be optimized to maximize the profit of the HES to a plant owner. To quantify the environmental benefits of the HES so that the HES can be optimized using profit, a price per ton of CO<sub>2</sub> is to be used. This quantity can be a function of time or constant. This allows the decision maker to only be concerned with one thing, profit, while still having an environmental concern.

Estimating the profitability of the HES with appropriate detail is complex. It is conjectured that the profitability of a HES like the one described above is heavily reliant upon how the system is controlled. One of the HES's key features is being able to take advantage of varying conditions, including the market prices for the inputs and outputs. How the system reacts to these changes is in the control scheme. The performance of the HES may increase for a different control scheme, and still yield a negative overall profit for various reasons. For example, due to the thermal cycling of multiple components, such as the turbines and heat exchangers, the overall life of these components can be drastically reduced in practice. This will be taken into account with additional maintenance and replacement costs. These costs may cause the plant to shut down or operate at reduced capacity factors more often than a stand-alone system. This is why it is important to optimize with respect to profitability as compared to only system performance. The control scheme is not the only alternative for designing optimized HES.

In addition to optimizing the current HES, additional avenues to increase profit will be explored. One area for exploration is that of varying the architecture of the HES for potential increases in profitability. For example, it may be the case that a system that uses a core and a non-core non-renewable load will result in a superior overall profitability for the system. Testing cases such as this may also be considered, however these other architectures will also need to be optimized, making the process difficult. Other methods that can further increase the profitability of the HES will also be explored.

Another alternative is, instead of assuming constant conditions and simulating the current system under those conditions, allowing for the system to

change or expand. This can also increase profit. One method that does this is Real Options Theory. Real Options Theory operates under the premise that evaluating the profitability of a design based on the average operating conditions is flawed [4]. In addition, a system will normally not stay the same throughout its life cycle, as conditions surrounding the system change, the system can be augmented in order to expand or vary how the system acts. This occurs in real life. For example, managers may elect to increase the size of a plant after it has already been built and is in operation. By taking this into account when first building a design, overall costs can be reduced with overall profitability and flexibility being increased.

## 6 Acknowledgments

The work presented in this paper has been supported and funded by Idaho National Laboratory, Energy Security Initiative, under Contract No. 00131206.

## Abstract

As part of the advanced small modular nuclear reactor (AdvSMR) R&D program, Oak Ridge National Laboratory (ORNL) is developing a Dynamic System Modeling Tool (MoDSim) to facilitate research and development related primarily to instrumentation and controls (I&C) studies of small modular reactors (SMRs).

The primary objective is to produce a demonstration product of a dynamic system modeling tool for SMRs. Functional Mockup Interface (FMI) has been used to allow the development of scoping models for non-Modelica users. This tool includes a web-based interface using Xogeny's FMQ platform for model configuration with local application deployment for simulation using FMI Add-in for Excel from Modelon; this toolchain is designed to allow plug and play access for users of various skill levels. The web-based interface allows true web-based access and solutions without requiring local applications. The initial installation of this tool has been tested on a liquid-metal small modular reactor (ALMR) concept modeled using Dymola and exported via FMI. This tool allows simulation to be performed within Excel without expertise in the native simulation language (Modelica) or model development and simulation environment (Dymola). This toolchain fulfills the Department of energy (DOE) project scope goal of developing a tool "*in a common and familiar environment to support a range of research activities requiring dynamic behavior simulation, modeling tools with easily re-configurable modules that reduce data input to typically available system level plant data*".

*Keywords: nuclear reactors; thermofluid systems; Dymola; Excel; web-based simulations; Advanced Liquid Metal Reactor.*

## 1 Introduction

Small modular nuclear reactors (SMRs) are modular nuclear power plants that are smaller (300 MWe or less) than current-generation base load plants (nominally 1,000 MWe or larger). SMR designs may include factory-fabricated reactors that can be transported by truck or rail to a nuclear power plant site. Small modular reactors offer the advantages of lower initial capital investment, intrinsic safety, scalability, and siting flexibility at locations unable to accommodate larger reactors. In addition, SMRs offer the potential to construct and operate a first reactor and later add more reactor modules at the same site (phased construction). This approach offers economic advantages but could generate numerous configurations of reactor modules, power conversion, and heat sink that will require unique capabilities from control and support systems.

The objectives of this project are to establish a configurable framework for the development of a dynamic simulation environment for SMRs using pre-developed simulation modules, initiate the development of selected modules, and demonstrate their use within an initial integration framework.

The DOE Work Scope includes the development of an interface and workflows (or guided processes) that allow the creation of self-consistent reactor power system designs without in-depth knowledge of the native modeling language or simulation environment. This interface must allow the user to provide input information, process input information

derived from the ruleset (i.e., preconfigured inputs based upon the user's choices) and create executable files to calculate a time-dependent response for the system. Currently the workflows established in the interface for novice users are limited to configured architectures that have been precompiled in Dymola. Novice users can select the subsystems and modify parameters for the generation of results without requiring knowledge of Dymola or Modelica. Additionally, the current interface tool also allows advanced users to create new systems, new models, even new architectures via access to source code in GitHub and use with Dymola. GitHub (<https://github.com/>) is a web-based platform that allows users to share, modify, and comment on code for project collaboration. The use of GitHub integration provides a framework for advanced users to push changes back to the ORNL project team and collaborate as part of the Open SMR community.

The ability to configure models easily (plug-and-play) with software tools requires a formal model architecture. This configurable model architecture is required to enable configuration via web applications. The configurable architecture also enables potential scripting of executable system configurations and FMU generation. The web-based application makes use of this hierarchical architecture structure to simplify the creation of new models from assembled components.

While it is difficult within the page length constraints to include all aspects of the project, it is very important that both unique aspects of this project be described within this paper. Thus, this paper includes the application of this approach to a novel space-advanced nuclear reactors as well as the generation of FMU simulations and application of web-based solutions. Unfortunately, a detailed discussion of both aspects is not possible within the publication constraints. Additional detail will be provided in further publications.

## 2 SMR Dynamic Modeling

### 2.1 LANGUAGE (Modelica)

Traditionally, modeling of complex reactor systems has been based on extensive, complex Fortran-based subroutines. Considerable time and effort were necessary to understand and manipulate these models. In contrast, the Modelica language has built-in features and open-source-toolsets for modeling fluid power systems. Physical systems are modeled by connect-

ing classes of components in series or parallel, and by specifying the important parameters of the objects. Fluids are defined as special classes that model the medium behavior using semi-empirical correlations or first-principles equation-of-state models that yield the full state of the medium as a function of two known states (e.g., pressure and enthalpy). These models can be sophisticated enough to support a wide range of operating regimes for fluids at the cost of computation time—and sometimes numerical stability. These property functions are frequently called during execution of simulations to calculate various engineering variables such as heat transfer coefficients and friction factors. The properties of water are already built into the standard Modelica Media library for use with the Modelica Fluid library. In addition to the Modelica Fluid Library, this project has made extensive use of the ThermoPower Library developed by the University of Milan [1]. The built-in water class has a complex set of routines that support working with water from sub-cooled to supercritical regions. As part of the project, ORNL implemented a number of heat transfer media, including liquid salts (flibe, flinak,  $\text{KFZrF}_4$ ) and liquid metals (sodium, NaK, PbBi eutectic) for use in Modelica. The Modelica models were based on the components and systems presented in [3] for the Power Reactor Innovative Small Module (PRISM) design concept. For validation and verification purposes, the results from running these models were compared with the results documented for the PRISM concept.

### 2.2 SOLVER (Dymola)

The simulation development and execution platform chosen for this SMR modeling effort is Dymola [4]. Dymola is a commercial modeling simulation environment developed by Dassault Systemes. Dymola has been used extensively within the automotive, aerospace, robotics and process system disciplines in part due to the extensive set of libraries developed and available within Dymola. The libraries include thermal and fluid dynamics. As a full simulation environment, a graphical interface to the model objects, as well as tools for the compilation and debugging of the models and analysis of the results are also included. To meet the project objective to provide access to dynamic simulation capability without special tools, export of Functional Mockup Units (FMUs) from Dymola is used in conjunction with FMI Add-in for Excel (FMIE) [5] from Modelon to allow simulation in Microsoft Excel. Co-simulation FMUs are generated for dynamic modeling in FMIE.

## 2.3 Architecture

Modelica and Dymola provide a highly convenient means to create reconfigurable model architectures which include high-level rules for systems, interfaces, and connections. As shown in Fig. 1, the ALMR Power Reactor Inherently Safe Module (PRISM) end-to-end plant systems architecture includes the following systems:

1. Direct Reactor Auxiliary Cooling System (DRACS),
2. Primary Heat Transport System (PHTS),
3. Intermediate Heat Exchanger (IHX),
4. Intermediate Heat Transport System (IHTS),
5. Steam Generator (SG),
6. Power Conversion System (PCS), and
7. Electrical Grid.

These systems will be defined later in the report in more detail. In addition to the plant systems, the following modules are included in the architecture:

1. Event Driver (ED),
2. Control System (CS), and
3. Communication bus.

The ED module generates signals for exciting the system. It performs two basic functions:

1. operational transients and
2. injection of faults.

Operational transients include power changes, load following commands, and intentional reconfiguration. A fault injection function introduces failures or performance degradation in identified plant components. Anticipated operational occurrences (AOOs) are handled through the fault injection function. The CS module performs continuous-time control functions for all actuation interfaces in plant systems based on sensory feedback.

Fig. 1 SMR modeling architecture

## 2.4 Models

A small modular reactor consists of several typical components and subsystems. These include the reac-

tor core, piping and primary pumps that make up the reactor and primary systems. Additional piping, heat exchangers, pumps and steam generator are also included that make up the intermediate loop subsystem. Finally, turbines, and process system components are included in the power conversion system as well as generators and other grid related components in the grid subsystem. A discussion of the specifics of these systems is included in the sections below.

The dynamic models are implemented by equations in Modelica using a hierarchical modeling approach. The component models are often based upon various model libraries that are available as open source or as commercial products. Additionally, a user can create component models from their own Modelica code to supplement the existing libraries. Some of the reactor modeling includes component models created by the ORNL team.

The ALMR reactor design that has been modeled is based on the variation proposed by GE in the mid-1990s and documented in GEF-00793 [3]. The end-to-end system models developed are based on the systems, components, and equations included in this reference. For validation and verification purposes, the results from running these models were compared with the results documented for the PRISM concept. System behavior was confirmed compared to previous model studies.

### 2.4.1 Reactor Core

Most of the component models for SMR's are specific implementations of traditional thermal power components. However, the reactor core is unique and requires special consideration. As a result, the equations for modeling the core will be considered.

Fig. 2 Reactor core component

The prompt portion of normalized heat generation is implemented with the *point kinetics* equations.

$$\frac{dn}{dt} = \frac{\rho_t - \beta}{\Lambda} n(t) + \frac{1}{\Lambda} \sum_{i=1}^6 \beta_i c_i(t) \quad (1.a)$$

$$\frac{dc_i}{dt} = \lambda_i [n(t) - c_i(t)] \quad (1.b)$$

where  $n(t)$  is normalized reactor power,  $c_i(t)$  is the normalized concentration of the  $i$ -th group delayed neutron precursor,  $\beta_i$  is the fraction of the  $i$ -th group precursor,  $\lambda_i$  is the decay constant for the  $i$ -th group precursor,  $\rho_t(t)$  is the total reactivity, and  $\Lambda$  is mean neutron generation time. The rate equations are subject to steady state initial conditions, i.e.,  $\dot{n} = \dot{c}_i = 0$ .

The delayed portion of normalized heat generation is implemented with the following:

$$Q_{n-decay} = 0.1 \left[ (t + 10)^{-\frac{1}{5}} - (t + T_s)^{-\frac{1}{5}} + 0.87(t + T_s) + 2 \times 10^7)^{-\frac{1}{5}} - 0.87(t + 2 \times 10^7)^{-\frac{1}{5}} \right] \quad (2)$$

where  $t$  is time after shutdown and  $T_s$  is the operation time prior to shutdown—both in seconds.

The reactivity feedbacks are modeled as follows:

$$\rho_f = \alpha_f (T_{fe} - T_{f0}) \quad (2.a)$$

$$\rho_c = \alpha_c (T_{ce} - T_{c0}) \quad (2.b)$$

$$\rho_t = r\theta_{CR} + \rho_f + r\theta_c \quad (2.c)$$

where  $\rho_f$  is the fuel Doppler reactivity feedback,  $\rho_c$  is the coolant density reactivity feedback, and  $\rho_t$  is the total reactivity feedback.

The axial neutron flux shape is implemented as follows:

$$\Phi(z) = \Phi_{max} \cos\left(\pi \frac{z}{L}\right) \quad (3)$$

where  $z$  is the axial spatial variable that varies between  $-L/2$  and  $L/2$ , and  $L$  is the active length of

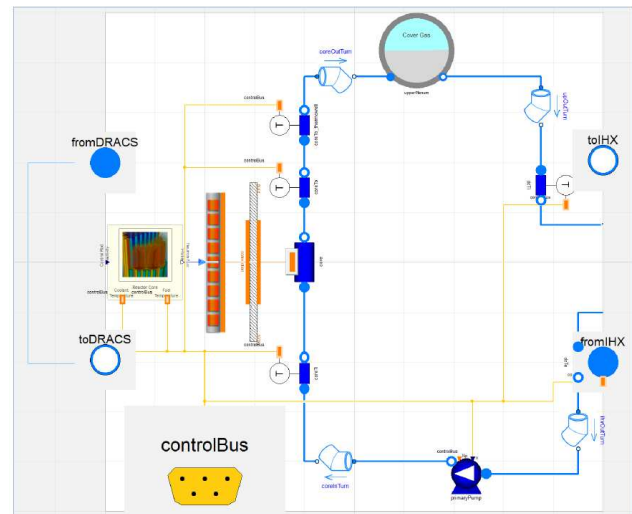

the fuel element. This particular representation is good for a wide range of reactor classes, but not quite so for Boiling Water Reactors, where flux shape is significantly skewed due to the boiling process.

For a given number of axial nodes, the integrated nodal flux is calculated with the following expression:

$$\begin{aligned} \phi_i &= \int_{-\frac{L}{2} + i\delta}^{-\frac{L}{2} + (i-1)\delta} \Phi_{max} \cos\left(\pi \frac{z}{L}\right) dz \quad (4) \end{aligned}$$

## 2.4.2 Primary Heat Transport System

The PHTS includes a reactor core model, a fuel pin thermal model, a discretized one-dimensional core flow model, a cover gas model, and a mechanical pump model. The Dymola/Modelica model diagram layer is shown in Fig. 3. The performance parameters of the mechanical pump are taken from the ALMR PRISM primary EM pump performance characteristics curve at 650 V, which is the operating point of all EM pumps under normal conditions. The mechanical pump will later be replaced with an EM pump model in the subsequent phases of the project. The model also includes four 90-degree turn elements to incorporate irrecoverable pressure losses due to turns and sudden expansion and contractions in the flow path. These loss elements are intended to match the total pressure drop during normal operating conditions across the core to the ALMR PRISM specifications.

**Fig. 3 SMR Primary Heat Transport System**

### 2.4.3 Intermediate Heat Transport System

The ALMR PRISM baseline design includes two IHXs connected to a single IHTS. The IHTS flow loop (Figure 4) also includes a mechanical sodium pump, a sodium expansion tank, a sodium-to-water steam generator, and a sodium dump tank. The sodium dump tank is not modeled in the IHTS implementations. However, this tank should not have an impact on simulation results as this safety system is activated only under accident conditions where the sodium in the IHTS reacts with steam or air.

The ALMR PRISM intermediate sodium pump is a vertically oriented, single-stage, double-suction, free-surface, centrifugal pump driven by a constant-speed, 4000-hp (approximately 3000 kW), air-cooled induction motor. An auxiliary pony motor drive provides low flow (10%) capability for decay heat removal and other low-power or standby conditions. Its baseline design is to provide a flow of approximately 1900 kg/s at 96-m static head and 282°C. The main drive motor generates 3000-kW power at 1750 rpm.

Fig. 4 SMR Intermediate Heat Transport System

### 2.4.4 Intermediate Heat Exchanger

The ALMR PRISM Intermediate Heat Exchanger (IHX) is modeled using two one-dimensional flow elements connected through a radial metal tube element, as shown in Fig. 5. The metal tube element is radially and axially discretized; the number of nodes can be changed by the user. The material properties, that is, density, thermal conductivity, and specific

heat capacity, can also be defined and changed using the Dymola dialog interface.

The default medium on both sides of the IHX is sodium. However, both fluid media can be selected via the system dialog interface. A number of fluid models are provided in the drop-down menu for both shell-side fluid and tube-side fluid, such as incompressible sodium (default), compressible sodium, incompressible NaK, and compressible NaK. Additionally, the menu selection includes a number of incompressible salt models; however, selecting incompatible media may result in numerically unstable configurations as the default initial and boundary conditions are specified for the ALMR PRISM design in the implementations. In the later phases of the project, the menu selections will be bound to a certain reactor class logic, which will limit the number of fluid media options for a certain implementation. The fluid flow and the heat transfer models in the shell side and the tube side can also be selected via the system dialog interface.

Fig. 5 SMR Intermediate Heat Exchanger

### 2.4.5 Steam Generator

The ALMR PRISM steam generator is a vertically oriented, shell-and-tube counter-flow heat exchanger with water/steam on the tube side and sodium on the shell side. The tubes are straight and of double-wall construction. The double-wall tubes provide improved reliability by significantly reducing the probability of water or steam leaking into the sodium.

The Modelica implementation of the ALMR PRISM steam generator is shown in Fig. 6. The ALMR PRISM steam generator is not a helical coil construc-

tion; therefore, it uses different analytical formulations for representation of fluid heat transfer and pressure drops. Furthermore, in contrast to the IHX model as shown in Fig. 5, the steam generator model employs two cylindrical tubes, one inner tube one outer tube, to account for the double-walled construction of the tube bundle. The other tube model of the steam generator implementation introduces a small thermal resistance to account for small interface separation.

Fig. 6 SMR Steam Generator

### 2.4.6 Power Conversion System

The power conversion system model (Fig. 7) is comprised of several components, including the turbines, generator, flow control valve, and pump. Standardized modules that include representative equations/curves are used for these modules. No specialized modules for the ALMR were developed. Current implementation is a simplified version of the actual power conversion system where the feedwater heater trains, blowdown coolers, and the deaerator are eliminated. The implementation also uses a constant rotor input (on the left side of the rotor shaft as a boundary condition represented by the “shaftSpeed” element) to eliminate additional control requirements to maintain shaft angular speed. The rotor mass and rotational mechanics are represented by the rotor element.

The “steamInlet” and “condensateReturn” ports are implemented as vector objects whose number of elements must match the number of steam

generators, which in turn matches the number of reactor modules in a power block. In the current implementation, up to three steam lines can be allocated; however, this limitation will be removed later. Each steam line contains a “stopValve” element (shown as “stopVx”) to control steam flow from each stream. It should be noted that the “stopValve” elements are not modulating elements; they have binary states of OPEN or CLOSED. The valves’ opening and closing dynamics are represented by a linear ramp with a user-specified time constant to switch from one state to another. The streams from three steam generators are mixed via two “flowJoin” elements.

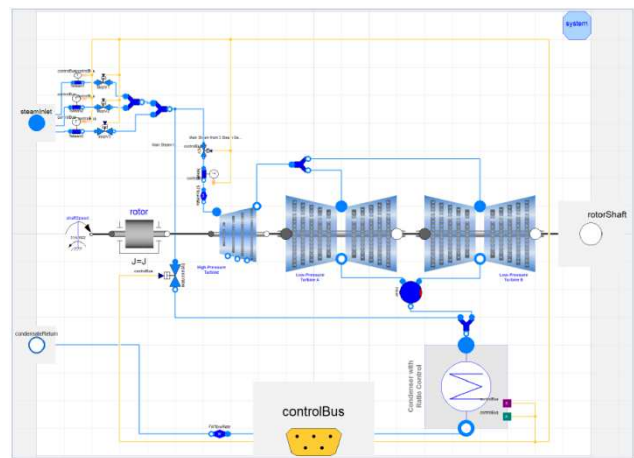

Fig. 7 SMR Power Conversion System

### 2.4.7 Grid

A simplified grid model has been developed. The Modelica implementation of the generator and the electrical grid is shown in Fig. 8. In the current implementation, the electrical generator is modeled as an ideal synchronous generator where the frequency in the electrical connector is the electromotive force (emf) of the generator. The frequency of generated electrical current is by default 60 Hz but can also be adjusted by the user. It should be noted that the generator frequency should match the grid frequency; otherwise, it will cause a generator trip and disconnection from the grid, which will in turn initiate a turbine trip.

The electrical grid is modeled with the *swing equation*, which calculates the *load angle* as a function of differences between the mechanical torque (provided by the turbine shaft) and the electrical torque (resistant torque generated by the electrical load). The load angle dictates the amount of power that can be transferred to the grid. The power sensor and the frequency sensor are used to monitor the load

angle of the network. If the frequency gets out of range, an anticipatory automatic trip is initiated for the turbine and the generator.

Fig. 8 SMR Grid System model

2.4.8 I&C

The purpose of this project is to design a system of modeling tools that allows rapid assessment of control system strategies overlaid upon reactor system models. For demonstration purposes, two different control strategies were chosen to allow multiple selection options to exist in the modeling tool: Strategy #1 – temperature regulation and Strategy #2 – temperature difference regulation.

The purpose of developing these systems models is to investigate potential control strategies for advanced SMR concepts. The I&C studies and concept development include identification of the model global outputs, determination of measurements, control actuation, and control methods and algorithms for a given system. The dynamic model of the process and plant physics provides model results and outputs for candidate measurements (system observability) and model inputs for candidate actuation (system controllability). The dynamic model also provides insights into the system time constants, degree of inherit stability, degree of coupled behavior, and input-output sensitivity. Figures 9-11 show the sensing instruments, model architecture and control logic associated with this simplified I&C control module that is overlain on the reactor systems model.

Figure 12 illustrates an example simulation in Dymola of a control system during energy demand changes. The PHTS primary pump and IHTS intermediate pump and record control rod reactivity are all actuated to regulate the reactor system temperatures as the heat sink changes. The generation of these outputs using the systems modeling approach with Modelica is relatively straightforward for the practiced simulation engineer. The goal of this project is to extend this capability to those engineers

who are not as familiar with these modeling and simulation environments.

### 2.5 FMI Add-in for Excel

Although simulation is a valuable tool for science and engineering, few scientists and engineers have the proper skill set or day to day need for modeling and simulation. As a result, the investment of time and resources to establish and maintain a modeling and simulation capability is often not justified. An open framework would provide an alternative approach which will open modeling and simulation capabilities to activities that cannot justify the investment in traditional modeling tools.

The development of these models initially requires some knowledge of Modelica and Dymola. Although most engineers may not be familiar with Modelica or Dymola, many engineers are familiar with and fairly skilled in Excel. Therefore, the project has built the initial interface tool around an Excel platform that allows the simple and intuitive generation, manipulation, plotting, and reporting of results using the FMIE [5] tool developed by Modelon. This tool (Fig. 13) allows the integration of Excel with compiled co-simulation FMUs for simulation. Many simulation environments (not just Modelica based) now allow the export of these FMUs. The use of the open standard FMI provides an opportunity for a flexible toolchain in terms of tools used for core model development, simulation, and engineering analysis along with associated licensing.

FMIE can process a model that has been compiled into an FMU by simulation platform like Dymola in a manner that facilitates performing dynamic simulations in Excel. The tool also supports changing model parameters, adjustment of the simulation start and stop times, for single or multiple simulations which can be run in parallel. The resultant input and output data variables can be selected for display in graphical or tabular form in a worksheet. FMIE also provides a scripting API which can be used for automation of analysis set-up, simulation, plotting, and post-processing.

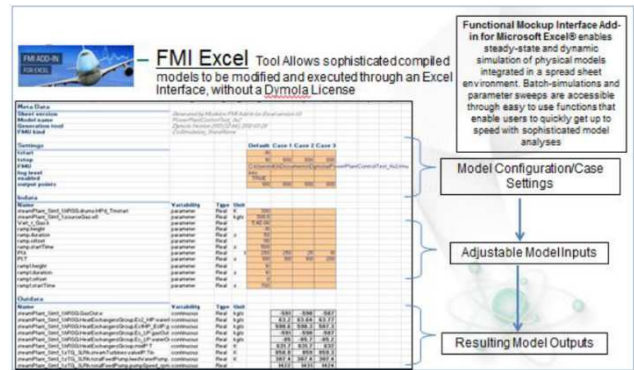

Fig. 13 Modelon FMIE interface

### 2.6 Collaboration

The initial user interface for MoDSim has been written in Excel (Fig. 14). This makes for easy integration with FMIE used to simulate the Modelica models outside of Dymola. Excel macro options that allow for the modification of inputs, the display of outputs, and the generation and plotting of results (Fig. 15) are provided along with the ability to display the metadata about the simulation. This interface tool, however, only serves as the prototype in terms of features and layout for the web application interface that is being developed. The principal limitation associated with the prototype Excel interface is its use as a local application on a machine. The widespread collaboration that is the intended goal is only truly achievable from a web-based platform.

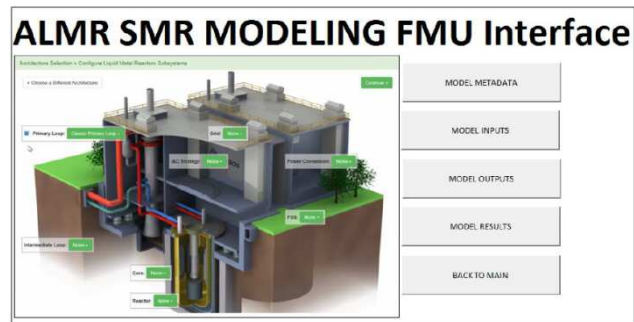

Fig. 14 SMR Excel interface

Fig. 15 SMR Excel interface - results

The heart of the collaborative effort is based on using an online open-source version control, issue tracking, and file sharing application. The application chosen is GitHub. Users can obtain a GitHub account and request access to the ORNL SMR folder (ORNL-WebSMR) displayed in Fig. 16. Access to this folder allows the user to work directly in the text-based Modelica models and make modifications, comments, etc. on the models. Additionally, issues can be raised and tracked as well as versions of the models created, archived, and documented. This allows collaboration within the user community.

Fig. 16 SMR GitHub model repository

The start page of the SMR web application built by Xogeny, Inc. is shown in Fig. 17. The web platform utilizes the architecture described in Section 2.3 along with configuration files that provide architecture, subsystem choice, parameters, and output information for use in generating the actual web application. These files are generated in the YAML (Yet Another Markup Language) language. The user can browse the available reactor architectures and then selects the one with which to work. Following the selection of the reactor architecture, the user can then configure the subsystems in the architecture as shown in Fig. 18. After subsystem selection, the user then has the option to modify the parameters in each subsystem (web app is populated with the default parameters from the FMU) as shown in Fig. 19.

The current workflow is then to generate a simulation with FMIE as shown in Fig. 20. The web application provides a download of a customized Excel sheet developed by Modelon that utilizes the scripting API in FMIE to automatically download the FMU populated with parameters entered by the user, execute the simulation, and plot the results. The resulting experiment sheet in FMIE can then be used to conduct batch simulations, modify additional parameter values, and automatically compare results between simulations. Figure 21 shows a sample experiment sheet with batch simulation compare. This automation with FMIE provides a one-click work-

flow that couples the web-based configuration and parameter setting with a local simulation running in Microsoft Excel.

Currently the web platform is an alpha product which still requires local installation of tools, and the alpha version is being used to define the requirements for the beta product. The beta version will be a completely web-based application that can be run from any user's desktop without the need to install any software. ORNL is working with Modelon and Xogeny to facilitate a web-based Modelica simulation application towards this end. The beta product is expected to be out in FY 2015. The goal of the web platform is to support both local and cloud-based simulations within licensing constraints of the development environments. As with any compiled simulation environment, the practical challenges of pre-configured models, initialization, and simulation performance must be handled in a robust way to ensure successful deployment and effective use of the simulation platform.

### 3 Conclusions

A growing number of programs within the DOE portfolio will benefit from the streamlined approach to collaborative modeling that this tool affords. Other actively funded activities in the DOE Advanced Reactors Program are planning to incorporate this tool

into their activities. This tool is well suited for work in the study of hybrid energy systems. ORNL is actively engaged in developing collaborations in the hybrid energy system space that utilized this approach. In particular, ORNL is working with the Idaho National Laboratory to create these hybrid energy system models that can be used to provide high level evaluations of potential energy concepts that make use of multiple energy generation paths. In the next phase of development, we will actively engage these projects and seek additional projects that will also benefit from this tool.

As a final note, the long-term success of this activity will be judged by three items: quality of the models developed, the number of users, and the ease of use. To this end, further development in the web-based platform is an important next step. The web-based platform provides opportunities for cloud-based modeling for both nonsensitive material as well as controlled access for sensitive, proprietary material. Additionally, the ability to create scripts that will allow for rapid assessment of parametric sweeps will simplify the input and output necessary for the user. However, it is critical that multiple projects and programs begin using this tool to generate a library of models that will form the backbone of this collaborative network for SMR dynamic modeling. By generating this simplified modeling platform it is hoped that a new paradigm for systems modeling will be created that will help facilitate the development of the next generation Small Modular Nuclear Reactor, but other complex engineering systems as well.

## Abstract

This paper presents an efficient and a novel implementation of a combined multiple shooting and collocation (CMSC) algorithm for the solution of nonlinear optimal control problems. The implemented algorithm is a modification of the approach proposed in [17, 18]. The new implementation is done under the JModelica.org framework along with CasADi and Ipopt. The framework uses a symbolic pre-calculation of functions and derivatives. Besides the integration of various components of JModelica.org, Ipopt, and CasADi, the implementation facilitates simpler modeling of optimal control problems along with a choice of options for various linear algebra algorithms. The paper gives a description of the algorithm and elaborates the components of the framework. Numerical experimentations show that the new implementation is efficient in comparison with the published results of other authors.

*Keywords: Nonlinear Optimal Control; Symbolic Automatic Differentiation; Nonlinear Programming; Multiple Shooting; Collocation*

## 1 Introduction

Optimization methods nowadays play pivotal roles in engineering and industrial applications. Most engineering applications are dynamic by nature. Frequently, such dynamic processes have model equations involving large-scale nonlinear differential equations. Hence, the solution of large-scale optimal control problems is difficult to achieve by solving the equations of the optimality conditions. Therefore, the modern approach follows the "first discretize, then optimize" strategy. In this way, the optimal control problem will be transformed into a nonlinear programming problem (NLP). This facilitates the implementation of efficient and state-of-the-art NLP solvers to determine highly accurate approximate optimal solutions to the

continuous optimal control problem.

The direct discretization of optimal control problems through the multiple shooting method was first proposed in [9]. On the other hand, the direct discretization of optimal control problems through collocation methods has been widely used for state constrained optimal control problems (e.g., [7, 10, 13]). The multiple shooting discretization results in block-structured matrices and facilitates easy parallelization of computations. However, the accuracy of the multiple shooting method can be highly augmented if it is combined with the collocation method. Therefore, recently, discretization of optimal control problems through a CMSC method is found to have enormous potentials for the solution of complex large-scale optimal control problems [17, 18].

In order to facilitate the industrial application of complex optimization algorithms, model-based optimization of dynamic systems is recently gaining greater momentum [1, 12]. The aim of this work is to implement the CMSC algorithm in the JModelica.org framework. We first divide the time horizon  $[t_0, t_f]$  into subintervals (finite elements). Subsequently, we use multiple shooting and collocation methods to discretize the optimal control problem and to transform it into an NLP. In our implementation, we use pre-calculated derivatives, i.e., Jacobian matrix in symbolic form by means of CasADi [3, 4]. The nonlinear optimization problem is solved by using Ipopt (**I**nterior **p**oint **o**ptimization solver, [19]). The total optimization tool-chain is provided in the JModelica.org framework [2].

The rest of the paper is organized as follows. Section 2 provides a general form of the considered optimal control problem. Section 3 presents the combined multiple shooting and collocation algorithm. Section 4 describes the implementation of the algorithm under the JModelica.org framework coupled with CasADi and Ipopt and section 5 presents case studies. The

comparative analysis in section 6 shows the high efficiency and viability of our implementation as compared to other implementations. The paper concludes in section 7 with a summary and future research work.

## 2 Problem definition

We consider the following general form of a nonlinear optimal control problem (NOCP):

$$\min_{u(t)} \left\{ J = E(x(t_f)) + \int_{t_0}^{t_f} L(x(t), u(t), t) dt \right\} \quad (1)$$

$$\text{subject to: } \dot{x}(t) = f(x(t), u(t), t), \quad x(t_0) = x_0, \quad (2)$$

$$g(x(t), u(t), t) = 0, \quad (3)$$

$$x_{min} \leq x(t) \leq x_{max}, \quad (4)$$

$$u_{min} \leq u(t) \leq u_{max}, \quad (5)$$

$$t_0 \leq t \leq t_f, \quad (6)$$

where  $x(t)^\top = (x_1(t), \dots, x_n(t))$  and  $u(t)^\top = (u_1(t), \dots, u_m(t))$  are the state and control vectors, respectively. The functions  $f$ ,  $h$ , and  $g$  are conveniently defined in appropriate function spaces. The dynamics of the process is described by (2) and we have algebraic equality constraints (3). In practical engineering or industrial application, state and control variables are usually bounded. Hence, (4) imposes lower and upper bounds on the states, while (5) defines bounds on the controls. The optimization variables (typically the controls) and state variables must satisfy the model equations, the state and control constraints and the boundary conditions. Furthermore, the optimization task is limited to a time horizon with an initial time  $t_0$  and a fixed final time  $t_f$ . In this paper, time-optimal control problems will not be considered.

The optimal control problem (1) - (6) is an infinite-dimensional problem. Since real-world applications have very complicated structure including nonlinearity and high dimensionality, indirect methods, like methods based on the Pontryagin's principle, are not suitable. Therefore, here the NOCP will be directly discretized by using a combined multiple shooting and collocation (CMSC) method and thereby it will be transformed to a finite-dimensional optimization problem.

## 3 An improved multiple shooting with collocation framework

For the multiple shooting and collocation discretization scheme, first the time interval  $[t_0, t_f]$  is divided into appropriate shooting intervals  $[t_i, t_{i+1}]$ ,  $i =$

$0, \dots, N-1$ . Then, on each shooting interval  $[t_i, t_{i+1}]$ , collocation nodes  $t_i = t_{i0} < t_{i1} < \dots, t_{iN_c} = t_{i+1}$  are defined, so that each state variable  $x_k(t)$  is approximated by the polynomial

$$\hat{x}_k(t) = \sum_{j=0}^{N_c} x_{ij}^{(k)} l_{ij}(t), \quad (7)$$

where  $l_{ij}(t)$  are the Lagrange polynomials

$$l_{ij}(t) = \prod_{\substack{s=0 \\ s \neq j}}^{N_c} \left[ \frac{t - t_{is}}{t_{ij} - t_{is}} \right], \quad j = 1, \dots, N_c, i = 1, \dots, N, \quad (8)$$

and the variables  $x_{ij}^{(k)}$ ,  $j = 1, \dots, N_c$ , represent the state values corresponding to the state variable  $x_k(t)$ ,  $k = 1, \dots, n$ , at the collocation points on  $[t_i, t_{i+1}]$  with the property that  $x_k(t_{ij}) = \hat{x}_k(t_{ij}) = x_{ij}^{(k)}$ . Hence, the combined multiple shooting and collocation scheme transforms the NOCP into an NLP with the additional constraints

$$h_{i+1}^k = \hat{x}_k(t_{(i+1)0}), \quad i = 0, \dots, N-1; k = 1, \dots, n \quad (9)$$

to be imposed along with the discretized constraints (2)-(5). The equations (9) guarantees the continuity of the state trajectories at the end point of each shooting interval. In the following  $h_{i+1}^x = (h_{i+1}^1, \dots, h_{i+1}^n)^\top$  and  $\hat{x}_{i+1}(h_i^x, v_i, t_{i+1}) = (\hat{x}_1(t_{(i+1)0}), \dots, \hat{x}_n(t_{(i+1)0}))^\top$  are used for the sake of brevity. The expression  $\hat{x}_{i+1}(h_i^x, v_i, t_{i+1})$  indicates that the state variables are dependent on the initial state  $h_i^x$ , the controls  $v_i$  and the end time point  $t_{(i+1)0} = t_{i+1}$  on the interval  $[t_i, t_{i+1}]$ . The resulting nonlinear optimization problem can be written as

$$\min_{h_0^x, \dots, h_N^x, v_0, \dots, v_{N-1}} \left\{ E(h_N^x) + \sum_{i=0}^{N-1} L(h_i^x, x_i, v_i) \right\} \quad (10)$$

$$\text{subject to: } h_{i+1}^x - \hat{x}_{i+1}(h_i^x, v_i, t_{i+1}) = 0, \quad i = 0, \dots, N-1, \quad (11)$$

$$G(h_i^x, x_i, v_i) = 0, \quad i = 0, \dots, N-1, \quad (12)$$

$$h_0^x - x_0 = 0, \quad (13)$$

$$x_{min} \leq h_i^x \leq x_{max}, \quad (14)$$

$$u_{min} \leq v_i \leq u_{max}, \quad (15)$$

In problem (10) - (15) on the  $i$ -th shooting subinterval,  $h_i^x$  represents parameterized initial conditions for the vector of state variables,  $\hat{x}_i$  is the state on the collocation point at the end of interval  $i$ , the vector  $x_i$  consists of all coefficients of the collocation polynomials corresponding to the states on the  $i$ -th interval and  $v_i$  are

parameterized control variables. The discretization of the states uses the Radau collocation method. Using the function  $G$ , equation (12) represents the discretized form of the equations (2, 3). The control variables are usually parameterized as piecewise constant functions. E.g., in each subinterval  $[t_i, t_{i+1}]$ ,  $i = 0, \dots, N - 1$ , the control variables are assumed to take constant values and the state trajectories will be approximated by the collocation method. The unique feature of CMSC lies in the fact that it utilizes the advantages of both multiple shooting and collocation methods. Detailed discussions on multiple shooting and collocation methods are found in [8, 9, 16].

In the objective (10) the variable  $x$  does not appear exclusively as an optimization variable. Hence, after appropriate aggregation of variables, at each step of the optimization algorithm, we can solve for  $x$  in terms of  $(h, v)$ , so that we have  $x(h, v)$ . In this way the equality constraints (12) can be eliminated by reducing the number of optimization variables. However, in this work, constraints on the coefficients of the collocation polynomials are not considered inside the collocation intervals, but only at the end-points of the intervals.

Therefore, the problem (10) - (15) can be equivalently written as

$$\min_{h,v} F(h, x(h, v), v) \tag{16}$$

$$\text{subject to : } H(h, v) = 0 \tag{17}$$

$$x_{min} \leq h \leq x_{max} \tag{18}$$

$$u_{min} \leq v \leq u_{max}, \tag{19}$$

where  $H$  in equation (17) provides a compact representation of the equations (11) - (13). Consequently, to solve the nonlinear optimization problem (16) - (19) we use the state-of-the-art optimization solver Ipopt [19]. At each iteration of Ipopt, the nonlinear model equations are solved by using a local Newton algorithm along with a linear algebra solver for the determination of the Newton-steps to determine state variables for given values of  $h$  and  $v$ . Future investigations will consider the implementation of a globalized Newton method with appropriate linear algebra solvers.

All function values and gradients, required in the optimization framework, are pre-calculated and made available in symbolic form. Symbolic derivatives are calculated by using CasADi and stored in matrices or vectors to facilitate faster accessibility. For this, it is needed to compute the sensitivities  $\frac{\partial F}{\partial v}$ ,  $\frac{\partial F}{\partial h}$ ,  $\frac{\partial H}{\partial v}$ , and  $\frac{\partial H}{\partial h}$  in symbolic representations. Further details are found in [17, 18].

The computational framework is summarized

graphically in Fig. 1 and Algorithm 1 provides a description in general terms. More detailed discussions on the CMSC method are found in [17, 18].

**Algorithm 1** : A general CMSC

- 1: **Input**: Time horizon, number of subintervals, number of state and control variables, lower and upper bounds for the control and state variables, model equations, objective function, initial guesses, optimizer options.
- 2: Initialization of the NOCP
- 3: Define continuity and path constraints
- 4: Initialize the n-point collocation for each subinterval
- 5: Compute states at collocation points and sensitivities
- 6: Compute objective function and gradient
- 7: Compute constraint function values and Jacobian
- 8: Solve the equations of the Karush-Kuhn-Tucker (KKT) optimality conditions
- 9: **if** KKT condition not satisfied **then**
- 10:     GOTO 3
- 11: **else**
- 12:     STOP.
- 13: **end if**
- 14: **Output**: optimal state and control trajectories, optimal objective function value, number of iterations and CPU time.

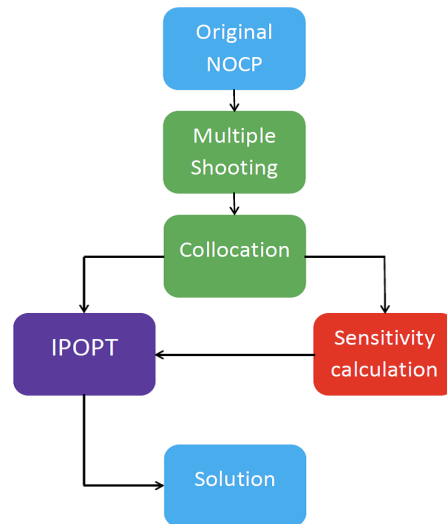

Figure 1: : Combined multiple shooting and collocation (CMSC) framework

Algorithm 1 is general for CMSC from the work of [17, 18]. This work implements a modified and improved version of Algorithm 1. Hence, Algorithm 2 provides a modified CMSC.

**Algorithm 2** : A modified CMSC

- 1: **Input:** Time horizon, number of subintervals, number of state and control variables, lower and upper bounds for the control and state variables, model equations, objective function, initial guesses, optimizer options, number of collocation points in subintervals, user-defined options, e.g., choice of a linear algebra algorithms, etc.
- 2: Calculate in symbolic form the Jacobian of the system and all directional derivatives.
- 3: Corresponding to the number of subintervals, states/controls, and collocation points, construct derivative matrices
- 4: Initialize and construct symbolic representations of the objective function and corresponding gradient.
- 5: Initialize and construct symbolic representation of the constraint functions and corresponding Jacobian.
- 6: Give an initial guess for the optimization variables
- 7: Set options for Ipopt to provide Hessian approximation, tolerance of the solution, and other user specified options.
- 8: Call the Ipopt solver
- 9: Call plotting routine and save the results.

The improvements provided in Algorithm 2 are:

- the symbolic pre-calculation to obtain representations for the values of the objective function, constraints, and corresponding sensitivities (Jacobians and derivatives),
- facilitate the use of several linear algebra algorithms to give the user a choice of options and improve the efficiency of computations,
- implementation on JModelica.org platform for a wider public accessibility.

Section 4 discusses the software implementation of Algorithm 2.

## 4 Framework and software components

In the framework shown in Fig. 2, the NOCP is modeled under JModelica.org using a Python script. Then the problem is discretized using our CMSC with the help of CasADi to obtain an NLP. Subsequently, CasADi is again invoked to generate symbolic expressions for the derivatives. Finally, JModelica.org

invokes Ipopt to solve the NLP by using the pre-calculations. All problem definitions and our custom implementations are done using the Python programming language.

Figure 2: : Software framework

In the next subsections, we give a brief review on the software components.

### 4.1 JModelica.org

JModelica.org [2] is a Modelica-based open source software platform for modeling and solving optimal control problems and implementation of user-developed algorithms. JModelica.org was first developed at the Department of Automatic Control, Lund University. Currently, it enjoys active support from the industry (Modelon AB) as well as academic and research institutions. Since JModelica.org is extensible through user-designed algorithms, we have decided to implement our algorithm under this framework.

Among the salient features of JModelica.org are:

- support for mixed-language programming mode,
- easy and smoother integrability of custom numerical libraries,
- support for object-oriented modeling based on Modelica,
- wider public access owing to simpler user interfaces.

### 4.2 CasADi

CasADi is an open source software library for symbolic automatic differentiation of functions [5]. CasADi uses computer algebra techniques to implement the forward and adjoint automatic differentiation techniques and facilitate the pre-computation of gradients and Jacobian of objective functions and constraints, respectively.

One of the major features of CasADi is its high integrability to widely available open source numerical libraries and optimization solvers. CasADi is written using C++ programming language. However, it can be interfaced to numerical solvers based on various programming language implementations, e.g., C, C++, Python, FORTRAN, etc. The recent integration of CasADi to the JModelica.org platform [4] is one proof for its high integrability and applicability for the solution of complex optimal control problems. Therefore, in our implementation, we have exploited the potential of CasADi for symbolic pre-computation of derivatives in order to improve the efficiency of computations.

### 4.3 Ipopt

Ipopt is a software implementation of an interior point algorithm coupled with a filter line-search algorithm [19]. Ipopt is a state-of-the-art solver for large-scale NLP problems. Consequently, it facilitates the efficient solution of large-scale optimal control problems using the "first discretize, then optimize" approach.

In general, Ipopt can be used to solve NLP problems of the form

$$\min_{x \in \mathbb{R}^n} f(x) \quad (20)$$

subject to :

$$g_{min} \leq g(x) \leq g_{max}, \quad (21)$$

$$x_{min} \leq x \leq x_{max}, \quad (22)$$

where  $f(x) : \mathbb{R}^n \rightarrow \mathbb{R}$  is the objective function, and  $g(x) : \mathbb{R}^n \rightarrow \mathbb{R}^m$  is the constraint function. The vectors  $x_{min}$  and  $x_{max}$  are the bounds on the variables  $x$ , and the vectors  $g_{min}$  and  $g_{max}$  denote the lower and upper bounds on the constrained function  $g(x)$ . Furthermore, equality constraints can also be stated in the above formulation by setting the corresponding components of  $g_{min}$  and  $g_{max}$  to the same value. The functions  $f(x)$  and  $g(x)$  can be nonlinear and non-convex. Theoretically,  $f(x)$  and  $g(x)$  are required to be twice continuously differentiable. However, Ipopt is capable of working with first order information, so that Hessian matrices can be approximated numerically.

## 5 Case studies

To investigate the performance of the modified method, the following two case studies are considered.

### 5.1 A nonlinear batch-reactor

The system has two state variables  $x_1(t)$  and  $x_2(t)$  (corresponding to concentrations of two species) and one control variable  $u(t)$  (reaction temperature). The objective of this benchmark problem is to achieve a maximum product output of  $x_2(t_f)$ . The NOCP is formulated as follows:

$$\max_{u(t)} x_2(t_f) \quad (23)$$

subject to :

$$\dot{x}_1(t) = - \left( u(t) + \frac{u^2(t)}{2} \right) \cdot x_1(t), \quad (24)$$

$$\dot{x}_2(t) = u(t) \cdot x_1(t), \quad (25)$$

$$x_1(t_0) = 1, \quad (26)$$

$$x_2(t_0) = 0, \quad (27)$$

$$0 \leq \begin{pmatrix} x_1(t) \\ x_2(t) \end{pmatrix} \leq 1, \quad (28)$$

$$0 \leq u(t) \leq 5, \quad (29)$$

$$0 \leq t \leq 1. \quad (30)$$

The objective function in equation (23) describes the amount of output of the second species at the final time. This example has been also studied in [6, 14, 17, 18].

Figure 3: : Optimal solution of the NOCP (23) - (30)

The results shown in the Fig. 3 is obtained by using Algorithm 2 with 160 subintervals. In the next section we will present a comparative analysis of results

obtained from our Algorithm 2 and similar solution methods of other authors.

## 5.2 A satellite control problem

A nonlinear optimal control problem of a rigid satellite initially undergoing a tumbling motion is considered. The problem data are given as follows [17]:

- $I_1 = 10^6, I_2 = 833333, I_3 = 916677$  represent principal moments of inertia, respectively
- $T_{1s} = 550, T_{2s} = 50, T_{3s} = 550$  are time constants
- Initial states:  $x_1(0) = 0, x_2(0) = 0, x_3(0) = 0, x_4(0) = 1, x_5(0) = 0.01, x_6(0) = 0.005, x_7(0) = 0.001$
- Time horizon:  $[t_0, t_f] = [0, 100]$
- Fixed terminal state:  
 $x_{t_f}^\top = (0.70106, 0.0923, 0.56098, 0.43047, 0, 0, 0)$

The aim of the optimal control is to determine the torques that bring the satellite to rest in the specified time  $t_f = 100$ , while minimizing the performance index. The NOCP is defined as follows [17]:

$$\min_{u(t)} \left\{ \|x(t_f) - x_f\|^2 + \frac{1}{2} \int_{t_0}^{t_f} \|u\|^2 dt \right\} \quad (31)$$

$$\text{subject to: } \dot{x}_1 = \frac{1}{2} (x_5 x_4 - x_6 x_3 + x_7 x_2) \quad (32)$$

$$\dot{x}_2 = \frac{1}{2} (x_5 x_3 + x_6 x_4 - x_7 x_1) \quad (33)$$

$$\dot{x}_3 = \frac{1}{2} (-x_5 x_2 + x_6 x_1 - x_7 x_4) \quad (34)$$

$$\dot{x}_4 = -\frac{1}{2} (x_5 x_1 + x_6 x_2 + x_7 x_3) \quad (35)$$

$$\dot{x}_5 = \frac{(I_2 - I_3) x_6 x_7 + T_{1s} u_1}{I_1} \quad (36)$$

$$\dot{x}_6 = \frac{(I_3 - I_1) x_7 x_5 + T_{2s} u_2}{I_2} \quad (37)$$

$$\dot{x}_7 = \frac{(I_1 - I_2) x_5 x_6 + T_{3s} u_3}{I_3}. \quad (38)$$

Here  $x^\top(t) = (x_1(t), \dots, x_7(t))$  is the state vector and  $u^\top(t) = (u_1(t), u_2(t), u_3(t))$  is the control vector of the torques acting for the respective body-principle axes. The model equations (32) - (35) are the kinematic equations associated to the orientation and (36) - (38) are the dynamic equations associated to the motion of the satellite. The state variables  $x_1(t) - x_4(t)$  are the Euler parameters and  $x_5(t) - x_7(t)$  are the angular rates.

To solve this problem using Algorithm 2, we divide the time horizon into 50 subintervals and use a 3-point

collocation on each subinterval. This leads to an NLP with 507 variables and 357 constraints. The results of our implementation are depicted in Figs. 4 - 6.

Figure 4: : Optimal states  $x_1 - x_4$

Figure 5: : Optimal states  $x_5 - x_7$

It takes 291 milliseconds of CPU time for the computation and the obtained optimal value of the objective function is 0.463968. In contrast, the optimal value of the objective function in [17] is 0.468287 obtained in 531 milliseconds of CPU time.

## 6 Comparative analysis

In this section we use the problem (23) - (30) for the purpose of comparison. Tables 1 - 4 present results obtained from similar, but different optimization methods. Note, that these results have been obtained using different computational platforms. Nevertheless, some ideas can be gained by observing the results obtained.

 Figure 6: : Optimal controls  $u_1(t), u_2(t), u_3(t)$ 

However, our modified CMSC algorithm is comparable to the collocation algorithm suggested in [15], since the implementation in [15] and of our modified CMSC are both done on the same type of computer with 3.2 GHz CPU frequency.

Table 1: CPU time (in milliseconds)

Number of subintervals	Modified CMSC	CMSC [17]	Collocation [15]	Multiple Shooting [14]	
				Unc., Sp.	Con., Co.
5	4	188	4	4	3
10	6	290	8	6	5
20	8	350	12	9	9
40	12	480	20	12	17
80	24	547	48	24	57
160	40	735	102	58	341
320	81	NaN	268	159	2717

In Tables 1 and 2

- Unc.: uncondensed SQP,
- Con.: condensed SQP,
- Sp.: Block structured QP solver using MA57,
- Co.: Matrix condensing and dense QP solver qpOASES [11].

Table 2: Number of iterations

Number of subintervals	Modified CMSC	CMSC [17]	Collocation [15]	Multiple Shooting [14]	
				Unc., Sp.	Con., Co.
5	14	16	17	7	7
10	16	21	24	9	9
20	19	21	21	9	9
40	22	25	20	10	10
80	27	23	23	10	11
160	18	23	23	12	12
320	14	27	27	12	14

As shown in Tables 1 and 2, the modified CMSC method performs more efficient, both in terms of CPU time and number of iterations, as compared to pure simultaneous (collocation) method. This facilitates the future use of Algorithm 2 for the model predictive control scheme on longer prediction horizons.

Considering Table 3, for the discretization using 5 subintervals, the collocation scheme of [15] provides lower function values as compared to Algorithm 2, but the CPU time of the modified CMSC method is better than the one reported in [17].

Table 3: Comparative results from discretization (5 subintervals)

	Objective function	Number of optimization variables	Number of constraints
Modified CMSC	0.56817	17	12
CMSC by [17]	0.56817	18	12
Collocation algorithm by [15]	0.57302	101	86
Multiple shooting by [14]	0.56838	18	10

Table 4: Comparative results from discretization (160 subintervals)

	Objective function	Number of optimization variables	Number of constraints
Modified CMSC	0.57354	482	322
CMSC by [17]	0.57354	483	322
Collocation algorithm by [15]	0.57354	3046	2566
Multiple shooting by [14]	0.57354	483	320

As shown in Table 4, our Algorithm 2 shows a higher performance in terms of CPU time as compared to all presented algorithms, still obtaining the the same objective function value as reported by other authors.

## 7 Conclusion and future work

This paper presents the first prototype of a modified combined multiple shooting and collocation method. The major difference from the original version of the CMSC approach in [17, 18] consists in using pre-calculated derivatives and their symbolic representation. That is, in every iteration of the optimization algorithm, sensitivities are automatically available without further calculations. The optimizer is provided with symbolic derivatives which are to be evaluated at the given iterate. This leads to accurate results with speedup of the overall computation time.

This preliminary investigation shows that the implemented algorithm has a competitive performance compared to other similar investigations. There is also a potential for parallel implementation of the proposed algorithm, whereby constraints to be considered on the coefficients of the collocation polynomials inside the shooting intervals. Furthermore, the modified CMSC method will be implemented to work directly with Modelica models along with a choice of local and global nonlinear equation solvers. Hence, the proposed framework will be refined to make it highly transparent, so that end-users can solve various types of applied optimal control problems. In addition, the algorithm will be extended to handle nonlinear model predictive control (NMPC) problems.

# DOML - a Compiler Environment for Dynamic Optimization Supporting Multiple Solvers\*

Tomasz Tarnawski   Radosław Pytlak

Warsaw Technical University, Institute of Automatic Control and Robotics  
ul. św Andrzeja Boboli 8, 02-525 Warsaw

## Abstract

The Modelica language may serve well as a base for defining optimal control problems, given a few relatively minor syntax extensions. One example proving that point is Optimica and another one is DOML (Dynamic Optimization Modeling Language) – installed on IDOS (Interactive Dynamic Optimization Language) and described in this paper. The DOML implementation is, actually, heavily based on the (open source) compiler of Optimica but it provides a number of important features absent in its precursor. One main extension of the compiler lies in its built-in mechanism supporting the use of many different optimization solvers (selected on the fly, depending on the content of the problem definition) and to seamlessly add new, external, solvers. In result, the range of problems that may be specified with DOML and solved in the IDOS environment is quite wide and keeps growing. The scope of problems ranges from some static optimization problems through regular ODE, parametric optimization, minimum time problems, up to DAE with higher index. DOML language extensions also provide preliminary support for multi-objective optimization and PDE problems.

*Keywords:* dynamic optimization; optimal control; Optimica

## 1 Introduction

Dynamic Optimization Modeling Language (DOML) was initially proposed ([23]) as a programming-language-independent communication format for newly developed Interactive Dynamic Optimization Server (IDOS, described e.g. in [22]). The IDOS server, envisioned by its

proponents as "the NEOS for optimal control", provides an on-line environment for dynamic optimization. It receives inputs — definitions of dynamic optimization problems specified in DOML — from its users and responds with solutions (if) found. Although still under development, IDOS is already operational, on-line at [32]. The main mode of working with the server is through a web browser, where the (logged-in) user may type problem definitions in DOML, submit tasks, view results etc. The elements and functions of the IDOS server, including exemplary computational results, have already been described in a few publications (e.g. in [22], [23] and [24]) and, in particular, in a parallel paper to be presented on the very same 10<sup>th</sup> Modelica Conference ([25]). Hence, here the functioning of IDOS itself will not be discussed any further, the core focus goes to the DOML format and its implemented compiler (as installed on IDOS).

The DOML format provides a mean for defining optimal control problems in a slightly extended Modelica syntax. In that respect it is very similar to Optimica (initially proposed in [2]) and in fact implementation of its compiler<sup>1</sup> is based on the (open source) Optimica compiler, available at [31]. Since Optimica itself has been presented in numerous papers, in particular on the Modelica Conference (e.g. [3]), it is not discussed here in much detail. Instead, the focus lies on the main features of DOML that set it apart from Optimica.

As stated above, DOML compiler is installed on a on-line-accessible server ([32]) and is used to interpret the input form (remote) users entering problems they want solved. In contrast, Optimica compiler comes as a part of a downloadable and locally installed JModelica.org environment, where the user is mainly exposed to Python

\*The work presented in the paper has been partially supported by NCBiR grants: R02-0009-06, PBS1/A7/6/2012

<sup>1</sup>DOML compiler is developed as open source. Contact the authors for setting up access to code repository

programming console as a mode of working with compiled problems, numerical packages and optimization solvers (see e.g. [4]). That architectural contrast dictates the main difference between the two compilers: DOML compiler provides inherent, built-in support for generating code for a multitude of different solvers and numerical packages (and new solvers may still be added to the environment) while in JModelica.org environment implementing any extensions or different optimization algorithms is (only) possible through Python scripts (see [26] for an example) – executed *on top* of the Optimica compiler.

One design principle for the IDOS server was its ease of use, particularly for users with limited programming skills. Hence, it seemed highly desirable to avoid any meanders on the road from a problem to its solution, such as the need of using other (programming) languages, learning environment’s internal API or studying interfaces to numerical libraries. In effect, all that an IDOS user must provide is the problem definition in DOML and DOML is then the only language that one really needs to comprehend in order to use the server. (However, as discussed later, an advanced user with good acquaintance with the compiler’s and server’s internals has also the ability to extend the server’s functionality and to implement own solving algorithms).

We find the need for implementing support for multiple solvers to be justified and intuitive. For once, dynamic optimization problems come in many different kinds (e.g. parametric, minimum time, DAE with higher index, etc) and so one solver would not be general enough to solve all of them efficiently and accurately; solvers dedicated to particular problem kinds simply do the job better. The second reason is to open the possibility for applying "solver chaining" i.e. a strategy of using two (or more) solvers consecutively on one problem. The first one yields a crude approximation while the next guarantees a more accurate solution but requires a reasonably good initial guess (and possibly other warm-starting information) – that may be taken from the first solver. Automation of such procedure seems very tempting, yet it poses a number of challenges and in some cases may plainly be impossible (e.g. due to the nature of information needed by some second-line solvers, such as [17]). Currently, a user must recode the problem manually through editing in the results

obtained from the first solver and resubmit the file. For more details on chaining solvers in IDOS see e.g. [24].

The paper is organized as follows. The following section 2 provides a general introduction to the DOML compiler. Section 3 proceeds towards the technical aspects dealing with the paper’s key issue — implementation of multi-solver support. Additional attention is devoted to the more advanced topic of supplementing the compiler with external code generators (section 3.1). Next, in section 4, the set of currently deployed solvers is briefly presented, together with (selected) code generators within the compiler implemented to couple with these solvers. Finally, section 5 provides supplementary information on other important features proposed in DOML (and setting it apart from Optimica) yet less tightly related to multi-solver support.

## 2 Compiler Overview

On the most general level, the working of DOML compiler is identical to that of Optimica. It reads in an input `.mo` file into memory, where it creates own representation of all elements of the problem’s definition. Based on that, it generates output file(s) written in a regular programming language (mostly C/C++) — therefore the compiler, formally, is actually more of a translator (from Modelica to C/C++). The produced files may then be placed as input to the standard (`gcc`) compiler and linker (bringing in required external libraries) to produce an executable file that will carry out the actual solving algorithm.

The generation of C (C++) code is template-driven: in order to produce any output, the compiler reads in an external *template* file – resembling closely a regular C++ file where only certain spots are specially marked (with so called *tags*). These tags represent places in the code where external snippets of code are to be pasted, e.g. the `$n_real_x$` tag will be replaced with the number of state variables defined in the model. The code generating method reads in the template file(s) and reproduces it to the output. Every time it comes across a tag, however, it replaces it in the output with an appropriately elaborated fragment of code — depending on the tag it may be a single number literal or several lines of C/C++ code. A special mechanism dispatches the calls to the right

code (or: snippet) generating methods based on the textual content of the tag.

The compiler is fully implemented in Java. Its executable, *together with all required template files*, is packed into a single Java jar file: `DOMLCompiler.jar` — which is where the differences against Optimica start. Typical execution of the compiler, on an exemplary input file `theInput.mo`, would take the form of:

```
> java -jar DOMLCompiler.jar theInput.mo
-o outDir
```

and all produced output would end up in `outDir` directory. It proved very convenient to supplement the set of templates with a `Makefile` so that in the output folder, next to C/C++ source code (and possibly other auxiliary) files, a `Makefile` would also be present. Then, simply running

```
> make
```

in that directory produces the executable to run and solve the problem.

The set of generated files constitutes, essentially, a problem-specific implementation of a dynamic optimization algorithm and most usually it makes an extensive use of (external) numerical libraries — through their APIs. Naturally, the generated files (and, in particular, the build commands in `Makefile`) must closely correspond with the libraries installed on the computer. As the compiler provides the problem-specific information, its back-end — the code generating *engine* — becomes responsible for "mating" the compiler with the solver(s). The two *pistons* of that engine are: the collection of template files (mentioned above) and the Java class implementing the logic for producing code snippets for each tag. Then their common *crankshaft*, to keep with the comparison, would be the set of tags present in the templates and rendered by the Java class (technically, it is in fact a fair number of small internal classes defined within the main code generator class; each of them is responsible for interpreting its separate tag).

The design of the DOML compiler provides for an easy way for adding and/or replacing back-ends. Such back-end block, composed of a code generating class together with its related templates, can therefore be viewed as a plug-in to the compiler (especially, since it can be packaged into a completely separate jar file, as described in detail in section 3.1). The concrete code generator is selected and loaded on the fly, based on the con-

tent of the input `.mo` file. Irrespective of the code generator eventually employed, the mode of executing problems under DOML is always the same: first run `jar`, then `make`.

In that respect, DOML is very different from Optimica which contains only built-in (and "hard-coded") code generators — to C and to XML. The C generator targets a single, specific optimal control solver environment (contained within JModelica.org environment). Admittedly, the XML code generator grants the user more flexibility, as the produced files may be imported by other tools (as discussed in [1]). The flipside of that approach is that it burdens the user with handling yet another file format (XML, this time) that he or she has to transport from one environment to another — either manually or through Python scripting (not mentioning, that such additional tools would then also need to be installed). This may be perfectly fine for users proficient with programming, scripting and managing multiple tools installed on their computers, but not all of them are. As already indicated, IDOS targets different users — ones, that would prefer not to (learn and) do all that, and instead to have one simple tool (a web browser) and one language (DOML) for solving all their (optimal control) problems.

### 3 Implementation of Multiple-solver support

In the context of DOML compiler, the term *solver* refers to a set of templates together with numerical libraries used by them and needed to build the executable. In other words, each solver is an implementation of a particular dynamic optimization algorithm; as soon as it is filled with problem specific data it may be compiled and executed. The actual collection of solver packages deployed on IDOS server (and required libraries installed alongside) is discussed in [25] and here touched upon in section 4. For the purpose of the current discussion, it is sufficient to recognize that there may be present quite a few different packages implementing algorithms for solving distinct kinds of optimization problems and with time still new packages may be implemented and plugged-in to the environment.

In DOML compiler environment each solver's code generating class — i.e. the class containing the logic to fill up all templates for particular

```

package pl.pw.DOML.codegen;

public abstract class BaseDOMLGen
    extends OptimicaCGenerator {

    public static BaseDOMLGen
        loadGenerator(String solverName,
                      FDOMLClass fc,
                      Properties props) {
        ...
    }

    public abstract ArrayList<String>
        getTemplateFNames();

    public void
        generate(String templateF,
                 String outF) { ... }

    ...
}

```

Listing 1: BaseDOMLGen class excerpt

solver — must be a subclass of BaseDOMLGen. Excerpts of this class, shown on listing 1, present its most important features. It:

- implements static method `loadGenerator()` for searching, loading and instantiating the appropriate, concrete code generating class. It utilizes Java reflection mechanism to look for proper compiled Java classes.
- declares `getTemplateFNames()` abstract method that every generator must override to communicate (through call-back) its set of template file names to the compiler. This way, each code generator may be tied to its own, completely separate set of templates.
- implements `generate()` method that carries out the process for each template file (whose name is provided as the first parameter) by reading it and dispatching calls to individual tag-generating methods.

Any code generator class derived from BaseDOMLGen needs to implement only the `getTemplateFNames()` method and the logic of generating code snippets for its specific tags (i.e.: tags present in templates associated specifically with that generator).

The class searching and loading mechanism relies on the use of Java annotation `@Solver` defined

specifically for that purpose. Each code generator implemented according to the description above must be appropriately annotated, where at least the solver's unique name must be given — as on the example below with "olado" :

```

@Solver("olado")
public class DOMLGen4Olado
    extends BaseDOMLGen { ...

```

All template files used by that solver must then reside in the jar file, inside its `/templates/olado` subdirectory.

The annotation `@Solver` also provides means for specifying the kinds of problems that a given solver package can handle, through a set of attributes defining whether the package requires (TRUE), accepts (DONT\_CARE) or disallows (FALSE) certain qualities and elements of a problem. The default value for all `@Solver`'s attributes is FALSE, hence the ones not applicable may be omitted. Example below illustrates the point:

```

@Solver(value = "rkcon",
        freeFinalTime
            = ApplicableTo.TRUE,
        minFinalTime
            = ApplicableTo.DONT_CARE,
        residualEquations
            = ApplicableTo.DONT_CARE,
        finalStateConstraints
            = ApplicableTo.DONT_CARE)
public class DOMLGen4RKcon
    extends BaseDOMLGen {

```

As of now, this annotation's attributes describe, whether the given solver is applicable to:

- with respect to the problem's structure — static optimization, ODE or DAE systems, parametric optimization (in particular: optimization of the system's initial state), PDE problems;
- with respect to the elements present in the definition — problems with: free final time (in particular, where final time is the objective), equations specified in residual form, integer-valued decision variables, multiple objectives;
- with respect to the kinds of constraints defined — box constraints, constraints on the final state, general functional constraints or non-stationary constraints.

This setup should not yet be considered final but it is well past the proof-of-concept stage. Having the above list as a rough guidance, the goal of development efforts of the IDOS server is to furnish a host of solvers covering typical cases of dynamic optimization problems. The current state of efforts, as far as code generators implemented and the set of corresponding libraries installed, is briefly discussed in section 4.

When executing a problem specified in DOML, one may force the use of a particular package through (Modelica-like) annotation `solver` handled by the DOML compiler, as so:

```
annotation(solver="olado");
```

If such annotation is omitted in the DOML input (or `solver` is specified as "auto"), the compiler makes its best effort to load the generator class that fits the current problem. Upon entering the code generation stage (i.e. after parsing input file, doing semantic analysis and problem transformations e.g flattening or alias elimination) the compiler queries the object containing the AST representation of the input — to classify the problem along the lines sketched above. Then, it browses available code generator classes (subclasses of `BaseDOMLGen`) and tries to match their `@Solver` description to that classification. If an exact counterpart cannot be found, a simple (preliminary) heuristic is used to choose the closest match. An object of the selected class is instantiated and used thereupon.

### 3.1 External code generators

In the mechanism described above, the logic responsible for browsing for available code generator classes implements one additional, powerful feature. The searching is not limited to the content of the `DOMLCompiler.jar` file, but in fact incorporates all jar files found in the current folder. This way any external solver, packaged (together with its templates) into a jar file, may equally well be used by the compiler task. An advanced user may therefore implement own solver jar package (which is the harder part) and add it seamlessly and non-intrusively to the compiler (which then is as easy as uploading the jar file on the server).

When implementing own solver package, say under the name `mySolverPack`, one must produce a Java jar file that fulfills the following minimum requirements:

- it must contain the code generator class — subclass of `BaseDOMLGen` — annotated as `@Solver("mySolverPack")` and implementing `getTemplateNameNames()` that returns a collection of names of solver's template files (including a makefile);
- it must contain all template files placed in `/templates/mySolverPack` subfolder;
- templates may use only numeric libraries installed on the server (installing extra libraries on user accounts is not yet supported), the makefile should be written accordingly;
- the code generating class must handle appropriately solver-specific tags appearing in the templates.

Preferably, the annotation `@Solver` should also specify applicability of that package (as discussed earlier); otherwise, one will be able to use the solver only by specifically requesting its name through annotation in the DOML input file.

The above requirements clearly imply, that this functionality is meant for advanced users—developers of optimization algorithms. Preparing the set of templates calls for a good knowledge (and at least some practice of use) of libraries installed on the server while implementing own code generator class is possible only with good familiarity of the compiler's internal API (in particular: the data structure representing the compiled input problem).

## 4 Implemented solvers and code generators

At the moment the IDOS server can handle control problems described with ordinary equations and differential–algebraic equations but the incorporation into the IDOS solvers for problems with partial differential equations is also under way.

The IDOS server enables solving optimal control problems by using essentially different methods ranging from ones based on *a priori* discretization through utilizing variable stepsize integration and adjoint equations to shooting methods applied to differential equations derived from necessary optimality conditions. These methods and solvers are discussed in some detail in [25].

Obviously, not all solvers can be used on every problem. The compiler is fit to cooperate with

the installed solvers, through the following code generator classes implemented in DOML compiler:

- `DOMLGen40lado` — ODEs are discretized *a priori* and then the large-scale NLP problem solved by a static optimization solver (Ipopt [29], KNITRO, etc)—the library OLADO is described in [5] and uses several interior point methods ([16],[11]) for QP problems to which solvers refer;
- `DOMLGen4cvodes` — ODEs treated as continuous time (adaptive stepsize integration using SUNDIALS, [15]), the optimization problem solved with the help of adjoint equations (in the reduced space) and the Ipopt package—the solver is based on cvodes procedure ([28]) from SUNDIALS;
- `DOMLGen4bndsc0` — indirect shooting method using the BNDSO package developed by Oberle ([17]) ;
- `DOMLGen4Pantelides` — higher index DAEs, implementing the Pantelides' graph based initialization algorithm ([19]), also Maxima package for symbolic differentiation is used ([30]);
- `DOMLGen40ladoBonmin` — ODEs with integer valued controls, solved through *a priori* discretization of ODEs as applied in the OLADO package and with the help of MIP solvers from BONMIN package ([6],[7]);
- `DOMLGen4cvodesBonmin` — ODEs with integer valued controls, the optimization problem solved with the help of adjoint equations (evaluated by SUNDIALS programs) and BONMIN package;
- `DOMLGen40ladoHqp0muses` — various dynamic optimization solvers based on HQP and OMUSES packages ([9],[10]);
- `DOMLGen4RKon` — index one DAEs treated by implicit Runge–Kutta scheme, optimization problem solved in reduced space by RKCON solver (special treatment of state constraints)—the justification for the solver RKCON is presented in [20];
- `DOMLGen4Radau` — up to index three DAEs treated by RADAU5 (implicit R-K) solver ([14],[12],[13]), optimization problem solved

in reduced space by RKCON solver, the package is based on adjoint equations for higher index DAEs derived in [21].

The above list is not exhaustive as, for instance, a few of other back-ends undergo testing and/or are under construction — e.g. `DOMLGen4PDE` or `DOMLGen4staticIpopt` (where names imply their purpose).

## 5 Other enhancements in DOML

The main direction of extending DOML syntax revolved around the idea of "chaining" of solvers, i.e. using a number of solvers in a sequence so that a succeeding solver would (use as an initial guess and) improve on the solution arrived at by its predecessor. Usually an approximate solver would be used first, followed by one that is more accurate yet also more sensitive (susceptible) to the choice of starting point.

One of DOML language proposed features is an external package added into the Modelica Standard Library — `Modelica.DOML` — with its predefined (/built-in) data types and functions. Currently `Modelica.DOML` contains two subpackages: `internal` and `Inputs`. Importantly, the definitions in `Modelica.DOML.internal` are automatically visible in any DOML file i.e. it is always implicitly imported by the compiler (therefore, specifying explicitly `import Modelica.DOML.internal.*`; would be redundant and will have no additional effect). The package `internal` contains, among others, the definition of `Formula` class needed for certain aspects of solver chaining (but also e.g. `Domain` class used in defining PDE problems). In turn, the purpose of `DOML.Inputs` was to allow for easy definition of known (predefined) signals, most notably with `Spline` – using tabular values to produce piece-wise constant (degree = 0) or continuous (degree  $\geq 1$ ) signal, based on polynomial interpolation.

A simple and intuitive language extension (or perhaps just a bug fix to `Optimica`) was to allow, in certain cases, *continuous* variability in the right-hand-side expression defining the value of the `initialGuess` attribute. If a variable's value can change over time, then it seems reasonable to allow the user to provide an initial guess for it that also is not constant over time. After that enhance-

```

Modelica.DOML.Inputs.Spline
  u_init(startTime=0, finalTime=1,
          table=[0,0; 0.2,.096;
                 0.4,.1; 0.6,.1;
                 0.8,.096; 1,0],
          degree = 1);
Real u(initialGuess = u_init.y);

```

Listing 2: Specifying on initial guess signal for a continuous variable

```

class Formula
  parameter Boolean linear;
  Real lagrange(dual = true);
  parameter Integer order;
end Formula;

```

Listing 3: Definition of the predefined class **Formula**.

ment, the above-mentioned `Spline` may be used to feed an arbitrary signal as an initial guess of a variable, as illustrated on listing 2. This way, a user can run optimization with a fairly good starting point, for instance obtained by pre-solving the problem with a different (simpler) solver or with coarser discretization — a typical implementation of the strategy of "chaining of solvers".

Next to the (near optimal) trajectories found for variables and controls, other (by)products of (pre)solving an optimal control problem may be available and beneficial when warm-starting a high-precision solver. Among such, are the values of adjoint variables and Lagrange multipliers arrived at near the solution. (Adjoint variables and Lagrange multipliers are, arguably, two names representing the same fundamental concept hence, for the sake of simplicity, for both cases the syntax provides the same name: `lagrange`). Assigning the `lagrange` values to equations (/constraints) needs a mechanism for identifying particular formulas. In DOML it is devised by means of labeling them, as so

```
eq_x1: der(x1) = p1*x1 - p2*x2*x3;
```

with simultaneously declaring the "label variable" as **Formula** `eq_x1`; . The compiler checks if all variables of type **Formula** are referenced as labels and, conversely, that all labels used next to equations are appropriately declared variables. The **Formula** class is declared in `DOML.internal`, as shown on listing 3.

The objects of the new predefined type **Formula**

are meant to be used to specify attributes describing the particular equation or constraint – most notably the above mentioned adjoint variable/Lagrange multiplier, but for prospective use other attributes were defined as well. Similarly to the earlier example, one can now specify an `initialGuess` for the lagrange attribute associated with a particular equation or constraint. Such additional information may be beneficial, or plainly required, in certain solvers (e.g. BNDSCO).

The last to discuss modification of DOML vs. Optimica lies in a slightly different way of defining the objective within an **optimization** class. DOML breaks up with Optimica's objective attribute and introduces two keywords, **minimize** and **maximize**, in its stead. Each has an almost identical meaning to Modelica's **parameter** keyword, but in addition signals that the given parameter holds the objective value.

The modification was motivated by its following advantages:

- it clearly indicates the direction of optimization; in some domains the default of minimization may not be as natural.
- objective variables can now have meaningful names;
- it becomes possible (and strikingly simple) to define multi-objectives problems in a natural way e.g. with:

```

maximize Real profit =... ;
minimize Real deliveryTime =... ;

```

(implementing a multi-objective solver is, naturally, quite another issue)
- it makes it possible to define problems with integer valued (or even Boolean valued, for that matter) objective functions (again, we are not touching on the implementation aspect here).

A number of other important language extensions is related to using DOML to specify and (prospectively) solve PDE problems. This aspect also deserves attention but is clearly beyond the scope (and page allowance) of this paper. This aspect of implementation is described in [23] and was partially inspired by [27].

## 6 Summary and future work

IDOS (Interactive Dynamic Optimization Server) provides an environment for defining and solving optimal control problems in DOML (Dynamic Optimization Modeling Language) — a modeling language derived from Modelica (/Optimica). The main focus of the paper was put on these features of the server's environment — in particular, of the DOML compiler — that provide support for applying different solvers to different problems. Additional information about the current range of implemented solvers was also provided.

A number of features proposed in DOML set it apart from Optimica. The authors believe, that these modifications deserve to be called "improvements" and/or "extensions" as they seem to enhance both expresiveness and applicability of the language. Their presentation and discussion is scattered throughout the paper and therefore, for clarity and readability, here we (re)state them all together in a concise manner. The new features of DOML are:

- implementation of multiple solvers with a mechanism for adding (plugging-in) new code generators (vs. hard-coded, closed set of code generators in Optimica);
- `annotation(solver)` allowing the user to choose a particular solver package to be used;
- support for continuous variability of the `initialGuess` attribute (vs. parameter variability in Optimica) adds flexibility in defining initial (warm-starting) point of computations, e.g. with using provided `Spline` signal generator;
- mechanism for labeling equations and constraints (missing in Modelica/Optimica);
- mechanism for referencing (and warm-starting) adjoint variables / Lagrange multipliers of (labelled) formulas;
- keywords `maximize` and `minimize` defining the objective function with indicating the direction of optimization (vs. `objective` attribute in Optimica)  
note: makes it possible to define multiple-objective problems, now the objective does not have to be real-valued.

Apart from the above list, the lion's share of the DOML compiler functionality is inherited directly from the (JModelica.org) Optimica compiler whose authors, naturally, deserve due recognition and honor.

Currently, significant parts of the server's functionality are still under development and testing. There is still much room for improvement, for instance as far as robustness (e.g. in cases of some less usual formulations that are acceptable from the language point of view but not recognized by code generating rules) or graceful error handling are concerned. A further reaching to-do list also contains: polishing the mechanism for problem classification and choosing solvers/generators (more advanced rules for matching most appropriate solver to a given problem) and better support for chaining of solvers (possibly, through producing solver's output in the form of "enriched" input, with solution pasted in as, e.g. the value of control's `initialGuess` attribute; such output could then be directly used to warm-start another solver).

One central goal in the design of the environment was to provide mechanisms for easily extending the compiler's code generating functionality in order to support a growing number of solver packages. As discussed in some detail above, the goal has already been reached successfully. In result, the compiler offers a remarkable feature: extensions of its code generating functionality is possible virtually on the fly — by simply adding an external jar file and without any interference with the compiler's executable. With this mechanism, remote users of IDOS may be enabled to implement own solver packages and deploy them on the server. If the proposed solution catches on and stands the test of time, IDOS could become an important, extensible, multi-user environment for solving wider and wider range of optimal control problems — "the NEOS of optimal control".

## Abstract

Efficient calculation of the solutions of nonlinear optimal control problems (NOCPs) is becoming more and more important for today's control engineers. The systems to be controlled are typically described using differential-algebraic equations (DAEs), which can be conveniently formulated in Modelica. In addition, the corresponding optimization problem can be expressed using Optimica.

Solution algorithms based on collocation methods are highly suitable for discretizing the underlying dynamic model formulation. Thereafter, the corresponding discretized optimization problem can be solved, e.g. by the interior-point optimizer Ipopt. The performance of the optimizer heavily depends on the availability of derivative information for the underlying optimization problem. Typically, the gradient of the objective function, the Jacobian of the DAEs as well as the Hessian matrix of the corresponding Lagrangian formulation need to be determined. If only some or none of these derivatives are provided, usually numerical approximations are used by the optimizer internally.

OpenModelica supports the Optimica language and is capable of automatically generating the discretized optimization problem using collocation methods as well as the whole symbolic machinery available. In addition, all necessary derivative information is determined using the automatic differentiation capabilities of ADOL-C, which has now been integrated into the OpenModelica environment.

*Keywords:* Modelica; optimization; automatic differentiation; collocation; OpenModelica; ADOL-C

## 1 Introduction

The aim of this paper is to describe an efficient new solution process implemented in OpenModelica [11] for nonlinear optimal control problems. This effort continues the development of the collocation approach already discussed in [3], which has been successfully tested using the algorithmic differentiation tool CasADi [18]. Several enhancements, e.g. special treatment of the first collocation interval, integration of the automatic differentiation tool ADOL-C, as well as efficient and stable calculation of all derivative information, have been realized in OpenModelica and are demonstrated within this paper.

Efficient calculation of first order derivatives is possible with OpenModelica based on symbolic differentiation and has been successfully demonstrated using real world problems in [5]. This calculation of the derivatives benefits on the one hand from the simplification of expressions and on the other hand from the code, which is efficiently generated by OpenModelica. For optimization purposes the second order derivatives are important as well, since most of the optimization algorithms rely on them, e.g. Ipopt [19], which is used in this work. Second order derivatives are currently not symbolically available in OpenModelica, but could be provided numerically based on the already mentioned first order derivatives.

Another possibility is using the automatic differentiation tool ADOL-C, which is capable of working directly with the generated code of OpenModelica and has already been used successfully with Ipopt. Moreover, ADOL-C comes with a lot of additional features, e.g. efficient calculation of derivatives of different or-

ders. Last but not least, the implementation leads to a very fast solution with little memory costs for the underlying NOCP. The modeling and problem description is done in Modelica [8] extended with the optimization objective functions specified in Optimica [1]. This paper is organized as follows. In section 2, the mathematical representation of the nonlinear optimal control problem is discussed. The main idea of discretizing the NOCP based on orthogonal collocation principles is described in section 3. The efficient realization of the derivative calculation using ADOL-C is demonstrated in section 4. Section 5 presents the implementation details with respect to scaling, initialization and derivative calculation. Finally, the performance of the newly developed tool chain is discussed in section 6. The paper concludes the work with final remarks and suggestions for future work.

## 2 Nonlinear Optimal Control Problem (NOCP)

In many applications the NOCP is described by the following mathematical representation [10]:

$$\min_{u(t)} J(x(t), u(t), t) = E(x(t_f), u(t_f), t_f) + \int_{t_0}^{t_f} L(x(t), u(t), t) dt \quad (2.1)$$

s.t.

$$x(t_0) = x_0 \quad (2.2)$$

$$\dot{x}(t) = f(x(t), u(t), t) \quad (2.3)$$

$$\hat{g}(x(t), u(t), t) \leq 0 \quad (2.4)$$

$$r(x(t_f)) = 0 \quad (2.5)$$

where  $x(t) = [x^{(1)}(t), \dots, x^{(n_x)}(t)]^\top$  and  $u(t) = [u^{(1)}(t), \dots, u^{(n_u)}(t)]^\top$  are the state vector and control variable vector for  $t \in [t_0, t_f]$ , respectively. The constraints (2.2), (2.3), (2.4) and (2.5) represent the initial conditions, the nonlinear dynamic model description based on differential algebraic equations (DAEs), the path constraints  $\hat{g}(x(t), u(t), t) \in \mathbb{R}^{n_g}$  and the terminal constraints [3]. With respect to the implementation in Ipopt and the Modelica language, it is appropriate to split the box constraints from  $\hat{g}(x(t), u(t), t) \leq 0$ , i.e.

$$\begin{array}{lclcl} x_{\min} & \leq & x(t) & \leq & x_{\max} \\ u_{\min} & \leq & u(t) & \leq & u_{\max} \end{array}$$

and to introduce so-called slack variables for the rest

$$g(x(t), u(t), t) + s(t) = 0$$

with  $s(t) \geq 0 \in \mathbb{R}^{n_g}$ . Therefore, it is possible to use the attributes `min` and `max` already available in Modelica for the description[9].

## Modelica model description

The mathematical representation of a Modelica model is typically given by DAEs

$$F(x(t), u(t), y(t), t) = 0.$$

However, most Modelica tools, especially OpenModelica, are capable of converting this formulation (by means of the so-called BLT transformation [2]) into a semi-explicit ODE form as formulated also in (2.3)

$$\begin{array}{l} \dot{x}(t) = f(x(t), u(t), t), \\ y(t) = h(x(t), u(t), t). \end{array}$$

In general, there is no closed expression for the functions  $f$  and  $g$ , but rather, iterative techniques, e.g., Newton's method, are employed to solve the so-called occurrent linear or nonlinear algebraic loops [2].

At this point it is possible to choose between two strategies for the discretization of (2.3). On the one hand, it is feasible to transform these algebraic loops into residual form and to add them subsequently to the discretized NOCP formulation. This approach has the advantage that the costs for solving the algebraic loop in each evaluation of the function  $f$  are saved. However, the solver space as well as the workload of the optimizer increases. On the other hand, the algebraic loop can be solved during each optimizer step by a linear or nonlinear solver, depending on the type of problem. This procedure might have the drawback, that the solution of these algebraic loops might be also quite time consuming, especially in the case of a highly nonlinear equation system.

This paper focuses on the second strategy. The semi-explicit ODE form is generated using OpenModelica and solved for each optimizer step. In addition, a more general NOCP formulation can be converted by means of the BLT transformation to a semi-explicit NOCP as stated in (2.1), (2.2), (2.3), (2.4) and (2.5).

## 3 Collocation

Previous work [3] has shown that solving the NOCP with a collocation approach is efficient. Therefore, the choice of collocation nodes is important, since that influences the stability and order of the integration method [7, 16]. The RADAU IIA method [4] is

one possible method to choose the collocation nodes. RADAU IIA is an implicit Runge-Kutta method and is typically described in the form [16]:

$$\begin{bmatrix} x_{i,1} - x_i \\ \vdots \\ x_{i,m} - x_i \end{bmatrix} = \Delta t_i \cdot (A \otimes I) \cdot \begin{bmatrix} f(x_{i,1}, u_{i,1}, t_{i,1}) \\ \vdots \\ f(x_{i,m}, u_{i,m}, t_{i,m}) \end{bmatrix} \quad (3.1)$$

with  $x_{i,j} = x(t_{i,j})$ ,  $x_i := x(t_i)$ ,  $u_{i,j} = u(t_{i,j})$ ,  $t_{i,j} := t_i + \tau_j \cdot \Delta t_i$  and  $t_i := t_0 + \sum_{l=1}^i \Delta t_l$  where  $\Delta t_i$ ,  $i = 0, \dots, n$  is the length of a subinterval and  $\tau_j \in [0, 1]$ ,  $j = 1, \dots, m$  are the collocation nodes.  $A$  and  $I$  are the Butcher and identity matrix, respectively. If  $\det(A) \neq 0$ , equation (3.1) can be transformed [7] to the following form

$$F_i(\cdot) := (A^{-1} \otimes I) \cdot \begin{bmatrix} x_{i,1} - x_i \\ \vdots \\ x_{i,m} - x_i \end{bmatrix} - \Delta t_i \cdot \begin{bmatrix} f(x_{i,1}, u_{i,1}, t_{i,1}) \\ \vdots \\ f(x_{i,m}, u_{i,m}, t_{i,m}) \end{bmatrix}$$

This form leads to a sparse structure for the Jacobian matrix, since in equation (3.1) the sparse structure is destroyed by multiplication of the dense matrix  $A$ .

The RADAU IIA can be interpreted as a Lagrange interpolation of the state  $x^{(l)}(t)$  [3, 4]

$$x^{(l)}(t_i + \tau \cdot \Delta t_i) \approx \sum_{j=1}^m p_j(\tau) \cdot x_{i,j}^{(l)} \text{ for } \tau \in [0, 1].$$

The corresponding Lagrangian polynomials are  $p_j$ . In order to handle constraints for  $\text{der}(u)$  the control variable  $u^{(l)}(t)$  needs to be interpreted as a Lagrange interpolation as well:

$$u^{(l)}(t_i + \tau \cdot \Delta t_i) \approx \sum_{j=1}^m p_j(\tau) \cdot u_{i,j}^{(l)}.$$

Therefore, it is possible to calculate  $\text{der}(u)$  as

$$\frac{du^{(l)}(t)}{dt} = \frac{\partial u^{(l)}(t_i + \tau \cdot \Delta t_i)}{\partial \tau} \cdot \Delta t_i \approx \Delta t_i \cdot \sum_{j=1}^m \frac{\partial p_j}{\partial \tau}(\tau) \cdot u_{i,j}^{(l)}.$$

Moreover, the constraints based on RADAU IIA result in an unbounded expression  $f(x_0, u_0, t_0)$ , since the node  $\tau_j = 0$  is not part of the RADAU IIA integration scheme, especially the expression  $u(t_0)$  is unbounded. The principle is visualized in figure 1. This issue can be addressed by using the LOBATTO IIIA method, which includes the nodes  $\tau_1 = 0$  and  $\tau_m = 1$ . Thus, the LOBATTO IIIA method yields an influence of  $u(t_0)$  on the NOCP. Therefore, the principles of the collocation discretization will be applied not only to states, but also to the control variables. This approach is referred to as total collocation [3, 18].

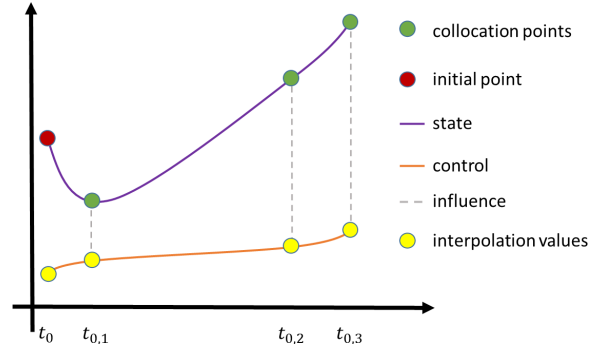

Figure 1: RADAU IIA schema

### 3.1 Lobatto IIIA

In comparison to RADAU IIA the LOBATTO IIIA method has a singular matrix  $A$  [16]. The number of nonzero elements of the Jacobian matrix can be reduced by multiplying the matrix  $A$  with  $B^{-1}$  so that

$$\begin{aligned} [0 \mid B^{-1}] \cdot A &= [0 \mid B^{-1}] \cdot \begin{bmatrix} 0 & 0 & \cdots & 0 \\ a_{2,1} & a_{2,2} & \cdots & a_{2,m} \\ \vdots & \vdots & \ddots & \vdots \\ a_{m,1} & a_{m,2} & \cdots & a_{m,m} \end{bmatrix} \\ &= [0 \mid B^{-1}] \cdot \begin{bmatrix} 0 & 0 \\ A_1 & B \end{bmatrix} = [\hat{A}_1 \mid I]. \end{aligned}$$

Furthermore, the equation (3.1) can be transform for the special case LOBATTO IIIA as follows

$$\begin{aligned} \hat{F}_0(\cdot) &:= (B^{-1} \otimes I) \cdot \begin{bmatrix} x_{0,2} - x_0 \\ \vdots \\ x_{0,m} - x_0 \end{bmatrix} - \\ &(A_1 \otimes I) \cdot \Delta t_0 \cdot \begin{bmatrix} f(x_{0,1}, u_{0,1}, t_{0,1}) \\ \vdots \\ f(x_{0,1}, u_{0,1}, t_{0,1}) \end{bmatrix} + \quad (3.2) \\ &\Delta t_0 \cdot \begin{bmatrix} f(x_{0,2}, u_{0,2}, t_{0,2}) \\ \vdots \\ f(x_{0,m}, u_{0,m}, t_{0,m}) \end{bmatrix} \end{aligned}$$

Note that  $x_0$  is bounded and solved with equation (2.2), so  $x_0$  is known for the optimization process. Thus, there is no need to differentiate equation (3.2) with respect to  $x_0$ , this results only in nonzero elements for  $u_0$ .

Besides, for RADAU IIA and LOBATTO IIIA applies

$$x_0 = x_{0,1} \quad \text{and} \quad x_{i+1} = x_{i,m},$$

which is solved symbolically without the optimization loop.

### 3.2 Discretized Lagrange term

Now, it is possible to use the property of the collocation method that

$$x(t_{i,j}) \approx x_{i,j}$$

for the approximation of the Lagrange term (2.1) based on quadrature formulas. Obviously, it makes sense to apply methods of Lobatto and Radau quadrature.

$$\begin{aligned} \Phi(\mathbf{x}, \mathbf{u}, \mathbf{t}) &:= \Delta t_0 \cdot \sum_{j=1}^m \hat{w}_j \cdot L_{0,j} + \sum_{i=1}^{n-1} \Delta t_i \cdot \sum_{j=1}^m w_j \cdot L_{i,j} \\ &\approx \int_{t_0}^{t_f} L(x(t), u(t), t) dt \end{aligned} \quad (3.3)$$

where  $L_{i,j} := L(x_{i,j}, u_{i,j}, t_{i,j})$ ,  $\hat{w}$  represents the Lobatto weights,  $w$  the Radau weights, and the abbreviations  $\mathbf{x} := [x_{0,1}, \dots, x_{n,m}]$ ,  $\mathbf{u} := [u_{0,1}, \dots, u_{n,m}]$ , and  $\mathbf{t} := [t_{0,1}, \dots, t_{n,m}]$ .

### 3.3 Discretized NOCP

Finally, the NOCP can be discretized:

$$\min J(\mathbf{x}, \mathbf{u}, \mathbf{s}, \mathbf{t}) = E(x_{m,n-1}, u_{m,n-1}, t_{m,n-1}) + \Phi(\mathbf{x}, \mathbf{u}, \mathbf{t})$$

s.t.

$$\begin{aligned} c(\mathbf{x}, \mathbf{u}, \mathbf{s}, \mathbf{t}) &\stackrel{!}{=} \mathbf{0} \\ u_{\max} &\leq \mathbf{u} \leq u_{\min} \\ x_{\max} &\leq \mathbf{x} \leq x_{\min} \\ \mathbf{0} &\leq \mathbf{s} \end{aligned}$$

where

$$c(\mathbf{x}, \mathbf{u}, \mathbf{s}, \mathbf{t}) := \begin{bmatrix} \hat{F}_0(\cdot) \\ g(x_{0,1}, u_{0,1}, t_{0,1}) + s_{0,1} \\ \vdots \\ g(x_{0,m}, u_{0,m}, t_{0,m}) + s_{0,m} \\ F_1(\cdot) \\ g(x_{1,1}, u_{1,1}, t_{1,1}) + s_{1,1} \\ \vdots \\ g(x_{1,m}, u_{1,m}, t_{1,m}) + s_{1,1} \\ F_n(\cdot) \\ g(x_{n,1}, u_{n,1}, t_{n,1}) + s_{n,1} \\ \vdots \\ g(x_{n,m}, u_{n,m}, t_{n,m}) + s_{n,m} \\ r(x_{n,m}, u_{n,m}, t_{n,m}) \end{bmatrix}$$

and  $x_{0,1} = x_0$  with  $\mathbf{s} = [s_{0,1}, \dots, s_{m,n}]$ ,  $s_{i,j} = s(t_{i,j})$ .

### 3.4 Nonlinear optimization

Now, the original NOCP is transformed to a nonlinear optimization problem, where the optimizer needs to find the optimal discretized control vector  $\mathbf{u}$  and to adapt  $\mathbf{x}, \mathbf{s}$  so that the constraints are fulfilled. For this operation the optimizer requires the first order derivatives from  $E(\cdot)$ ,  $\Phi(\cdot)$  and  $c(\cdot)$  as well as the second order derivatives from the Lagrangian function

$$L(z, \lambda, \mathbf{t}) = E(\cdot) + \Phi(\cdot) + \lambda^\top \cdot c(\cdot) \quad (3.4)$$

to find the solution. The sorting of  $c(\cdot)$  and  $z = [\mathbf{x}, \mathbf{u}, \mathbf{s}]$  is substantial for a good Jacobian- and Hessian-structure. The block

$$G_i(\cdot) := \begin{bmatrix} F_i(\cdot) \\ g(x_{i,1}, u_{i,1}, t_{i,1}) + s_{i,1} \\ \vdots \\ g(x_{i,m}, u_{i,m}, t_{i,m}) + s_{i,m} \end{bmatrix}$$

can be sorted more efficiently, if this is investigated in more detail. Furthermore, it applies

$$\frac{\partial x_{i,j}^{(l)}}{\partial x_{a,b}^{(c)}} = \frac{\partial x_{i,j}^{(l)}}{\partial u_{a,b}^{(d)}} = \frac{\partial u_{i,j}^{(e)}}{\partial u_{a,b}^{(d)}} = \frac{\partial u_{i,j}^{(e)}}{\partial x_{a,b}^{(c)}} = 0$$

for  $i, a = 0, \dots, n$ ,  $j, b = 1, \dots, m$ ,  $l, c = 1, \dots, n_x$ ,  $e, d = 1, \dots, n_u$  and  $l \neq c$ ,  $e \neq d$  as well as

$$\frac{\partial x_{i,j}^{(l)}}{\partial x_{i,j}^{(l)}} = 1 = \frac{\partial u_{i,j}^{(e)}}{\partial u_{i,j}^{(e)}}$$

Therefore, the Jacobian and Hessian matrices become very sparse. Furthermore, it should be taken advantage of the cyclic structure in  $c(\cdot)$ , which results from the same structure in  $G_1(\cdot), \dots, G_n(\cdot)$ .

## 4 Derivatives

There are at least three different ways to compute the derivative information required by a calculus-based optimization approach: Finite Differences, Symbolic Differentiation and Algorithmic Differentiation. The first technique, i.e., finite differences (FD), is based on the Taylor expansion and yields to relatively imprecise derivative information. Furthermore, the resulting computational cost is high in comparison to the two other approaches. For example, the gradient of a scalar-valued function with  $N$  input variables is approximated using FD with  $N + 1$  function evaluations. For these reasons, FD approximations of derivatives

will not be considered in this section. Alternatively, one may analytically derive expressions to evaluate the exact derivative based on the obtained formula. This can be done by hand, which results in an error-prone process, or automatically as provided, e.g., by Maple. Natural a Modelica compiler like OpenModelica has also capabilities to differentiate symbolically a Modelica model (see [5], [2]).

This purely symbolic method usually yields a very efficient way to compute first-order derivatives for closed-form expressions. However, the computation of higher-order derivatives or the handling of iterative solution procedures still form major challenges for this approach. The usage of algorithmic differentiation (AD), also called automatic differentiation, offers a third alternative to compute gradients, Jacobians and/or Hessians required for optimization. Based on the exploitation of the chain rule, AD provides derivative information of arbitrary order within working accuracy for a function  $F : \mathbb{R}^N \rightarrow \mathbb{R}^M$  evaluated in a code segment on a computer [14]. The complexity estimates for the two basic approaches of AD, namely the forward mode and the reverse mode, are based on the operation count  $O_F$ , i.e., the number of floating point operations required to evaluate  $y = F(z)$ . Using the forward mode, one computes the required derivatives together with the function evaluation in one sweep. This approach yields one Jacobian-vector product  $\nabla F v, v \in \mathbb{R}^N$  for no more than 2.5 times  $O_F$ . One vector-Jacobian product, or equivalently  $\nabla F^\top w, w \in \mathbb{R}^M$ , is obtained using the reverse mode in its basic form also for no more than four times  $O_F$ . If  $M = 1$ , i.e.  $\nabla F$  corresponds to the gradient of a scalar-valued function, this complexity bound for the reverse mode is completely independent of the number  $n$  of input variables. Therefore, it is also known as the *cheap gradient result*. More details about AD can be found in the books [15] and [17] as well as on the web-page [www.autodiff.org](http://www.autodiff.org).

#### 4.1 Efficient Jacobian evaluation

For the examples considered here, the Jacobian of the equality constraints  $c : \mathbb{R}^N \rightarrow \mathbb{R}^N$  is an almost square matrix of dimension  $N$ , where  $N = (n + 1) \cdot m \cdot (n_x + n_g)$ . Hence, as a first approach to evaluate the full Jacobian, one may compute the Jacobian-vector products

$$\frac{\partial c}{\partial z_i}(z) = \nabla c(z) e_i, \quad i = 1 \dots, N,$$

where  $e_i$  denotes the  $i$ th unit vector, yielding the  $N$  rows of the Jacobian using either the symbolic approach or the forward mode of AD  $N$  times. For the forward mode of AD, the following theoretical bound of the computational cost to evaluate the full Jacobian can be shown [15]

$$\text{OPS}(\nabla c(z)) \leq 2.5NO_F,$$

where  $\text{OPS}(f)$  denotes the number of floating point operations required to evaluate  $f$ . To reduce this operation count, one may use the so-called vector forward mode, where not only one derivative information is propagated with the function evaluation but a bundle of  $p$  directional derivatives. Hence, for a so-called seed matrix  $\Sigma \in \mathbb{R}^{N \times p}$  this variant of AD yields the Jacobian-matrix product  $\nabla c(z)\Sigma \in \mathbb{R}^{N \times p}$  at a computational cost that can be bounded above by

$$\text{OPS}(\nabla c(z)\Sigma) \leq (1 + 1.5p)O_F,$$

see [15]. Using  $\Sigma = I_N$  as the identity matrix in  $\mathbb{R}^{N \times N}$ , one obtains the full Jacobian with the vector forward mode of AD at a computational cost bounded above by  $(1 + 1.5N)O_F$  instead of  $2.5NO_F$  when using the standard forward mode of AD. This makes a significant difference if  $N$  is large or the function evaluation is costly.

#### 4.2 Exploiting the structure of the Jacobian

The derivative computation described so far completely ignores any structure within the Jacobian matrix. However, for the target applications of this research project, the Jacobian of the equality constraints has a block structure as shown in Fig. 2 for the Van der Pol oscillator. When computing the full Jacobian using

Figure 2: Van der Pol oscillator: Jacobian structure with 50 subintervals

the approach as explained in the last subsection, a lot of zero entries are computed, despite the fact that one knows that these entries are zero. To exploit the inherent structure of a sparse Jacobian, so-called compression techniques were developed. In the general case all compression techniques rely on the following four-step procedure: First determine the *sparsity structure* of the Jacobian  $\nabla c(z)$ . Second, obtain a suitable seed matrix  $\Sigma$  that defines a column partition of the Jacobian using, for example, a specialized *coloring* on the adjacency graph of the Jacobian. Then compute the *compressed* Jacobian matrix  $B = \nabla c(z)\Sigma$ . Finally, recover the numerical values of the entries of  $\nabla c(z)$  from  $B$ . The sparsity structure may be known from the application, as can be seen from the block structure in the example of the Van der Pol oscillator, or determined by a suitable variant of AD as explained in [15]. In our applications the structure is known apriori so the first two steps may be skipped and a seed matrix is available directly from the block structure. Appropriate coloring methods with the corresponding recovery strategies for the general case are discussed for example in [12]. The compressed Jacobian  $B$  is evaluated using the vector forward mode of AD. For our applications, one may consider also the sparsity structure within the blocks of the Jacobian to reduce the computational cost even further. This will be the subject of future work.

### 4.3 Exploiting the structure of the Hessian

Using a combination of the forward mode and the reverse mode of AD, one can compute Hessian-vector products for a function  $F(z)$  for a computational cost not larger than ten times  $O_F$  [15]. To exploit this facility to the full extend, for the target applications of this research project once more the sparsity of the Hessian can be taken into account. This is due to the fact that these derivative matrices have also a block structure as illustrated again for the Van der Pol oscillator in Fig. 3. The four step procedure explained above has to be adapted appropriately for the computation of second-order information in the general case. The sparsity structure of the Hessian may be known from the application, as is the case for the application discussed here, or it may be determined by a suitable variant of AD as described for example in [20]. For the general case corresponding coloring approaches together with suitable recovery strategies are presented in [13]. In our applications the seed matrix is obtained directly from the block structure known apriori.

Figure 3: Van der Pol oscillator: Hessian structure with 50 subintervals

## 5 Implementation Details

The rough principle of the implementation is visualized in figure 4. At the first step the optimizer re-

Figure 4: Implementation details

quires a sufficiently good starting point. In order to keep the constraint error for equation (2.3) small the method in OpenModelica creates a starting solution based on a simulation run. The initial guess of the control variable is set constant with the value of the start attribute. Obviously, a good setting of the initial values of the control variables can accelerate the NOCP solution process. Furthermore, this implementation supports the attribute `nominal` in Modelica for scaling variables and constraints. The effects will be presented in section 6.1.

### Coupling of OpenModelica and ADOL-C

The AD tool ADOL-C [21] uses the technique of operator overloading provided by the C++ standard to implement a wide variety of AD-based techniques. Within the research project described in this paper, the C code generation of OpenModelica was adapted such that ADOL-C can be used to evaluate the blocks in the Jacobian of the equality constraints and the blocks of the Hessian of the Lagrangian for a class of generic test problems. That is, the block structure was ex-

exploited manually. To compute the required derivative information the standard drivers `jacobian(...)` and `hessian(...)` of ADOL-C were used. For the applications considered here, the `jacobian(...)` routine uses the vector forward mode as described above. The current coupling of OpenModelica and ADOL-C allows a flexible choice between the symbolic derivative computation already implemented in OpenModelica and the AD-based derivative computation provided by ADOL-C. The structure of the coupling is illustrated in Fig. 5.

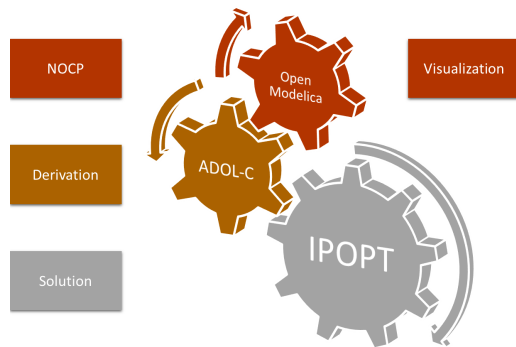

Figure 5: Structure of the coupling

## 6 Modelica Application and Performance Measurements

### 6.1 Model formulation

Currently, the user can influence the solution convergence by using native Modelica attributes like `nominal` and `start`. It should be emphasized that it is not the natural way to use `start`, since this attribute is usually reserved for initial values at start time for the simulation. Nevertheless, the initial trajectory of all problem variables is provided by a simulation, where all control variables are kept constant equal to the value of the `start` attribute. The described formulation of scaling and start trajectory will be shown on a simple model, based on the Batch Reactor found in [4]. The model was modified so that the states have the `nominal` values  $10^{10}$  and  $10^{-10}$ . The mathematical formulation is given by

$$\begin{aligned}
 & \min_{u(t)} x_2(t_f) \\
 & \text{s.t.} \\
 & x_2(t) = 10^{10} \cdot y_2(t) \\
 & x_1(t) = 10^{-10} \cdot y_1(t) \\
 & 10^{-10} \cdot \dot{y}_1(t) = - \left( u(t) + \frac{u(t)^2}{2} \right) \cdot x_1(t) \\
 & 10^{10} \cdot \dot{y}_2(t) = u(t) \cdot x_1(t) \\
 & u(t) \in [0, 5], y_1(0) = 1, y_2(0) = 0, t_f = 1
 \end{aligned}$$

which can easily be formulated in a Modelica/Optimica representation:

```

optimization BatchReactor(
    objective = cost(finalTime),
    finalTime = 1)
  Real cost = -x2;
/*DAE Modelica*/
/*states */
  Real y1(start=1e10,
          fixed=true, nominal=1e10);
  Real y2(start=0,
          fixed=true, nominal=1e-10);
/* tuner */
  input Real u(min=0, max=5, start=1.0);
protected
  Real x1;
  Real x2;
equation
  x1 = 1e-10*y1;
  x2 = 1e10*y2;
  1e-10*der(y1) = -(u+u^2/2)*x1;
  1e10*der(y2) = u*x1;
end BatchReactor;

```

When setting the correct values for the nominal attribute the solution is calculated as expected. Setting the `nominal` attribute to 1 yields the wrong result, nevertheless the optimizer finishes without any error detection.

### 6.2 Combined Cycle Power Plant

A more industry-relevant benchmark is a model of a combined cycle power plant model, see figure 6. The model contains equation-based implementations of the thermodynamic functions for water and steam, which in turn are used in the components corresponding to pipes and the boiler. The model also contains components for the economizer, the super heater, as well as the gas and steam turbines. The model has one input, 10 states, and 131 equations. For additional details on the model, see [6].

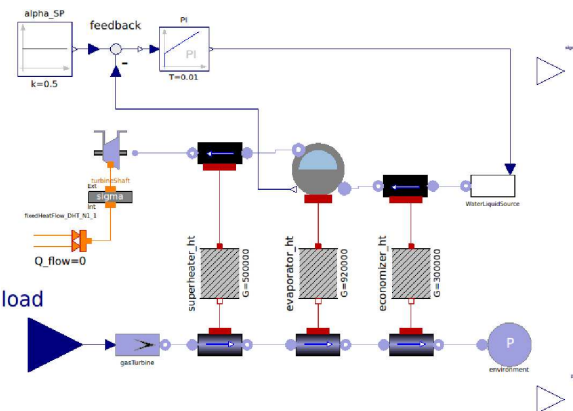

Figure 6: CombinedCycle display with OMEdit

Figure 7: Optimal start-up trajectories. The upper curve shows the pressure in the evaporator, the middle curve shows the thermal stress in the steam turbine shaft and the lower curve shows the control input represented by the load.

The optimization problem is set up to use 50 collocation points that results in 1651 variables for the NOCP and was solved on a PC with a 3.2GHz Intel(R) Core(TM) i7. The algorithm requires an initial trajectory of all problem variables, which is provided by a simulation where the rate of change of the gas turbine load is set to a constant value. The optimization results are shown in figure 7 and 8 and correspond with the results that are discussed in detail in [6]. Here, the trajectories are smoother, and the performance has been improved substantially.

options		iteration	time [s]
Jacobian	Hessian		
ADOL-C	ADOL-C	39	2.29472
ADOL-C	BFGS	48	0.86425
OMC	BFGS	48	0.88558

Table 1: Time measurements of the solving process.

In table 1 the time measurements of the solving process are summarized for different options of derivatives calculation. One can see that the solution with ADOL-C needs less iterations, which is a strong indication that the solution is more accurate and more

Figure 8: Optimal start-up trajectories. The upper curve shows the live steam temperature, the middle and low curves show the turbine rotor surface and mean temperatures.

stable. This is even more important for stiff models. However, the calculation of the Hessian with ADOL-C need currently a factor of three more computational time. Alternative approaches for a further improvement of the runtime needed for the Hessian calculation are the subject of current research.

## 7 Conclusions

This paper presents a newly developed tool chain for solving nonlinear optimization control problems. The underlying dynamic model formulation is done in Modelica and Optimica. The demonstrated solution method is based on orthogonal collocation methods, whereby the first interval is specially treated in order to consider control variables and their derivatives also at the initial time point. The derivative information is derived using the automatic differentiation tool ADOL-C, which efficiently calculates the corresponding Jacobian and Hessian matrices for the discretized optimization problem. Special treatments of the matrices with the focus on yielding optimal sparsity patterns with respect to block and cyclic structure are performed. The resulting optimization process proves to be stable and efficient.

## Abstract

Dynamic optimization problems involving differential-algebraic equation (DAE) systems are traditionally solved while retaining the semi-explicit or implicit form of the DAE. We instead consider symbolically transforming the DAE into an ordinary differential equation (ODE) before solving the optimization problem using a collocation method. We present a method for achieving this, which handles DAE-constrained optimization problems. The method is based on techniques commonly used in Modelica tools for simulation of DAE systems.

The method is evaluated on two industrially relevant benchmark problems. The first is about vehicle-trajectory generation and the second involves startup of power plants. The problems are solved using both the DAE formulation and the ODE formulation and the performance of the two approaches is compared. The ODE formulation is shown to have roughly three times shorter execution time. We also discuss benefits and drawbacks of the two approaches.

*Keywords: dynamic optimization, symbolic transformations, causalization, collocation*

## 1 Introduction

Industrial usage of optimization of large-scale dynamic systems has increased during the last decades. Dynamic optimization problems occur in many different fields and applications, and include parameter estimation and optimal control. Applications of optimal control include minimization of material and energy consumption during set-point transitions in power plants [1] and chemical processes [2], minimizing duration of vehicle maneuvers [3], and trajectory optimization in robotics [4].

The applications of optimal control are diverse and

occur in both online and offline settings. Online optimal control is usually done in the form of Model Predictive Control (MPC). Offline applications include finding optimal trajectories, which can be used either as a reference during manual control or as nominal trajectories combined with online feedback handling deviations due to model uncertainty and disturbances. Another offline application is the identification of system bottlenecks, for example by analyzing adjoint variables.

This paper considers models described by differential-algebraic equation (DAE) systems, and investigates the benefits of applying symbolic transformations to the DAE before applying numerical optimization methods. The DAE is transformed into an ordinary differential equation (ODE). This will often lead to a drastically reduced number of system variables, as the algebraic variables are eliminated from the equation system. On the other hand, the transformed equations will also be denser and consist of more expressions of higher complexity. This transformation is common practice in simulation of DAEs in Modelica tools [5], but is traditionally not done in the context of DAE-constrained optimization, where the DAE is instead usually retained in its natural semi-explicit or implicit form.

The technique is evaluated in two case studies. The first case concerns generation of time-optimal trajectories for road vehicles. The second case concerns optimal startup of combined-cycle power plants.

The main contributions of this paper are the demonstration of how a method commonly used in Modelica tools can be applied to dynamic optimization problems and experiments indicating the potential of the method. While similar methods have been used before [6, 7], this paper studies the properties of the approach when compared to the more traditional approach that discretizes the full DAE.

The paper outline is as follows. Section 2 presents the background of transforming low-index DAEs into ODEs by causalization, the formulation of dynamic

optimization problems and their solution, and the tools used in the implemented framework. Section 3 discusses how the DAE causalization technique is used to transform DAE-constrained optimization problems into ODE-constrained problems. Section 4 explains the case studies used to evaluate the method and Section 5 presents the corresponding results. Finally, Section 6 concludes the paper and discusses future work.

## 2 Background

We present the standard approach of transforming a DAE into an ODE by causalization. We then discuss the formulation of general optimization problems involving dynamic systems and common methods for solving these. We finally present the tools used to implement the methods presented in this paper.

### 2.1 Causalization of DAEs

In the first step of the compilation process in a Modelica tool chain, a compiler front-end transforms Modelica source code into a flat representation, consisting essentially of lists of variables, functions, equations, and algorithms. Based on this model representation, symbolic operations such as alias elimination and index reduction are applied to reduce the size of the model and to ensure that the resulting DAE is of most index 1. In this section, we outline the steps needed to transform an implicit DAE into an ODE, which is one of the key elements of the method investigated in this paper. We introduce the following notation:

- $t$  time
- $t_f$  final time
- $x$  state (differentiated variables)
- $\dot{x}$  time derivative of state
- $y$  algebraic variables
- $u$  inputs
- $p$  parameters without predetermined values

The initial time is assumed to be 0 and the final time  $t_f$  may or may not be predetermined, but is always finite. The variables  $x, \dot{x}, y$ , and  $u$  depend on time. This dependence will be implicit in certain expressions throughout the paper.

We consider nonlinear nonhybrid index-1 DAE systems of the form

$$F(t, \dot{x}(t), x(t), y(t), u(t), p) = 0, \quad t \in [0, t_f]. \quad (1)$$

From an integrator perspective, we introduce

$$z := (\dot{x}, y), \quad v := (t, x, u, p)$$

to denote the unknown and known variables of the equation system, respectively. By reordering the arguments of  $F$ , the DAE can be written

$$F(z, v) = 0. \quad (2)$$

The conceptual idea of DAE causalization commonly used in Modelica tools is to compute the inverse relationship of  $F$ :

$$z = g(v). \quad (3)$$

The DAE can then be written as the ODE

$$\dot{x} = \bar{F}(t, x, u, p), \quad (4)$$

where the algebraic variables are internal in the right-hand side function. In general, there is no closed expression for the function  $\bar{F}$ . Rather, iterative techniques, such as Newton's method, are employed to solve algebraic loops required for computation of  $z$ .

Modelica models are typically of large scale but sparse in the sense that each model equation contains references only to a small number of equations. Graph algorithms can be employed to exploit this structure. Two commonly used algorithms that are used for this purpose are *matching algorithms*, such as the Hopcroft Karp algorithm, and Tarjan's algorithm [8] for computing *strong components*. The result of Tarjan's algorithm is used to permute the variables and equations of the DAE into Block Lower Triangular (BLT) form.

To demonstrate this procedure, let us consider an exemplary DAE system with five equations and five unknowns, where the DAE system is given by

$$\begin{aligned} F_1(z_1, z_5, v) &= 0, \\ F_2(z_3, v) &= 0, \\ F_3(z_1, z_2, z_3, z_4, v) &= 0, \\ F_4(z_1, z_3, z_5, v) &= 0, \\ F_5(z_2, z_5, v) &= 0. \end{aligned} \quad (5)$$

Note that the variable  $v = (t, x, u, p)$  is known and needs not be considered in the following analysis. The dependence on the  $z$  variables can be shown in the following incidence matrix:

	$z_1$	$z_2$	$z_3$	$z_4$	$z_5$
$F_1$	*	0	0	0	*
$F_2$	0	0	*	0	0
$F_3$	*	*	*	*	0
$F_4$	*	0	*	0	*
$F_5$	0	*	0	0	*

(6)

An asterisk in (6) in row  $i$  and column  $j$  denotes that the residual function  $F_i$  contains a reference to the variable  $z_j$ . Application of the BLT procedure yields the following permuted incidence matrix:

$$\begin{array}{c|ccccc}
 & z_3 & z_1 & z_5 & z_2 & z_4 \\
 \hline
 F_2 & * & 0 & 0 & 0 & 0 \\
 F_4 & * & * & * & 0 & 0 \\
 F_1 & 0 & * & * & 0 & 0 \\
 F_5 & 0 & 0 & * & * & 0 \\
 F_3 & * & * & 0 & * & *
 \end{array} \quad (7)$$

By reordering and grouping the variables according to

$$\bar{z}_1 := z_3,$$

$$\bar{z}_2 := (z_1, z_5),$$

$$\bar{z}_3 := z_2,$$

$$\bar{z}_4 := z_4,$$

the DAE (5) can be written

$$G_1(\bar{z}_1, v) = 0, \quad (8a)$$

$$G_2(\bar{z}_1, \bar{z}_2, v) = 0, \quad (8b)$$

$$G_3(\bar{z}_2, \bar{z}_3, v) = 0, \quad (8c)$$

$$G_4(\bar{z}_1, \bar{z}_2, \bar{z}_3, \bar{z}_4, v) = 0, \quad (8d)$$

where the functions  $G_i$  are constructed from the functions  $F_j$ . For demonstrative purposes, we assume that (8a) and (8d) can be solved explicitly for  $\bar{z}_1$  and  $\bar{z}_2$  respectively, and that (8b) and (8c) can not be solved analogously. The DAE can then be represented by the following sequence of assignment statements and implicit equation systems:

$$\bar{z}_1 \leftarrow g_1(v), \quad (9a)$$

$$G_2(\bar{z}_1, \bar{z}_2, v) = 0, \quad (9b)$$

$$G_3(\bar{z}_2, \bar{z}_3, v) = 0, \quad (9c)$$

$$\bar{z}_4 \leftarrow g_4(\bar{z}_1, \bar{z}_2, \bar{z}_3, v). \quad (9d)$$

where (9b) and (9c) require iterative methods to be solved. It is typical for Modelica models to contain only a small number of implicit equation systems that require iteration and a large number of trivial, for example linear, equations that can be solved symbolically.

For a general DAE, the BLT procedure results in a sequence of equation systems of the form

$$\begin{array}{l}
 \bar{G}_1(\bar{z}_1, v) = 0, \\
 \vdots \\
 \bar{G}_i(\bar{z}_1, \dots, \bar{z}_i, v) = 0, \\
 \vdots \\
 \bar{G}_b(\bar{z}_1, \dots, \bar{z}_b, v) = 0,
 \end{array} \quad (10)$$

where  $b$  is the number of blocks in the BLT form and the unknown of each equation is  $\bar{z}_i$ . Some equations can be solved explicitly by symbolic manipulation, while the rest needs to be solved iteratively.

Given values of the known variables in  $v$ , the sequence of solved and unsolved blocks (10) allows for the computation of the corresponding state derivative and algebraic vectors contained in  $z$ . Accordingly, the DAE has been causalized into an ODE of the form (4).

We consider the class of DAEs that can be transformed into an ODE where no implicit systems of equations need to be solved. This lets us redefine each unknown  $\bar{z}_i$  to be a single scalar variable and compute it explicitly as

$$\bar{z}_i = g_i(\bar{z}_1, \dots, \bar{z}_{i-1}, v), \quad i = 1, \dots, n_z, \quad (11)$$

where  $n_z$  is the total number of states and algebraic variables. While this class of systems is limited, the proposed method is trivially extendible to systems containing implicit systems by simply exposing the implicit systems to the numerical optimization method used in the end, in which case some algebraic equations will remain in the transformed DAE.

## 2.2 Dynamic optimization

Consider the DAE-constrained optimization problem:

$$\begin{aligned}
 &\text{minimize } \phi(t_f, \dot{x}(t_f), x(t_f), y(t_f), u(t_f), p) \\
 &\quad + \int_0^{t_f} L(t, \dot{x}(t), x(t), y(t), u(t), p) dt, \quad (12a)
 \end{aligned}$$

$$\text{w.r.t. } t_f, \dot{x}, x, y, u, p,$$

$$\text{subject to } F(t, \dot{x}, x, y, u, p) = 0, \quad (12b)$$

$$F_0(\dot{x}(0), x(0), y(0), p) = 0, \quad (12c)$$

$$\dot{x}_L \leq \dot{x}(t) \leq \dot{x}_U, \quad (12d)$$

$$x_L \leq x(t) \leq x_U, \quad (12e)$$

$$y_L \leq y(t) \leq y_U, \quad (12f)$$

$$u_L \leq u(t) \leq u_U, \quad (12g)$$

$$p_L \leq p \leq p_U, \quad (12h)$$

$$h_e(t, \dot{x}, x, y, u, p) = 0, \quad (12i)$$

$$h_i(t, \dot{x}, x, y, u, p) \leq 0, \quad (12j)$$

$$H_e(\dot{x}(t_f), x(t_f), y(t_f), u(t_f), p) = 0, \quad (12k)$$

$$H_i(\dot{x}(t_f), x(t_f), y(t_f), u(t_f), p) \leq 0, \quad (12l)$$

$$\forall t \in [0, t_f].$$

The objective (12a) consists of the terminal cost  $\phi$  and the integral of  $L$ , which is the accumulated cost. Constraint (12b) is the DAE describing the system dynam-

ics. Constraint (12c) enforces the DAE initial conditions, which are often given on the form  $x(0) = x_0$ . Constraints (12d)–(12h) are variable bounds. Constraints (12i) and (12j) are path constraints on equality and inequality form, which can be seen as generalizations of the variable bounds, where the functions  $h_e$  and  $h_i$  define the boundary. The variable bounds are separated from the path constraints because some solvers allow for more efficient treatment of the bounds. Constraints (12k) and (12l) are terminal constraints on equality and inequality form. These are similar to the path constraints, but instead of being enforced at all points in time they are only enforced at  $t_f$ .

There are many approaches to solving dynamic optimization problems of the form (12). Until the 1970s, problems were solved using dynamic programming or Pontryagin’s maximum principle. These approaches are ill-suited for large-scale problems and problems with inequality constraints. Modern techniques often involve finding an approximate solution to the infinite-dimensional optimization problem by transcribing it into a finite-dimensional nonlinear program (NLP). These are called direct methods. The main difference among direct methods is how to handle the dynamic equations of the system. This paper employs direct local collocation. Another common approach is direct multiple shooting. See [9, 10] for overviews on direct local collocation and other direct methods.

The main idea of direct local collocation is to first divide the time horizon into a certain number of elements. Then within each element, the constraints (12b) and (12d)–(12j) are enforced at only a finite number of points, called collocation points, instead of at every point in the element. There are different schemes for choosing the placement of the collocation points with different numerical properties. The results in Section 5 have been generated using Radau points.

The constraints resulting from the collocation procedure are considered as interpolation conditions on the time-dependent variables  $x$ ,  $y$ , and  $u$ . Thus the sought approximate optimal trajectories to (12) become piecewise-polynomial, where the degrees of the polynomials are determined by the number of collocation points. The state derivative  $\dot{x}$  is obtained by differentiating the corresponding polynomials for the state  $x$ . The integral term in the objective (12a) is approximated as a sum using quadrature. See [11] for a complete description of the used collocation method, and also possible generalizations of (12). Once the discretization procedure is completed, the infinite-

dimensional dynamic optimization problem (12) has been transformed into an NLP of the following general form:

$$\text{minimize} \quad \tilde{f}(\tilde{x}), \tag{13a}$$

$$\text{with respect to} \quad \tilde{x} \in \mathbb{R}^{n_{\tilde{x}}},$$

$$\text{subject to} \quad \tilde{x}_L \leq \tilde{x} \leq \tilde{x}_U, \tag{13b}$$

$$\tilde{g}(\tilde{x}) = 0, \tag{13c}$$

$$\tilde{h}(\tilde{x}) \leq 0. \tag{13d}$$

The number of discretization points is affected both by the number of elements and the number of collocation points within each element. An increase in either of these directly corresponds to an increase in the number of variables and constraints in the NLP (13).

In this work, (13) is solved using a gradient-based method. This requires the NLP functions  $f$ ,  $g$ , and  $h$  to be twice continuously differentiable with respect to all of the NLP variables  $\tilde{x}$ . In particular, this requirement implies differentiability of the DAE-residual  $F$ , which excludes the possibility of solving optimization problems involving hybrid systems.

When using direct methods for dynamic optimization problems involving DAEs, the time discretization method is typically applied to the DAE in its natural semi-explicit or implicit form [9, 10]. In this paper, we instead consider causalizing the DAE as described in Section 2.1 and then eliminating the algebraic variables in the optimization problem as described in Section 3. The result is an ODE-constrained optimization problem of the following form:

$$\begin{aligned} \text{minimize} \quad & \bar{\phi}(t_f, \dot{x}(t_f), x(t_f), u(t_f), p) \\ & + \int_0^{t_f} \bar{L}(t, \dot{x}(t), x(t), u(t), p) dt, \end{aligned} \tag{14a}$$

$$\text{with respect to} \quad t_f, \dot{x}, x, u, p,$$

$$\text{subject to} \quad \dot{x} = \bar{F}(t, x, u, p) = 0, \tag{14b}$$

$$\bar{F}_0(\dot{x}(0), x(0), p) = 0, \tag{14c}$$

$$\dot{x}_L \leq \dot{x}(t) \leq \dot{x}_U, \tag{14d}$$

$$x_L \leq x(t) \leq x_U, \tag{14e}$$

$$u_L \leq u(t) \leq u_U, \tag{14f}$$

$$p_L \leq p \leq p_U, \tag{14g}$$

$$\bar{h}_e(t, \dot{x}, x, u, p) = 0, \tag{14h}$$

$$\bar{h}_i(t, \dot{x}, x, u, p) \leq 0, \tag{14i}$$

$$\bar{H}_e(\dot{x}(t_f), x(t_f), u(t_f), p) = 0, \tag{14j}$$

$$\bar{H}_i(\dot{x}(t_f), x(t_f), u(t_f), p) \leq 0, \tag{14k}$$

$$\forall t \in [0, t_f].$$

The objective and constraint functions occurring in

problem (14) are defined analogously to those occurring in problem (12).

This paper investigates the possibilities of transforming problems on the form of (12) to the form of (14) and the impact this has on the solution of the NLPs resulting from collocation methods.

### 2.3 Tools

The proposed method has been implemented using the open-source platform JModelica.org [12]. JModelica.org is a tool targeting simulation and optimization of large-scale dynamic systems. The systems are described using Modelica, and the optimization is formulated with the Modelica extension Optimica [13].

The framework uses IPOPT [14] to solve the NLP (13). IPOPT uses a sparse primal-dual interior point method to find local optima to large-scale NLPs. To this end, it uses first- and second-order derivatives of the NLP functions  $f$ ,  $g$ , and  $h$  in problem (13). The implemented framework uses CasADi [15] (Computer algebra system with Automatic Differentiation) to obtain these derivatives, and also to perform the transformation from (12) to (14). CasADi is a low-level tool for efficiently computing derivatives using algorithmic differentiation (AD) while preserving sparsity, and is tailored for dynamic optimization.

## 3 Proposed method

This section presents the proposed method for transforming the DAE-constrained optimization problem (12) into an ODE-constrained optimization problem of the form (14). We then compare the properties of the untransformed problem to those of the transformed problem.

### 3.1 Problem transformation

The first step is the causalization of the DAE in (12b), as described in Section 2.1. Under the assumption that all equations in (10) can be solved explicitly by symbolic manipulations, this yields the system of equations (compare with (11))

$$\bar{z}_i = g_i(\bar{z}_1, \bar{z}_2, \dots, \bar{z}_{i-1}, v), \quad i = 1, \dots, n_z, \quad (15)$$

where  $\bar{z}_i$  is a state derivative or an algebraic variable. The explicit solution for  $\bar{z}_1, \bar{z}_2, \dots, \bar{z}_{i-1}$  is then inlined into (15). The resulting equations are described by the

following recursive relations:

$$\bar{g}_1(v) := g_1(v), \quad (16a)$$

$$\bar{g}_i(v) := g_i(\bar{g}_1(v), \bar{g}_2(v), \dots, \bar{g}_{i-1}(v), v), \quad (16b)$$

$$\bar{z}_i = \bar{g}_i(v), \quad i = 1, \dots, n_z. \quad (16c)$$

By expanding the variables  $v$  and  $z$  and separating the state derivatives from the algebraic variables in (16c), the equations can be written in the form

$$\dot{x} = \bar{F}(t, x, u, p), \quad (17a)$$

$$y = k(t, x, u, p), \quad (17b)$$

where each scalar component of  $\bar{F}$  and  $k$  is equal to  $\bar{g}_i$  for some  $i$ . Thus (17a) gives rise to the constraint in (14b). Equation (17b) is used to eliminate the algebraic variables in the objective function and remaining constraints of (12). To demonstrate, the function  $h_i$  in (12j) is transformed according to

$$\begin{aligned} h_i(t, \dot{x}(t), x(t), y(t), u(t), p) \\ &= h_i(t, \dot{x}(t), x(t), k(t, x(t), u(t), p), u(t), p) \\ &=: \bar{h}_i(t, \dot{x}(t), x(t), u(t), p). \end{aligned}$$

Constraint (12f) is not possible to transform in this manner, since the algebraic variables have been eliminated. This is handled by transforming (12f) into its more general form (12j), which has consequences discussed in Section 3.2, and then transforming it as demonstrated above. By eliminating the algebraic variables in the objective and remaining constraints in the same manner, the optimization problem (12) has been transformed into the equivalent problem (14).

### 3.2 Method properties

A significant benefit of transforming the original DAE-constrained problem into an ODE-constrained problem is the reduction of system variables and equations, which directly leads to a smaller NLP after applying a collocation method. However, while the constraints will be fewer in number their expressions will be more complex, which may lead to expression graphs that in the end require more memory to store and more time to evaluate than the expression graphs in the original problem. On the other hand, component-based physical modeling will often lead to a great amount of trivial algebraic equations that can be solved explicitly without increasing expression complexity. It thus stands to reason that the proposed method is well suited to be used in a Modelica framework.

The elimination of algebraic variables will make the incidence matrix for the dynamic equation system

denser. However, the sparsity in the NLP does not mainly stem from the structure of the dynamic equations, but rather from the largely decoupled dependency of NLP variables representing system variable values in different elements. Hence in many cases, the loss of sparsity in the DAE will not have a significant impact on the solution of the NLP constructed by collocation methods.

When employing interior-point methods to solve NLPs originating from dynamic optimization problems, it is often beneficial to introduce artificial bounds on system variables to prevent the solver from leaving the domains of the involved functions. When the algebraic variables are eliminated from the problem, it is no longer possible to use these artificial bounds on algebraic variables. This can lead to difficulties in obtaining convergence in the numerical solver.

Experience has shown that seemingly trivial modifications in the original problem formulation can lead to drastically different convergence behavior in the NLP solver. By explicitly solving these trivial equations by performing the proposed transformation, increased robustness to small model modifications is attained.

The inlining step performed to obtain (16c) gives rise to a great amount of expression duplication in the expression graph for the right-hand side of (16b) because of the recursive nature of the equations. This can be avoided by storing the expressions used to evaluate  $\bar{g}_i$  in a function and calling these functions when evaluating  $g_i$ . This paper does, however, not consider this proposition any further.

## 4 Benchmark problems

Two different optimal-control cases are presented for evaluation of the proposed transformation method: vehicle trajectory generation and startup of a combined-cycle power plant. The vehicle models are implemented in a flat manner, with condensed and complex equations, whereas the power plant model is implemented in an object-oriented fashion with a large number of simple equations.

### 4.1 Vehicle trajectory generation

The first considered case is a minimum-time problem, where we seek the time-optimal maneuver for an automobile in a hairpin turn, see Figure 1. A methodology for solving this kind of problems has previously been investigated in [3, 16, 17]. We use two different chassis models in the evaluation. The first is a single-track model [18], where the two wheels on each axle

are lumped together. The model has three degrees of freedom: two translational and one rotational.

Figure 1: An example of a hairpin turn. Photo courtesy of RallySportLive.

The second model is a double-track model [19] with five degrees of freedom: two translational and three rotational. The suspension dynamics model is a rotational spring-damper system, and longitudinal and lateral load transfer is included.

The lateral slip  $\alpha$  and the longitudinal slip  $\lambda$  are defined as in [20]:

$$\dot{\alpha}_i \frac{\sigma}{v_{x,i}} + \alpha_i := -\arctan\left(\frac{v_{y,i}}{v_{x,i}}\right), \quad (18)$$

$$\lambda_i := \frac{r\omega_i - v_{x,i}}{v_{x,i}}, \quad (19)$$

where  $\sigma$  is the relaxation length,  $r$  is the wheel radius,  $\omega_i$  is the wheel angular velocity for wheel  $i$ , and  $v_{y,i}$  and  $v_{x,i}$  are the lateral and longitudinal wheel velocities for wheel  $i$  with respect to an inertial system, expressed in the coordinate system of the wheel.

The tire forces  $F_{x0}$  and  $F_{y0}$  for the longitudinal and lateral directions under pure slip conditions are computed with the Magic formula [20], given by

$$F_{x0,i} = \mu_x F_{z,i} \sin\left(C_{x,i} \arctan\left(B_{x,i} \lambda_i - E_{x,i}(B_{x,i} \lambda_i - \arctan B_{x,i} \lambda_i)\right)\right), \quad (20)$$

$$F_{y0,i} = \mu_y F_{z,i} \sin\left(C_{y,i} \arctan\left(B_{y,i} \alpha_i - E_{y,i}(B_{y,i} \alpha_i - \arctan B_{y,i} \alpha_i)\right)\right), \quad (21)$$

for each wheel  $i = 1, \dots, 4$ . In (20)–(21),  $\mu_x$  and  $\mu_y$  are friction coefficients and  $B$ ,  $C$ , and  $E$  are parameters.

We have chosen two different approaches for modeling the tire forces under combined slip constraint, both of which are described next. A straightforward model of combined slip is based on the friction ellipse, and is described by the elliptical relation

$$F_{y,i} = F_{y0,i} \sqrt{1 - \left(\frac{F_{x0,i}}{\mu_{x,i} F_{z,i}}\right)^2}, \quad (22)$$

where  $F_{x0}$  is used as an input variable [21]. However, here the driving/braking torques are used as input. The main limitation with this model is that the longitudinal force does not explicitly depend on the lateral slip.

Another approach to tire modeling, which is inspired by the Magic Formula, is to scale the nominal forces (20)–(21) with weighting functions  $G_{\alpha,i}$  and  $G_{\lambda,i}$ , which depend on  $\alpha$  and  $\lambda$  [20]. The relations in the longitudinal direction are

$$H_{\alpha,i} = B_{1,i} \cos(\arctan(B_{2,i}\lambda_i)), \quad (23)$$

$$G_{\alpha,i} = \cos(C_{\alpha,i} \arctan(H_{\alpha,i}\alpha_i)), \quad (24)$$

$$F_{x,i} = F_{x0,i} G_{\alpha,i}, \quad (25)$$

and the corresponding relations in the lateral direction are given by

$$H_{\lambda,i} = B_{1,i} \cos(\arctan(B_{2,i}\alpha_i)), \quad (26)$$

$$G_{\lambda,i} = \cos(C_{\lambda,i} \arctan(H_{\lambda,i}\lambda_i)), \quad (27)$$

$$F_{y,i} = F_{y0,i} G_{\lambda,i}. \quad (28)$$

To summarize, four different model configurations were investigated for the vehicle trajectory generation, all having three control inputs. The combination of single-track chassis model and friction ellipse for tire modeling (ST-FE) has 13 states and 13 algebraic variables. The corresponding numbers for the combination of single-track chassis model and weighting functions (ST-WF) are 13 states and 23 algebraic variables. Considering the double-track model with friction ellipse model (DT-FE), it has 21 states and 36 algebraic variables. For the combination of double-track model and weighting functions (DT-WF), the corresponding numbers are 21 states and 56 algebraic variables.

For each model configuration, the time-optimal trajectories in the hairpin turn are to be determined. An initialization procedure based on a driver model presented in [18] is used. The optimization problem is formulated over the time horizon  $t \in [0, t_f]$  and the objective of the optimization is to minimize the final time  $t_f$  of the maneuver. Accordingly, the dynamic optimization problem to be solved can be written as:

$$\begin{aligned} & \text{minimize} && t_f, \\ & \text{subject to} && T_{i,\min} \leq T_i \leq T_{i,\max}, \quad i \in \{1, 2, 3, 4\}, \\ & && |\dot{T}_i| \leq \dot{T}_{i,\max}, \quad i \in \{f, r\}, \\ & && |\delta| \leq \delta_{\max}, \quad |\dot{\delta}| \leq \dot{\delta}_{\max} \\ & && x(0) = x_0, \\ & && x(t_f) = x_{t_f}, \quad y(t_f) = y_{t_f}, \\ & && \Gamma(X_p, Y_p) \leq 0, \\ & && F(\dot{x}, x, y, u) = 0, \end{aligned} \quad (29)$$

where  $x_0$  are the initial conditions for the state variables,  $x_{t_f}$  and  $y_{t_f}$  are the desired values at the final time  $t = t_f$ , and  $(X_p, Y_p)$  is the position of the center-of-gravity of the vehicle. The wheel driving and braking torques  $T = (T_f \ T_r)$  of the front and rear wheel axles, as well as the steer angle  $\delta$  of the front wheels are considered as inputs. The inputs are equally distributed between the wheels at the respective axle, that is,  $T_1 = T_2 = T_f/2$  and  $T_3 = T_4 = T_r/2$  for the double-track chassis model. In practice, the terminal constraints are only applied to a subset of the model variables. Further,  $\Gamma(X_p, Y_p)$  is a mathematical description of the road constraint for the center-of-gravity of the vehicle for the maneuver. These constraints in the geometric two-dimensional  $XY$ -plane are formulated as super-ellipses.

Figure 2 shows the geometric path and the time-optimal control inputs obtained for ST-WF. For more details about the solution method and the model parameters used, see [3, 17].

Figure 2: The geometric path and control inputs are shown for the time-optimal hairpin maneuver when using a single-track model with the weighting functions. The black bars in the left plot indicate the direction of the car every second.

## 4.2 Combined-cycle power plant startup

The second considered case concerns optimal startup of combined-cycle power plants (CCPP). The model used is described in [1]. The model has 9 states, 128 algebraic variables, and 1 control variable. The task is to minimize the time required to perform a warm startup of the power plant. This problem has become highly industrially relevant during the last years, due to an increasing need to improve power-generation flexibility. The startup process is considered finished when

the normalized load input signal  $u$  to the steam turbine, starting at 15 %, has reached 100 % and the evaporator pressure  $p$ , which is a state with an initial value of approximately 3.47 MPa, has reached 8.35 MPa.

In order to reduce the wear and tear on the steam turbine, which is one of the most expensive parts of the power plant, the thermal stress in the turbine  $\sigma$ , which is an algebraic variable, may not exceed 260 MPa. This is the main limiting factor in the startup process. Another imposed constraint is that the derivative of the load input signal  $u$  may not be negative and may not exceed  $0.1/60 \text{ s}^{-1}$ . Since these bounds are applied to the derivative of the control variable, which is not supported by the current framework, we introduce the control variable  $\dot{u}$  and add the equation

$$\frac{du}{dt} = \dot{u}.$$

This converts the control variable  $u$  into a state, giving us a total of 10 states, and the control variable is now instead  $\dot{u}$ , on which we can impose the discussed bounds. The model diagram is displayed in Figure 3.

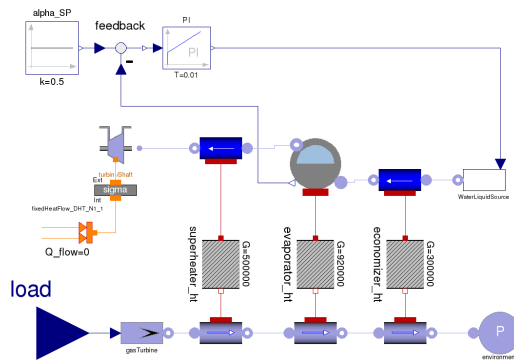

Figure 3: Power plant model diagram

The objective function is the weighted square deviation of the load input signal and the evaporator pressure from their respectively desired values, given by

$$f(z) = \int_0^{t_f} \left( 10^{-12} \cdot (p(t) - 8.35 \cdot 10^6)^2 + 0.5 \cdot (u(t) - 1)^2 \right) dt.$$

The final time is chosen to be  $t_f = 4000 \text{ s}$ . The obtained solution is displayed in Figure 4.

Figure 4: Optimal power plant startup

## 5 Results

The problems in the respective cases described in Section 4 were solved with the implementation described in Section 2.3. The solutions were obtained using JModelica.org revision [5625] and IPOPT version 3.11.3 with the linear solver MA57 [22]. The collocation discretization was done using 150 elements with 3 collocation points for each vehicle maneuver problem and 40 elements with 4 collocation points for the power plant startup problem. The solution procedure consists of the following three steps:

1. Model compilation, where the compiler of JModelica.org generates XML code that describes the system equations and optimization formulation. This code is then parsed by CasADi, which then creates symbolic representations of all the problem expressions.
2. Offline NLP setup, where the symbolic expressions created by CasADi in the previous step are used to construct the corresponding NLP by collocation. First- and second-order derivatives are computed by algorithmic differentiation while preserving sparsity.
3. Online NLP solution, where IPOPT solves the NLP constructed in the previous step. This is the only part of the solution procedure that would need to be performed in an online setting, such as MPC.

All problems were solved both with the model dynamics on DAE form and transformed to ODE form.

If the DAE is transformed into an ODE, the transformation takes place in the first step and is performed by CasADi. The respectively obtained solutions for the DAE and ODE formulations are the same up to tolerances.

For comparison of the two different strategies to solving the optimization problems, the time spent in step 2 and 3 of the solution procedure were measured separately for each of the optimization runs. The number of iterations required by IPOPT and the number of NLP variables have also been recorded. Table 1 displays the resulting numbers, where times are presented in seconds. The time spent in step 1 of the solution procedure is between 1 and 2 seconds for all of the problems and is largely unaffected by whether the ODE transformation is performed. These times are thus not presented.

Table 1: Solution times [s] for the considered model configurations with DAE and ODE form in the optimal control problem, respectively. In addition, the number of iterations required to solve the NLP and the total number of NLP variables are shown.

Problem		Offline	Online	Iter	NLP
ST-FE	DAE	3.6	10.6	112	20880
	ODE	3.5	5.0	83	15017
ST-WF	DAE	4.2	17.6	102	25390
	ODE	3.7	5.1	77	15017
DT-FE	DAE	9.0	152.2	303	39661
	ODE	10.5	46.0	151	23425
DT-WF	DAE	9.1	229.6	364	48681
	ODE	10.8	116.4	322	23425
CCPP	DAE	3.5	5.4	109	23574
	ODE	1.8	1.4	79	3771

There is no clear trend for the offline execution time in the four vehicle problems, whereas it is halved for the power plant. Both the number of iterations and the online execution times are shorter for the transformed problem in all compared scenarios. For the power plant, the difference in online execution time is approximately a factor of 4, whereas the vehicle examples exhibit a factor of between 2 and 3. This indicates that models containing a large amount of simple equations gain more from the proposed method, for reasons discussed in Section 3.2, but also that models with mainly complex algebraic equations gain speedups in the online NLP solution from the transformation.

## 6 Conclusions

We have presented a method for symbolically transforming a broad class of DAE-constrained optimization problem into an ODE-constrained optimization problem. The approach has been evaluated by measuring execution times for benchmark problems involving time-optimal trajectory generation for vehicles and startup of combined-cycle power plants.

The considered problems have been solved with both a traditional approach where the DAE is left intact in an implicit form, and with the presented method where the DAE system is symbolically transformed into an ODE before applying discretization techniques. Significant speedups have been observed in the solution of the NLPs resulting from a direct collocation discretization method.

While the method has exhibited great performance improvements, potential drawbacks have also been discussed. The most significant drawback is that while the dynamic equation system becomes smaller in size, the resulting expressions are often of much higher complexity.

Future work is the resolution of some of the discussed drawbacks of the approach, by only eliminating a suitable subset of the algebraic variables. A possible improvement in the opposite direction is to employ tearing techniques, which are often used for simulation of DAEs, to further reduce the number of variables exposed to the collocation method and the NLP solver. The interaction between the proposed method and other types of NLP solution methods, such as active set methods, is also worth investigating.

## Acknowledgments

We acknowledge Francesco Casella from Politecnico di Milano for granting the usage of the combined-cycle power plant model.

## Abstract

Offering services to stabilize the electrical grid is nowadays one of the major tasks of fossil power plants and also of significant economical relevance. However the effects on the power plants regarding the additional wear of components is uncertain. Usually the effects regarding control reserves, especially primary control occur with high frequencies and small amplitudes, which makes investigations based on measurement data impossible since the effects are masked by the noise of normal operation. In order to investigate this issue, a detailed model of a lignite power plant has been used, which was developed in Modelica for simulating and comparing scenarios with and without offering primary control reserves. The model comprises the entire water-steam cycle including turbines, preheaters and pumps, as well as a very detailed boiler model including the air supply, coal mills, a combustion chamber, heating surfaces and piping. Furthermore the power plants control system has been implemented in a very precise way. In addition the study involves an investigation on the input signals (grid frequency) and a calculation of lifetime consumption for specific components to evaluate the effects.

*Keywords: Power Plant, Dynamic Modelling, Control Reserves, Primary Control, Lifetime Consumption*

## 1 Introduction

In addition to the mere production of electrical energy, many fossil power plants are needed to provide control services, which are necessary to operate the electrical grid. In order to stabilize the frequency of the electrical grid, the consumption has to be compensated by the production at any moment. In order to guarantee this, it is required to activate or deactivate power production within seconds. The control reserves can be categorized within three corresponding grid services - primary control, secondary control and tertiary control as described in [5]. Although the necessity of granting grid services is undisputed, the consequences for fossil power plants are still uncertain. As the market for the mere production of electrical energy is declining for conventional plants, offering grid services (e.g. primary control reserves) gets more and more relevant. In order to investigate the dynamic effects on a lignite power plant, a method is presented which uses the dynamic simulation of a complex lignite fired power plant in Modelica. Similar models of a hard coal fired power plant and a combined cycle gas turbine power plant have been developed previously for different applications (e.g. [1], [2] and [3]). The dynamic model enables the user to calculate pressures and temperatures in various locations of the power plant and therefore computing mechanical and thermal stress in specific components. The results will be used to derive lifetime consumption and evaluate the effects of offering grid services, e.g. primary control reserves for this power plant.

## 2 Primary Control Requirements

The setpoint of the frequency in the European grid system is 50 Hz. The allowed variation of the mains frequency in normal mode is between 49.8 Hz and 50.2 Hz. If a failure occurs on the consumer or producer side the frequency can change within a few seconds. The primary control counteracts this. In figure 1, a typical trend for the mains frequency of one day is shown.

Figure 1: Trend of mains frequency of one day

Every power plant involved in the primary control has to provide at least 2 % of its effective power as primary control reserve, which has to be available within 30 s.

The dynamical behavior of a power plant is dominated by the dynamics of the steam generator and turbine. In order to provide additional electrical power in a short period of time, needed for primary control, different modes exist:

- Throttling of HP/ IP-valve: The power plant operates in all operating points with throttled high and intermediate pressure steam valves. This grants that the power plant can increase its output by opening the valves for a positive output demand and decrease its output by increasing the throttling of the valves.
- Low pressure preheater bypass: In this mode the power plant increases its electrical output by throttling the valves to the low pressure preheaters and the feedwater tank. In order to avoid thermal stress in the low pressure preheaters the speed of the condensate pump is decreased. The whole process leads to more steam in the turbine stages and thus to more electrical output. The limits of this mode are

the filling levels of the condenser and the feedwater tank. For a negative power demand the HP/IP steam valves are throttled as described in the previous point.

- High pressure preheater bypass: This mode is the same like the low pressure preheater bypass but uses the high pressure preheaters and the feedwater pump instead.

In order to investigate the influence of the primary control for a whole year, it is possible to simulate the whole year with the mains frequency as a model input, but it takes a lot of time. The implemented model has a ratio of real time to simulated time of about 1:1 to 1:10. Thus the simulation of one year would take at least one and a half month. In order to reduce simulation time the data of the mains frequency is analyzed and subdivided into characteristic signals, distinguishing between:

- changes in mains frequency, which occur every full hour, because of the changes of the power plants schedules
- noise due to the fluctuating consumer load
- power plant outage due to technical issues

These different signals will be extracted and analysed from the mains frequency data of one year. In the following, the changes in mains frequency every full hour are explained in more detail, because they have the highest amplitudes of all the characteristic signals. The basic strategy is to cut out the time data of the mains frequency and to classify these signals. Afterwards all signals in one class are averaged in order to get one signal for every class. For this purpose it must be ensured that the extremum of all the signals in one class are situated at the same time. This is realized by extracting the signals  $\pm 5$  minutes around the extremum, which can be in an interval of  $+7.5$  minutes after every full hour. Figure 2 shows all signals belonging to class 1, which contains such mains frequency changes of the year 2011 with amplitudes between  $-0.14$  Hz and  $-0.105$  Hz. Furthermore the averaged signal is shown. In order to consider the different intervals  $tn$  between the extremum and the full hour, this value is allocated to every extracted and classified signal. All signals in one class of amplitude are different in  $tn$ . An average  $tn, mean$  is calculated in order to avoid a multiplicative increase of simulation scenarios.

Figure 2: All signals of one class with the averaged signal in dark blue

The averaging of all mains frequency signals in one class minimizes the noise. In order to consider this noise a characteristic noise signal is added to the averaged signals of changes in mains frequency every full hour. The results of the classification are eight frequency signals for the changes of frequency every hour which are shown in figure 3. The eight frequency signals are considered as rep-

Figure 3: Scenarios of mains frequency changes which occur after every full hour. The extremum is situated  $t_n$  seconds after the full hour.

resentative inputs for subsequent investigations for all power plants participating in primary control in the ENTSO-E grid.

### 3 Power Plant System Model

#### 3.1 Reference Power Plant

The investigated power plant is a duo-block lignite power plant as shown in figure 4. Each of the blocks has two boilers, which provide steam

	Mono	Duo
Gros el. Output	265 MW	530 MW
Load Gradient	4 MW/min	8 MW/min
Primary Control	12.5 MW	25 MW

Table 1: Reference data of the Duo-Block Plant

for a mutual turbine. The block can be operated with both boilers (duo-operation) or using only one (mono-operation). One turbine has an electric output of about 530 MW. Coming from the turbine, the steam is condensed in two parallel condensers. Afterwards there is one common line of four low pressure preheaters. Then, the flow splits up for two feedwater tanks and parallel feedwater pumps and three high pressure preheaters. From there the flow enters the boilers. The boilers are using a forced circulation for the evaporation part and are equipped with parallel lines in the superheater section.

Figure 4: Investigated reference power plant

The investigated plant currently operates in base load, producing a significant amount of electrical energy. In addition to that, it offers considerable amounts of control reserves, especially primary control reserves, see Table 1 for reference data.

#### 3.2 Dynamic Process Model

The dynamic model has been built within Dymola using the open programming language "Modelica". The components used to build the model are mainly based on the "ThermalPower Library" developed by Modelon AB.

As the block arrangement in the real plant, the dynamic model consists of several components involving a diversity of different physics. An overview is given in figure 5. The general approach for all models involves the balance equations for mass and energy as well as a simplified momentum

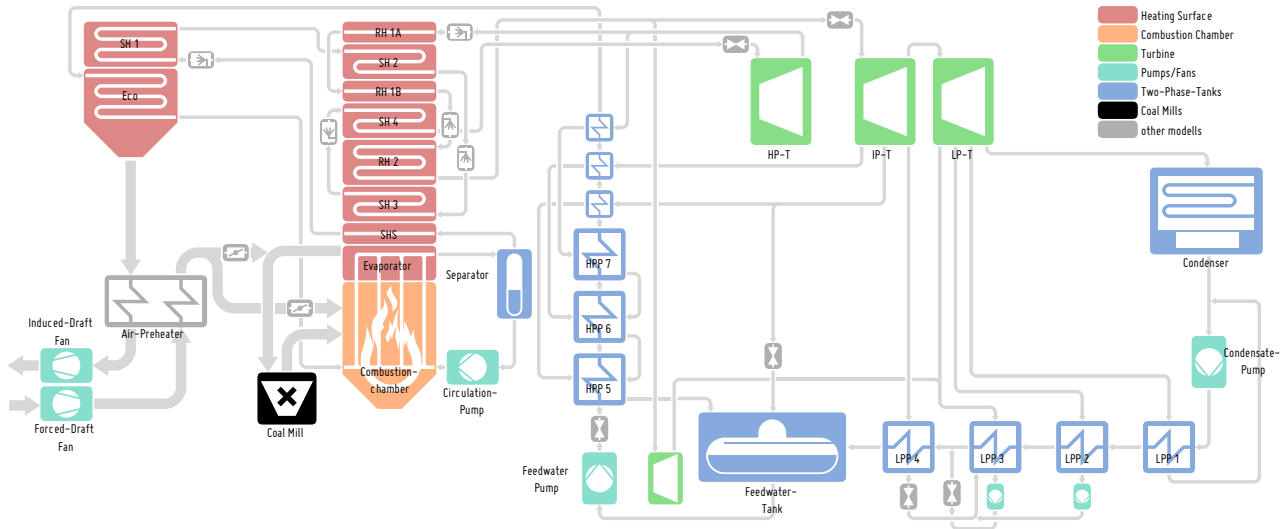

Figure 5: Implemented components of reference power plant

equation to calculate pressure drops. Using these equations as well as specific heat transfer assumptions for conduction, convection and radiation and the fluid properties for the involved mediums (flue gas, water) a power plant process can be described on a fundamental basis. A detailed explanation of physical backgrounds for all the basic models used here can be found in [6]. However the complex power plant system required some more sophisticated models which needed to be developed in order to reproduce the plants behaviour in an accurate way. One example for such a component is the lignite coal mill as presented in figure 6. The coal mill is not only responsible for grinding the coal to the desired size, but also for drying the lignite, as the water content of the fuel is usually between 50-60 %. As those effects have a significant impact on the overall process dynamics, a model had to be developed to describe the dynamic behaviour of the coal mills.

The coal mill model consists of three main paths. The gas path describes the hot flue gas which is re-circulated from the combustion chamber. Furthermore fresh air with lower temperature is added to control the temperature in the classifier of the mill. The ventilation effect of the mill is represented by a simple fan model based on the specific characteristic of the mill. The water path represents the water content of the coal which is evaporated in the mill. The energy used for evaporation is taken from the hot flue gas. After evaporation, the water is mixed with the flue gas. The coal containing a residual water content of 10-20% is represented by

the coal path.

Figure 6: Schematic of the lignite coal mill model

One essential part of the model is the changed lower caloric heating value due to the evaporation of the water. In order to describe this, a simple assumption based on [7] leads to reasonable results:

$$CV_x = \frac{CV_0}{(1 - X_{A,0})(1 - X_{W,0})} (1 - X_{A,x})(1 - X_{W,x}) \quad (1)$$

Wherein  $CV$  denotes the lower caloric heating value and  $X$  the mass content of a specific component (index  $A$  for ash,  $W$  for water). The indices  $x$  and  $0$  are representing the state before and behind the evaporation stage. The delay time for

the grinding of the coal has been identified by fitting the heat release to the measurement data. [8] gives some values for the delay time in each stage of the mill, which gives a reasonable starting point for this optimisation procedure. The water steam cycle has been adapted to a single boiler. For the model, components which are actually used by both boilers are represented as a symmetric part with the half size. This concerns the models for the steam turbine, as well as the low pressure preheater line.

### 3.3 Control System

For making simulation-based statements about the influence of different power plant operation modes the thermodynamic model is coupled to a reduced copy of the original power plant control system, which is implemented using the Modelica Standard Library components. The implemented control system uses the currently calculated physical values (i.e. live steam parameter, generated power at a specific coal input) and in a consequence adjusts set values (e.g. live steam pressure) and manipulated variables (e.g. position of the feed water valve) for the water-steam cycle. Because of this feedback the accuracy and the level of details of the modelled processes needs to be reasonably high. Figure 7 is showing the hierarchical structure of the control system, which has been coupled to the process model.

Figure 7: Overview on the control loops implemented in the model

Of particular interest is the Power Unit control which processes the incoming power and control reserve requests to a corresponding desired firing power. In detail the power plant control system sets the firing power using a map based pilot control. The expected electric power output is pre-

dicted by a transfer function based model of the firing process and the heat transfer in the boiler. The difference between this predictive value and the corresponding measurement is adjusted via a corrective control loop, as described in the VDI/VDE guideline 3508 [9]. Due to the slow transient response of the firing process, fast changes in the power output, as requested for primary control reserve, could only be conducted by using the steam storage of the boiler by altering the pressure set point until the firing process could catch up. The extracted energy needs to be filled up with a temporarily oversteered firing set point. In case of negative primary control request the pressure set point is increased until the steam production of the boiler could be reduced. By undershooting the firing power the stored steam mass could be discharged, while holding the desired electric power set point. This functionality is shown in figure 8.

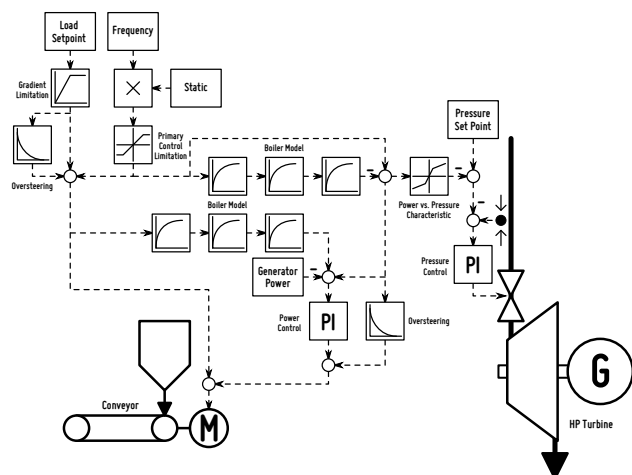

Figure 8: Schematic of the Power Unit Control

### 3.4 Validation of the Model

In order to validate the model, a scenario has been simulated covering the entire load range of the power plant from minimum load to nominal load. As required by the primary control investigation, the model has been operated in duo-operation, assuming both boilers in synchron operation.

In the model as well as in the power plant, the electrical gross output is controlled. Figure 9 shows the input schedule (green) which is used in both - the model and the real plant. The generator output (blue) is shown for the simulation (light color) and for the measurement (dark color). As in the real plant, one of the five mills in operation

Figure 9: Schedule of the reference scenario (green), validation of power output (measurement dark blue, simulation light blue)

Figure 11: Validation of boiler pressure (measurement dark, simulation light)

is shut down in very low load (at about 2.5 h), this mill is returning into operation at about 7 h, causing highly dynamic effects on the entire system. As can be seen from the plot, the simulated power generation fits the measurement not only in steady state points, but also for ramps and most of the dynamic oscillations.

Figure 10: Zoomed validation of power output (schedule green, measurement dark blue, simulation light blue)

In figure 10 a zoomed validation plot from the reference scenario is presented. In this detailed view, setpoint-changes with amplitudes and timescale of primary control activation is shown. It can be concluded that the models really accurately represents the power plants behaviour at fast setpoint-changes. However some effects like the steady state offset between 11.2 h and 11.8 h cannot be reproduced. A reason for that might be a changing caloric heating value of the coal in the power plant which is assumed to be constant in the model.

In Figure 11 pressures from the water-steam cycle are presented. The live steam pressure (red line) is controlled by the turbine valve to a constant value of 162 bar for the entire operation range. The pressure at the evaporator and the entry of the boiler are calculated by the model based on the pressure drop of the integrated components. As can be seen from the figure, this pressure drop is highly dependent on the load, because the flow of the steam changes accordingly. Comparing measured and simulated pressures, the model shows a high agreement regarding the pressure levels.

Figure 12: Validation of the temperatures (measurement dark, simulation light)

In Figure 12 some of the process temperatures are compared to the measurement data. The temperature in the deaerator is controlled to 174°C for the entire operation range. The temperature of the boiler-inlet is mainly dependent on the heat transfer in the high pressure preheaters. The temperature level in the evaporator is dependent on the pressure level, as there are two-phase conditions. The live steam temperature is being controlled by

the spray attenuators, however in very low load (between 2.5 and 7 h) the steam temperatures drop due to a shifting distribution of heat flux in the boiler and are out of their controlled range.

Figure 13: Validation of the coal mill model (measurement dark, simulation light)

A validation of the coal mill model based on the classifier temperatures is being presented in Figure 13. This temperature is very sensible as it represents the mixture of very hot recirculated flue gas from the combustion chamber, preheated fresh air and coal entering from ambient conditions. The simulated temperature is based on an aggregated mill model, which represents all the mills in operation, being able to switch on or off separate mills by changing the fan characteristics. The model is therefore being compared to all the mills which are permanently in operation for this scenario. It can be observed, that the average dynamic behaviour of the mill is represented quite well.

After an extensive validation based on measurement data, the dynamic model is used to calculate temperatures and pressures in critical components, thus enabling a calculation of thermal and mechanical stress according to structural mechanical approaches which are necessary derive lifetime consumption for specific simulation scenarios.

## 4 Structural Mechanics

The primary and secondary control leads to an increased number of load cycles of pressure and temperature changes within the power plant. As a result the fatigue of a component becomes more important than the creep fatigue. Particularly thick-walled pressurized components are affected by this

cyclic loading. For this reason, a routine in Matlab was developed in accordance with DIN EN 12952 [4], to determine the component stress and the lifetime until the detectable cracklength is reached. Figure 14 shows the schematic workflow of the lifetime determination until the detectable crack initiates.

Based on the pressure and temperature gradients the occurring stresses are determined in a first step. The mechanical stress  $\sigma_{\text{tang p}}$  is calculated with the boiler formula as follows.

$$\sigma_{\text{tang p}} = \left\{ \begin{array}{l} \alpha_m \cdot \frac{d_{\text{ms}}}{2 \cdot e_{\text{ms}}} \cdot p \quad \text{cylindrical shells} \\ \alpha_{\text{sp}} \cdot \frac{d_{\text{ms}}}{4 \cdot e_{\text{ms}}} \cdot p \quad \text{spherical shells} \end{array} \right\} \quad (2)$$

In addition to the pressure difference between internal and external pressures, the notch factors  $\alpha_m$  and  $\alpha_{\text{sp}}$  are considered. The notch factor depends on the geometry of the cylindrical shell and of the pipe nozzle. The thermal stress  $\sigma_{\text{ws}}$  is calculated from the temperature difference  $\Delta T$  between the two extreme values of the temperature-time function, the material factor  $\Phi_{\text{ws}}$  and the notch factor  $\alpha_T$  according to the following equation:

$$\sigma_{\text{ws}} = -\Phi_{\text{ws}} \cdot \Delta T \cdot \alpha_T \quad (3)$$

The material factor contains the elastic modulus, the Poisson's ratio and the coefficient of thermal expansion. The total stress is generated by superposition of the mechanical and thermal stress and subsequently counted with the rainflow counting [10].

In a next step, the damage  $\Delta S_i$  is calculated for each cycle (red frame in figure 14). For this, the cycles is converted to an  $R$ -ratio of  $R = -1$  using the Gerber parabola and then multiplied with a roughness coefficient and a temperature coefficient. By adding up each part the amount of damage could be obtained.

## 5 Results

In the following the results for the "class 1" scenario described in section 2 are shown. In order to investigate the influence of primary control on the life time reduction, a minus 25 % load change with and without primary control are compared with each other.

The strongly stressed components are the thick-walled outlet headers. Therefore, the headers at

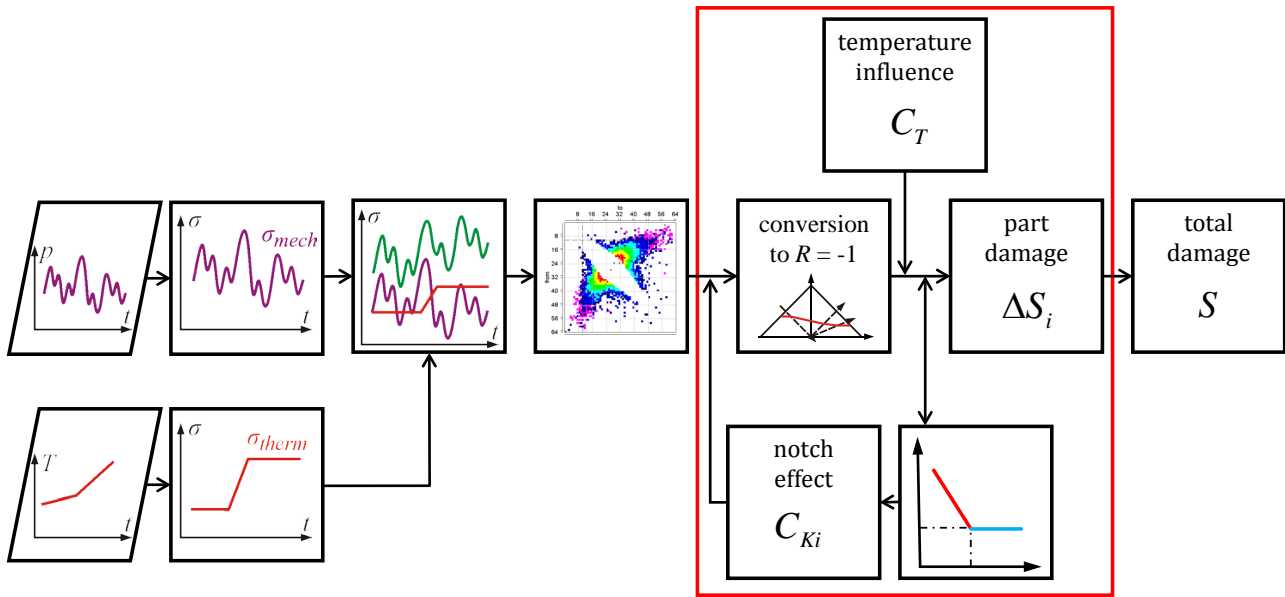

Figure 14: Schematic workflow of the lifetime determination

the outlets of superheater 4 and reheater 2 are considered first. Figure 15 shows the simulated pressure and temperature changes for the header of reheater 2. The solid lines represent the reference,

control can be seen. In temperature the impact persists longer. The entire temperature response is affected and in fact the total minimum is higher for the case without primary control.

Figure 15: Simulation results for pressure and temperature of the steam in the header of reheater 2.

which is the load change without primary control, the dashed ones represent the scenario with the primary control demand. In the first 10 minutes after the load change at  $t = 1$  h, in both pressure and temperature, the influence of the primary con-

For the specific geometry of the reheater header the mechanical, thermal and total stresses are calculated as described in section 4 and the results are shown in figure 16. While the mechanical

Figure 16: Mechanical, thermal and total stresses for the outlet header of reheater 2 (geometry of a cylindrical shell with a pipe nozzle).

stresses are nearly the same, the thermal stresses show a small difference due to primary control and therefore also the total stresses. In order to calculate lifetime consumption, the continuous dynamic processes have to be partitioned into discrete load cycles. Therefore the method of rainflow-counting is used as described in the previous section. The outcome is shown in figure 17 for the header of reheater 2. The red line represents the limit for the

Figure 17: Sorted stress amplitudes of the outlet header of reheater 2 and the fatigue limit for this component for the scenario without and with a primary control demand.

fatigue. Obviously this fatigue limit is exceeded for the header of reheater 2 in the case of the primary control scenario. The corresponding damage  $\Delta S$  is  $1.3 \cdot 10^{-8}$ , which is determined with the S-N-curve (Wöhler curve) of the header material. In the case of the reference scenario without primary control the amplitudes are smaller and the fatigue limit is not exceeded.

For the same scenarios the stress amplitudes of the outlet header of superheater 4 are presented in figure 18. Here a damage occurs for both cases without and with primary control and is about  $1.4 \cdot 10^{-6}$  and  $6.8 \cdot 10^{-7}$ , respectively. In contrast to reheater 2 the primary control scenario leads to smaller stress amplitudes than the pure load change.

In conclusion the results show that the impact of primary control on the life time reduction is not only determined by the pressure and temperature conditions but also strongly depends on the

Figure 18: Sorted stress amplitudes of the outlet header of superheater 4 and the fatigue limit for this component.

geometry of the component. Thus the structural mechanics calculations need to be done for all components of the power plant. Furthermore, several scenarios have to be investigated and connected with their annual occurrence to identify the overall damage of the power plant due to primary control.

## 6 Summary

A very comprehensive dynamic model of a lignite fired power plant has been developed as presented in this paper. The model allows a diversity of applications focussing on dynamic operation e.g. control optimisation, calculation of lifetime consumption or energetic optimisation. One example application is the ongoing investigation on the impact of primary control on this power plant. The result of a first scenario has been presented and explained on the example of two highly stressed components. In the next stages of this investigation, all the scenarios presented in section 2 will be simulated and multiplied with the share of their appearance in order to assess the overall impact of primary control.

## 7 Acknowledgement

The authors would like to thank VGB PowerTech and Vattenfall for providing financial support and input data as well as the participating delegates for

inspiring discussions and helpful hints from practical experience during the project meetings. Also we would like to thank all the people at the power plant for supporting the acquisition of design and process data.

## Abstract

This paper presents the development of a system model for a pre-combustion CO<sub>2</sub> capture process as part of an integrated gasification combined cycle power plant. This process entails the modelling of highly non-ideal, two-phase multi-component mixtures which are currently not supported by available Modelica media libraries or interfaces.

Therefore, an interface prototype was developed and tested for the modelling and simulation of the CO<sub>2</sub> capture process. Limitations concerning the modelling approach and improvements targeting the computational efficiency are discussed. Recommendations about the design of a library for the use of external property estimation code in Modelica conclude the treatment.

*Keywords:* pre-combustion CO<sub>2</sub> capture; two-phase, multi-component fluids; external fluid property code

## 1 Introduction

Pre-combustion CO<sub>2</sub> capture applied to integrated gasification combined cycle (IGCC) power plants is a promising technical solution to mitigate CO<sub>2</sub> emissions and therefore the effect of climate change [1]. The integration of the CO<sub>2</sub> removal unit with the very complex gasification process and combined cycle power plant leads to challenges especially regarding dynamic operation. Nowadays, dynamic performance of fossil-fuelled power plants becomes increasingly important as the share of electricity produced by renewable energy sources, which is inherently unsteady, is continuously growing. Therefore, the inte-

grated capture process has to be able to follow frequent and fast load changes to allow for flexible power production. In order to study the transient performance of the pre-combustion CO<sub>2</sub> capture unit during load variations, dynamic models of the entire system and models of the individual components have thus been developed using the Modelica modelling language. The models have been validated by comparison with experimental data obtained from a unique, fully instrumented CO<sub>2</sub> capture pilot plant, which has been realized at the Buggenum IGCC power station in the Netherlands by the utility company Vattenfall [2].

The main challenge of the model development is related to the computation of fluid properties, in particular phase equilibria, due to the fact that highly non-ideal, two-phase, multi-component fluids are involved in the capture process. Currently, Modelica medium models are not available for this type of fluids.

One possibility is to implement required medium models, just as the process models, in the Modelica language, with the advantage to be able to perform efficient simulations as the code can be optimized, provided the equation of state is written in a declarative way, which might not always be possible. However, the implementation of non-ideal fluid property models is rather time-consuming and not trivial, as dedicated solution algorithms might be required for efficiency and numerical robustness.

The other possibility is to make use of available thermophysical property packages and interface these tools with Modelica. Employing external tools for the computation of fluid properties provides some advantages: 1) typically the property software employs dedicated algorithms for fast and robust calculations of the fluid properties, 2) the property package can be interfaced with a wide variety of engineering software tools (e.g. steady-state and dynamic system mod-

<sup>\*</sup>Email: C.Trapp@tudelft.nl, P.Colonna@tudelft.nl

elling, component design, CFD, etc.) allowing for the use of the same thermophysical properties, thus eliminating one common source of uncertainty, 3) a wide range of pure fluids and fluid mixtures described with suitable and accurate equation of states are available in the property package.

This concept was successfully demonstrated with the ExternalMedia library [3] which supports two-phase, single-substance fluids all compatible to the Modelica.Media interface. However, multi-component fluids as required for the CO<sub>2</sub> capture process are not supported because the interface for multi-phase fluid mixtures is limited to two-phase pure (or pseudo-pure) components.

For this reason, a prototype for an interface supporting two-phase, multi-component fluids was developed and tested for the modelling and simulation of the CO<sub>2</sub> capture process.

The objective of the work documented here is to demonstrate the feasibility of modelling such a chemical process with Modelica by making use of external fluid property code and to indicate limitations concerning the modelling approach as well as to discuss possibilities for the improvement of the computational efficiency. Finally, recommendations shall be drawn for the design of a generic interface to external fluid property code.

## 2 Pre-combustion CO<sub>2</sub> capture process

The simplified process flow diagram of the CO<sub>2</sub> capture pilot plant built at the site of the Buggenum IGCC power station is depicted in Figure 1. The syngas from the gasifier entering the CO<sub>2</sub> removal unit is mixed with process water in order to obtain a pre-set H<sub>2</sub>O:CO ratio, and then it is fully evaporated and superheated by means of electrical heaters. The carbon monoxide present in the syngas is converted into hydrogen and carbon dioxide via a three-stage, sweet, high-temperature water-gas shift (WGS) process. The excess process water is recovered from the shifted syngas through condensation and then recycled. Subsequently, the carbon dioxide is removed from the syngas in the CO<sub>2</sub> absorber by means of physical absorption utilizing the solvent dimethylether of polyethylene glycol (DEPEG). The resulting H<sub>2</sub>-rich syngas is fed to the gas turbine of the combined cycle power plant and the CO<sub>2</sub> is recovered by three-stage depressurization of the loaded solvent. The lean solvent is recycled to the absorber, while the CO<sub>2</sub>-rich product stream is compressed to a state suitable for storage.

Throughout the evaporation and condensation in

the shifting section, vapour-liquid equilibrium of the syngas-water mixture is assumed, which requires rigorous fluid property computations. The water-gas shift reaction occurs at conditions where the syngas-steam mixture can be described as an ideal gas. Throughout the absorption section, vapour-liquid equilibrium of the syngas-solvent mixture is also a verified hypothesis.

The main differences between the pilot plant and a large-scale CO<sub>2</sub> capture process concern the heat integration in the shifting section. In a large-scale design the electrical devices used for heating, cooling and condensation are replaced by heat exchangers.

## 3 Model development

The thermophysical properties of the two-phase multi-component syngas-water/syngas-solvent mixtures are calculated with the Perturbed Chain - Statistical Associating Fluid Theory (PC-SAFT) equation of state [4] due to its success in predicting vapour/gas-liquid equilibria of complex fluids and mixtures for a broad range of conditions. This EoS has been validated against experimental measurements and data from literature [5] and implemented, together with fast and robust algorithms, into an in-house property package [6] which is interfaced with the dynamic modelling tool via the ModelicaFluidProp Modelica library.

### Library architecture

The ModelicaFluidProp library provides the functional interface that allows to integrate external fluid property codes into Modelica models. The library contains two parts, the Modelica front-end which makes various functions available for the calculation of different property sets (for instance "AllProps" or "TwoPhaseDeriv") and the C/C++ back-end, containing C++ objects that carry out the interfacing between the Modelica level and the external software tool.

The Modelica library contains a generic package FluidPropMedium. The actual external fluid property code is specified by setting values to constants such as ModelName, which defines the name of the external library, nComp, which specifies the number of fluid constituents and Comp, which defines the name of the individual constituents. The external medium model can be used in any component model and is not extending any medium package from the standard Modelica library.

The implemented set of functions in the FluidPropMedium package mirrors one-to-one property functions available in the external property tool which

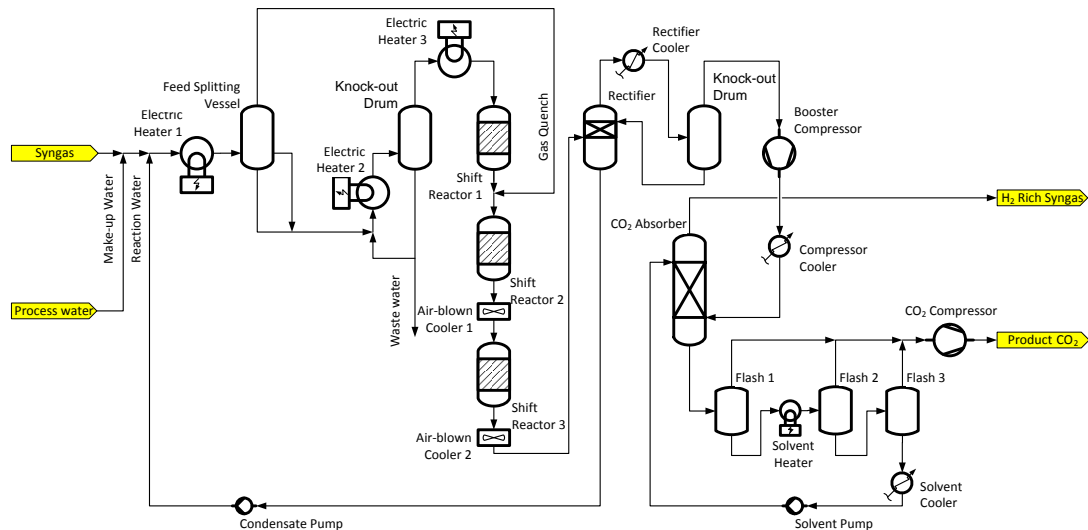

Figure 1: Process flow diagram pilot plant.

are interfaced with corresponding C-functions defined in the C interface layer.

In the following, the working principle of the library is explained, based on the exemplary code below:

```
import SI = Modelica.SIunits;

package SyngasDEPEG
  extends ModelicaFluidProp.FluidPropMedium(
    modelName="PC-SAFT",
    nComp=6,
    Comp={"carbon monoxide","hydrogen",
          "carbon dioxide","water","nitrogen",
          "DEPEG"})
end SyngasDEPEG;

model Example
  SyngasDEPEG.AllPropsOut prop;
  SI.Temperature T;
  SI.Pressure P;
  SI.SpecificEnthalpy h;
  SI.Density d;
  SI.MoleFraction Y[SyngasDEPEG.nComp]=
  SyngasDEPEG.reference_X;
  SI.MoleFraction Yliq[nComp]
  "Molar fractions of liquid phase";
  SI.MoleFraction Yvap[nComp]
  "Molar fractions of vapour phase";
equation
  (prop,Yliq,Yvap) =
  Medium.AllProps("PT",P,T,Y);
  h = prop.h;
  d = prop.d;
end Example;
```

The AllProps function of the FluidPropMedium package calls the corresponding C function of the interface and passes the specification of the thermodynamic state ("PT"), the values of pressure, temperature and composition as well as the constants for medium identification. The interface function handles the creation of an object for the external property code and the execution of the solver to compute

the required properties. The calculated fluid properties are passed via the prop record to the Modelica code. The AllProps function returns all primary thermodynamic properties such as  $P$ ,  $T$ ,  $v$ ,  $d$ ,  $h$ ,  $s$ ,  $u$ , etc. which can be computed with hardly any additional computational cost when solving the equation of state. Secondary thermodynamic properties such as heat capacity, speed of sound, various single-phase partial derivatives and transport properties are computed with a separate function as these properties are less often needed and require additional computations. The computationally expensive two-phase partial derivatives are combined in another property function.

The arrangement of primary and secondary fluid properties in meaningful functions allows for a flexible use and avoids unnecessary repeated computations.

## Process models

The objective is to develop physical-based component models which allow the modelling and simulation of the pre-combustion CO<sub>2</sub> capture process. The model structure shall facilitate the integration of external functions for thermophysical property calculations.

For the modelling of the CO<sub>2</sub> capture process various component models are required. Whenever possible models were reused from available Modelica libraries. For example, basic component models such as sinks, sources, valves, pressure drops, pumps, heat exchange and flow models, are taken from the ThermoPower library [7, 8] and adapted in terms of their media models which have been replaced with functional calls to the external property tool.

For the following components new models were implemented:

- **Flash vessel**

The process of phase separation is modelled under the assumption of thermodynamic equilibrium between the liquid and vapour phase at all times. This is a justified assumption since the process is typically designed to ensure sufficient mixing. The model describes the holdup of vapour and liquid with conservation equations which account for both phases together. Saturated conditions are assumed for the liquid and vapour outlet streams and therefore entrainment of liquid in the vapour flow is neglected. The flash vessel model is implemented as a "pure storage" component and hence frictional losses are not considered. The static pressure head due to the liquid level in the vessel is accounted for in the algebraic momentum balance. Heat transfer from the fluid (both vapour and liquid phase) to the vessel wall and accumulation of thermal energy in the wall as well as heat losses to the environment are neglected. Thus, also superficial condensation is assumed to be negligible.

- **Water-gas shift reactor**

The reaction of carbon monoxide with steam to produce carbon dioxide and hydrogen is described in a lumped-parameter model. The syngas entering and leaving the reactor is an ideal-gas mixture containing CO, CO<sub>2</sub>, H<sub>2</sub>, H<sub>2</sub>O, N<sub>2</sub>. Other trace constituents are neglected. The model accounts only for the WGS reaction. Intermediate reactions involving other chemical species are neglected. The reactor model is subdivided into five sub-models (Figure 2): reaction node, mixing gas volume, convective heat transfer, thermal storage and pressure drop.

Figure 2: Object diagram of reactor component.

The WGS reaction takes place in an infinitesimally small volume (reaction node) representing one finite discretization of the catalyst and reaches thermodynamic equilibrium. The accumulation of mass and energy in the bulk phase of

the reactor are described in a perfectly mixed volume (mixing gas volume) which receives the reaction products. This control volume exchanges heat with the catalyst by means of convection. The storage model describes the accumulation of thermal energy in the catalyst. Heat transfer to the environment is neglected.

The water-gas shift reactor is discretized in axial direction by an array of reactor models in order to correctly describe the gradual changes in reactor outlet conditions during transient operation. Changes in the reactor inlet conditions reach the reactor outlet with a delay due to thermal storage in the catalyst, which cannot be represented with a 0-dimensional model due to the high number of transfer units between the gas and the catalyst itself.

However, this one-dimensional discretization does not represent the the actual axial reactor profile as equilibrium conditions are assumed in each reactor model element for simplicity. In steady-state conditions the equilibrium temperature is reached at each discretization of the catalyst, which also determines the temperature dependent WGS reaction.

- **Pilot plant specific heater and cooler components**

Various electrical components for evaporation, superheating, cooling and condensation were in particular developed for the pilot plant process and will not be part of a large-scale plant in this specific configuration. The models were developed following a modular approach such that sub-models can be reused. The models were typically subdivided, if applicable, in flow models, heat transfer models and thermal storage models. Whenever possible models from the ThermoPower library were used, typically in case the medium was water or ideal gas, or adapted.

- **Absorption column**

The packed column model for physical absorption (no chemical reactions) is discretized in theoretical stages in axial direction and counter-current flow of the vapour and liquid is assumed. Each stage is modelled by an equivalent tray module ("pure storage") and a resistive module. By connecting a series of storage and resistive modules (Figure 3) a low index of the equation system can be maintained (detailed discussion see Section 4).

In the equivalent tray module, pressure, temperature and composition of the liquid and vapour

Figure 3: Model structure of the absorption column.

phase are determined by solving the conservation equations for mass and energy assuming thermodynamic equilibrium between liquid and vapour [9]. This module is based on the flash vessel model with its assumptions stated above. In the resistive module the momentum equation is substituted by empirical correlations to describe the hydrodynamics of the stage predicting the liquid and vapour flow rate as a function of the pressure difference between the stages, the liquid holdup and the packing characteristics. Empirical correlations for the pressure drop and liquid holdup are published by Stichlmair et al. [10] and Billet and Schultes [11].

## 4 Modelling approach / Lessons learned

The use of external fluid property functions in Modelica process models puts some restrictions on the model development. Specific attention requires the formulation of the differential model equations, the choice of state variables and the causality of the system model. These issues are addressed in the following.

### 4.1 Choice of state variables

For dynamic modelling of thermo-physical systems not only the choice of the system state variables is of importance but also the selection of the thermodynamic states used to determine fluid properties. In general, the system state variables should allow for an easy computation of the thermodynamic properties required to determine the system performance and the thermodynamic state variables should unambiguously determine the fluid state. Further, the choice of sys-

tem state variables can have a significant influence on ease of initialization, numerical robustness and computational speed.

In the following, three different possibilities for the choice of state variables and their influence on resulting differential and algebraic equation (DAE) system as well as simulations speed are analysed. As an example, dynamic mass and energy balances for describing storage of vapour and liquid in a volume under the assumption of thermodynamic equilibrium are used. These equations can be found in the flash vessel and absorber tray models.

### Explicit system state variables $M, u, X_i$

In the most simple way the dynamic mass and energy balance can be formulated as

$$\frac{dM}{dt} X_i + M \frac{dX_i}{dt} = w_{in} X_{in,i} - w_{liq} X_{liq,i} - w_{vap} X_{vap,i}, \quad (1)$$

$$M \frac{du}{dt} + u \frac{dM}{dt} = w_{in} h_{in} - w_{liq} h_{liq} - w_{vap} h_{vap}, \quad (2)$$

where  $M$  is the total mass,  $u$  is the internal energy,  $X_i$  is the component mass fraction vector whereby the subscript  $i$  ranges from 1 to the number of species in the mixture,  $w$  is the mass flow rate and  $h$  is the specific enthalpy. A formulation purely based on moles is also possible and might be the preferred choice as conversions between mole and mass are avoided.

Assuming  $M, u$  and  $X_i$  are selected as state variables and no other variables than the states appear under the time derivative the system solution can be obtained straightforward. This applies, for example, to a single flash vessel model where the index of the DAE system is 1. Section 4.2 covers the case of higher index problems, e.g. when dealing with a model of two flash vessels connected with a zero pressure drop.

The mass and energy equations represent a compact and very declarative formulation of the conservation equations. The pressure  $P$ , the temperature  $T$  and the mass composition  $X_i$  are chosen as thermodynamic states, therefore

$$prop = prop(P, T, X_i). \quad (3)$$

For this state selection property computations for two-phase mixtures are most efficient and robust with the used external media library (see Section 4.3). As the system states and thermodynamic states differ, implicit equations must be solved at each time step in order to determine the thermodynamic state variables.

Consequently, with the solution strategy used by Dymola the computational speed is affected by the iterations on the property function, which are anyway the most expensive part of the entire simulation.

### Implicit system state variables $P, T, X_i$

The Modelica language features the option to change states by means of the StateSelect attribute, without changing the declarative formulation of the dynamic mass and energy balance. Hence, pressure, temperature and composition can be selected as preferred states in accordance to the thermodynamic states with the aim to reduce iterations during the solution procedure. However, as the total mass and internal energy remain under the time derivative and not being states, the tool attempts to symbolically differentiate  $M$  and  $u$  with respect to the states  $P, T, X_i$  in order to establish a relationship between the old states, which have been discarded, and the newly selected states. This procedure fails as the external property call cannot be differentiated.

### Explicit system state variables $P, T, X_i$

In order to facilitate a feasible solution an explicit expression for  $\frac{dM}{dt}$  and  $\frac{du}{dt}$  needs to be provided as a function of the state variable derivatives  $\frac{dP}{dt}$ ,  $\frac{dT}{dt}$  and  $\frac{dX_i}{dt}$ . The needed time derivatives therefore read

$$\frac{dM}{dt} = -Md \left[ \left( \frac{\partial v}{\partial p} \right)_{T,X} \frac{dp}{dt} + \left( \frac{\partial v}{\partial T} \right)_{p,X} \frac{dT}{dt} + \left( \frac{\partial v}{\partial X_i} \right)_{p,T,X_{j \neq i}} \frac{dX_i}{dt} \right], \quad (4)$$

$$\frac{du}{dt} = \left( \frac{\partial u}{\partial p} \right)_{T,X} \frac{dp}{dt} + \left( \frac{\partial u}{\partial T} \right)_{p,X} \frac{dT}{dt} + \left( \frac{\partial u}{\partial X_i} \right)_{p,T,X_{j \neq i}} \frac{dX_i}{dt}. \quad (5)$$

The partial derivatives of  $u$  and  $v$  with respect to  $P, T, X_i$  need to be provided by the external media library. Two-phase partial derivatives of mixtures, which are based on properties obtained from the phase equilibrium calculations, are commonly not available among the typical thermophysical fluid properties and therefore have been specifically implemented in the framework of this model development. These mixture derivatives are currently computed numerically. Future work might consider the analytical formulation as implemented, for example, in Multiflash [12]. However, also the calculations based on analytical expressions is expected to be computational expensive [13].

These mixture derivatives cannot be fully expressed analytically and hence the numerical calculation affects the computational speed of the dynamic model.

In Figure 4 the simulation performance of a flash vessel with system states  $M, u, X_i$  and state variables  $P, T, X_i$  is compared. The simulation of the latter model requires 90 % less functional calls to the external property library promoted by the same choice for system and thermodynamic state variables. However, considering the computational time the latter model only leads to an improvement of 40 %. This is explained by the additional calculation of partial derivatives required when changing the states from  $M, u, X_i$  to  $P, T, X_i$ .

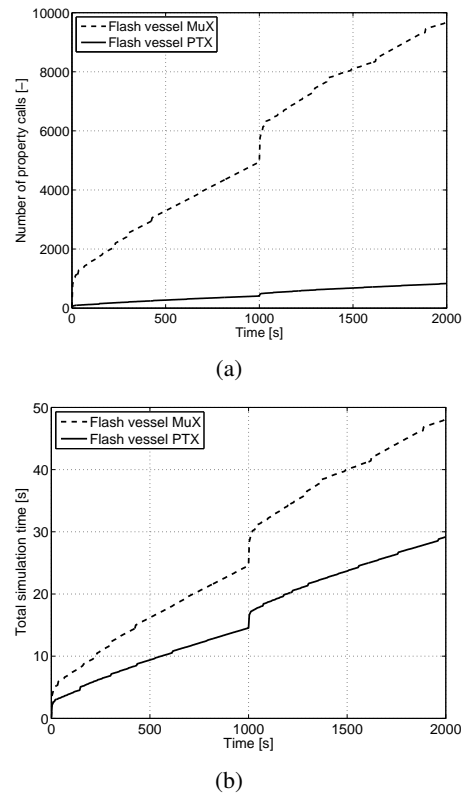

Figure 4: Comparison of flash vessel models with state variables  $M, u, X_i$  and  $P, T, X_i$ . a) Number of property calls. b) Total simulation time.

The observed difference in computational speed between both choices of state variables might also be related to the solution strategy employed by the software tool. Dymola was adopted for this project, and Dymola obtains the solution of the DAE system by iterating on a nested loop, and solving the ODE's in the outer and the algebraic equations in the inner loop. It might be possible that using a DAE solver directly on the original DAE system in this case might lead to a much smaller difference in computational speed between both solutions. However, a direct solution strat-

egy might entail more trouble during initialization and shorter time steps to achieve convergence might be required. A hybrid strategy where both approaches are applied, dynamically switched, might be interesting to explore.

## 4.2 Developing index-1 models

Considering a model containing two flash vessels, component mass and energy balance represented by equation 1 and 2, with zero or constant pressure drop, then the index of the DAE system is larger than 1, assuming  $M$ ,  $u$  and  $X_i$  are chosen as state variables.

The solution of a DAE system with higher index is commonly obtained by symbolic manipulation of the equations system in order to reduce its index to 1. Current simulation tools implementing the Modelica language employ state-of-the-art techniques for index reduction. Difficulties during index reduction might arise in case fluid property calculations must be symbolically differentiated. If the fluid correlations or equation of state are implemented as a Modelica media library, possibly accompanied with annotations to compute its time derivatives, symbolic manipulation can be performed by the tool resulting in a successful index reduction. However, in case external media libraries are used, interfaced with the Modelica models, index reduction fails as external functions cannot be manipulated. This can be resolved by either supplying any time derivatives required for index reduction or by developing the Modelica models such that the DAE system remains in the index-1 form. The latter approach has been followed for the dynamic modelling of the CO<sub>2</sub> capture pilot.

### Causal versus acausal approach

Following the acausal modelling approach, which is fully supported by Modelica, connections of sub-models might not respect the causality leading to a system of DAE's of higher index (example of two flash vessels described above). Therefore, a mixed approach is applied during the model development. The sub-models and interfaces are defined and developed in an object-oriented manner such that the models can be employed in an acausal context. However, the system has been analysed and decomposed into subsystems following the causal modelling paradigm in order to avoid the occurrence of higher order DAE systems [14]:

- Identification of bilaterally coupled variables of the models.
- Discretisation of the model in resistive and storage modules, namely solving the conservation

laws for flow and potential in different control volumes.

- Connect the resistive to the storage modules and vice versa such that potential variables are inputs of the resistive and outputs of the storage modules. Flow variables are inputs to the storage and outputs to the resistive modules.

By following a more causal development and arrangement of the models the DAE system can be maintained in the index-1 form which allows for a straightforward use of external property functions. The disadvantage of this approach is that it poses restrictions on the connection of modules. It might be necessary to include dummy modules with no process functionality in order to maintain the resistive-storage structure.

## 4.3 Improvement of computational time

Based on the current experience obtained from the modelling of the CO<sub>2</sub> capture process, the computation of thermodynamic fluid properties, in particular phase equilibria, accounts for the main share of the simulation time (in the order of 95 %). In addition, much more complex and hence computational expensive thermodynamic models are required when dealing with highly non-ideal, multi-component mixtures in comparison to fluid models for water or ideal gas. Therefore, an appropriate and smart use of property functions should be considered during the entire model development process. In the following, suggestions are presented, which might significantly contribute to a successful convergence and more efficient simulations.

### Choice of thermodynamic states

For an efficient use of external property functions in Modelica, it is necessary to have knowledge on the property calculations performed in the external tool. The thermodynamic state can be determined for different choices of independent variables, for example "PT", "Pv", "Ph", "Pq", "Tv", "Tq", "uv", etc., where  $P$  is the pressure,  $T$  is the temperature,  $v$  the specific volume,  $h$  is the specific enthalpy,  $q$  is the vapour quality and  $u$  is the specific internal energy. In case of mixtures the component fraction vector  $X_i$  is added to set of independent variables.

The external tool employs an isothermal ("PT") or an isenthalpic ("Ph") flash algorithm developed by Michelsen [15] for the PC-SAFT and cubic EoS's, which are robust and reliable equilibrium calculations based on the minimization of Gibbs free energy. If other thermodynamic states are chosen as input, then

Figure 5: Object diagram of a flash vessel with vapour and liquid control valves.

the solution is obtained by iteration on either the PT- or Ph-flash calculation. Any computations including the vapour quality  $q$  as input use a bubble/dew point calculation, which is much more difficult to perform and is far less robust than the flash algorithms.

To conclude, "PT" or "Ph" are recommended as thermodynamic states as these inputs allow for fast and robust fluid property calculations.

### Single and two-phase property calculations

The flash algorithm first determines the vapour and liquid composition of the fluid (computation of phase equilibrium), which indicates if the fluid state is in the two-phase or the single phase region. Then the vapour and liquid properties such as  $v$ ,  $h$ ,  $s$ , and  $u$  are computed. If applicable two-phase properties are calculated based on the single phase properties using appropriate mixing rules. The initial determination of the liquid and vapour composition is computationally very expensive and hence this step should be omitted if it is known a-prior that the fluid is present in the single phase. Therefore, the option of skipping the flash calculation and just performing a single phase calculation was implemented by using, for example, "PT-1ph" as input specification.

The flash vessel component is one example where this ability to explicitly indicate the fluid phase finds application. For the conditions in the vessel two-phase properties are required whereas in valves connected to the vapour and liquid outlet single phase properties are sufficient. Experience has shown, that by using single phase property computations where applicable throughout the process the simulation time can be reduced significantly (see Table 1).

### Redundant property calls

The model of a simple phase separation as depicted in Figure 5 provides another example on how the com-

putational efficiency can be improved by optimizing the property calculations. The flash vessel model contains a property call which determines required primary two-phase, liquid and vapour properties, such as  $h_{2ph}$ ,  $d_{2ph}$ ,  $h_{liq}$ ,  $d_{liq}$ ,  $h_{vap}$  and  $d_{vap}$ ,

$$prop_{2ph,liq,vap} = prop(P, T, X_{i,2ph}). \quad (6)$$

In the valve model connected to the vapour outlet of the flash vessel, the vapour density  $d_{vap}$  is required to close the set of conservation equations by

$$prop_{vap} = prop(P, T, X_{i,vap}). \quad (7)$$

It is obvious that, under the assumption of adiabatic operation and no frictional losses, both property computations provide the same result for the vapour density. However, the property calls are different due to the fact that in the vessel the two-phase mixture composition and in the valve the vapour composition is used as input. During the process of translating the model into a set of solvable equations, the compiler will not realize that the second property call is in principle redundant.

One solution to overcome this issue is to transfer the required density via additional output and input connectors from the flash vessel to the valve. This solution has been implemented as optional choice, which can be activated by the modeller. Another possibility would be the use of conditional connectors which transfer next to the flow and potential variables possibly an array of all fluid properties.

The improvement in computational time is summarized in Table 1. In comparison to the use of single phase property calls in the vapour valve the improvement is rather small. However, the aim is not to obtain the most efficient simulations but to demonstrate a modelling approach which might contribute to efficiency.

### Approximation of two-phase partial derivatives

One of the most time-consuming part of the property calculations is the computation of two-phase partial derivatives, which are for example required in the flash vessel component and absorber tray model (see equations 4 and 5)

The results of the partial derivatives are used in the mass and energy balances. Various tests indicated that if the change in the absolute value of the thermodynamic states during the simulations is small the resulting change in the value of the partial derivatives has hardly any impact on the simulation results. Therefore, following procedure has been implemented for the models of the CO<sub>2</sub> capture process.

Table 1: Simulation results of model with flash vessel and two control valves simulated for 2000 seconds.

Case	Valves	Vessel	Vessel	Total time [s]
	AllProps [s]	AllProps [s]	TwoPhaseDeriv [s]	
Reference (Valves normal "PT")	107.6	5.2	21.5	134.3
Valves "PT_1ph"	11.2	5.2	21.5	37.9
Vapour density transfer	7.2	5.2	21.5	33.9
Valves "PT_1ph", CallID	11.1	5.2	4.5	20.8

An additional variable (CallID) has been added to each two-phase component assigning each partial derivative function a unique identification. With this identification it is possible to distinguishably store simulation results in the Modelica-FluidProp interface of the different two-phase derivative calls throughout the modelled process (eg. LP Vessel CallID=1, MP Vessel CallID=2,...). Assuming the derivative function with the ID 1 is executed at a certain simulation time instance, then a check is performed if the difference between the current and the values from the previous time instance (which have been stored in the interface) are below a defined threshold. If that is the case, no property computation for the partial derivatives is performed but the stored results of the derivatives from the previous time instance are returned straight to Modelica. In case the threshold is exceeded, then a normal property calculation is performed with the external tool and the previous results stored in the interface are overwritten. This procedure has the benefit that computational time is saved if the change in the absolute value of the partial derivatives is marginal and thus has no impact on the solution. When modelling complex processes involving two-phase multi-component fluids a significant reduction in computational time can be obtained. Exemplary a comparison is provided for the model of the flash vessel with two control valves (see Table 1). The time spent for derivative computations reduces from 21.5 to 4.5 seconds for such a simple model.

## 5 Recommendations for a future interface

The presented model development approach leads to solvable models by making a smart choice for the thermodynamic and system state variables and by manually applying measures in order to keep the system in index-1 form. However, for reasons of numerical robustness, simulation speed and ease of initialization, a different choice of state variables might be more convenient than the one where the differentiated variables

are used as states. In order to allow for flexible state variable change and automatic index reduction partial derivatives of the thermodynamic properties are essential when using external tools, as demonstrated in this paper.

The goal is to design a Modelica library that interfaces to external property packages, whereby Modelica tools can automatically compute the total time derivatives of each variables in a set A (e.g. density, specific energy, specific enthalpy, ...) with respect to any meaningful subset of variables in a set B (e.g. pressure, temperature, specific enthalpy, ...) that uniquely identifies the thermodynamic properties of the fluid, including multi-component fluids and two-phase mixtures. This is required to successfully carry out the index reduction and/or state variable change task automatically. A first attempt on how to perform automated state variable change is presented by Wellner et al. [16].

At a higher level, this requires setting up a Modelica infrastructure where annotations point to the appropriate functions to compute all the required derivatives. At a lower level, it has to be ensured that the external property package can compute all required derivatives efficiently, i.e., by avoiding unnecessary duplicate computations.

## 6 Conclusions

This paper presents the development of a system model for a pre-combustion CO<sub>2</sub> capture process as part of an integrated gasification combined cycle power plant, which entails the modelling of highly non-ideal, two-phase multi-component mixtures. As this type of mixtures are currently not supported by available Modelica media libraries, an interface prototype was developed and tested with the fluid property package FluidProp for the modelling and simulation of the CO<sub>2</sub> capture process. Due to limitations regarding index reduction if using external property functions, an approach on how to develop index-1 models and choose system state variables as well as thermodynamic states appropriately is discussed.

For this type of simulations it appears that the computation of thermodynamic properties, in particular phase equilibria, accounts for the main share of the simulation time, therefore various ideas (single versus two-phase property calculations, decrease in redundancy, approximation of partial derivatives) are presented targeting computational efficiency. Further developments might focus on facilitating automated index reduction and making a wide range of partial derivatives available in a flexible and efficient manner. In an ideal setting, the tool allows for different choices of state variables and different solution strategies for the DAE system to find the best combination for the specific case of study.

## Acknowledgements

The work documented in this paper has been performed within the CO<sub>2</sub> Catch-up R&D programme aimed at demonstrating and optimising pre-combustion CO<sub>2</sub> capture technology for the energy sector. This programme is executed in a consortium of Vattenfall, TU Delft and ECN.

## Abstract

Models for dynamic simulation of a parabolic trough concentrating solar power (CSP) plant were developed in Modelica for the simulation software tool Dymola. The parabolic trough power plant has a two-tank indirect thermal storage with solar salt for the ability to dispatch electric power during hours when little or no solar irradiation is present. The complete system consists of models for incoming solar irradiation, a parabolic trough collector field, thermal storage and a simplified Rankine cycle. In this work, a parabolic trough power plant named Andasol located in Aldeire y La Calahorra, Spain is chosen as a reference system. The system model is later compared against performance data from this reference system in order to verify model implementation. Test cases with variation in solar insolation reflecting different seasons is set up and simulated. The tests show that the system model works as expected but lack some of the dynamics present in a real thermal power plant. This is due to the use of a simplified Rankine cycle. The collector and solar models are also verified against literature regarding performance and show good agreement.

*Keywords: concentrating solar power; parabolic trough; solar salt thermal storage; dynamic modeling; Dymola; Modelica.*

## 1 Introduction

Thermal solar power is a technology of which the solar irradiation on earth is harvested in order to produce power in the range of village type application of several kilowatts all the way up to grid connected power plants producing several hundred Megawatts. It is an environmentally friendly way of producing power not contributing to the rising amount of greenhouse gases and other hazardous particles that

are let out in the atmosphere by traditional fossil fired power plants.

The principle is to concentrate the solar irradiation using a configuration of mirrors to produce high temperature heat. The heat is then transported to a boiler where steam is produced for a steam turbine or the heat can be used to power a heat engine. A generator coupled with the turbine or heat engine is then producing electrical power. Some systems also have the capability to store heat for use during for instance cloudy days and at night. There is a range of different configurations available both in the way solar irradiation is concentrated and how the produced heat is used to generate power. The most common, in regards of development and number of units built, thermal solar power plants will be presented.

A thermal solar power plant can be divided into three subsystems consisting of the collector, the thermal storage and the power cycle. Another important aspect of the system is the medium that is used to transport heat from the collector field to the power cycle and the medium used for thermal storage. The different characteristics and the most common medium used in a typical thermal concentrating solar power plant will be presented.

### 1.1 Collector

The concentrating device of a thermal solar power plant consists of mirrors, the collector, focusing the incoming solar irradiation on to a heat-absorbing device, the receiver. This is done because the solar irradiation per square meter on earth is too small to heat anything to a desired temperature used in power generating applications. By concentrating the irradiation from a large area on to a small point high temperatures can be reached [1]. The arrangement of the mirrors differs depending on which type of CSP plant configuration that is used.

Most mirror configurations use a tracking system to follow the movement of the sun in the sky in order to maximize the heat collection throughout the day. This can be done with either one (east-west direction) or two axes (additionally north-south direction). Systems using one axis require less investment and maintenance cost at somewhat lower performance compared to two-axis tracking system.

### 1.2 Thermal storage

Thermal storage capability is the key to cost efficient and flexible CSP plant operation. With thermal storage the plant owner is able to dispatch power when it's most valuable which often is in the evening when there is low or little incoming solar irradiation and the electricity price is high. There are a number of thermal storage solutions that are both in operation and under development. The type that has gained the most attention in recent years is a system where heat is stored in molten nitrate. Other types use rock, sand and oil as storage media [2].

### 1.3 Power cycle

Most currently operating solar trough and power tower systems use a Rankine cycle for electricity production. Water is heated up in a boiler producing high-pressure steam that is fed into a steam turbine coupled to a generator. Temperature and pressure data depends on the turbine design and heat source. In CSP plant applications the thermal fluid medium reaches a temperature of 400 to 600 °C. This means that steam temperature of around 350 to 550 °C and a pressure of 100 bar is common. Some CSP plants use a heat engine (such as Stirling motor or Brayton cycle) to produce power. Most solar plants are located in sunny and dry climate and use an air cooled condenser instead of the more common use of water as cooling medium [3].

### 1.4 Thermal media

Different heat absorbing fluids are used in CSP plants operated today. The fluid is often mentioned the thermal heating fluid or just "THF" and is used to transport heat from the concentrating apparatus to the power cycle. Some systems that use a heat engine don't use any thermal heating fluid. The most common type of THF is a thermal oil that can be heated up to around 400 °C. There are also systems that use molten salt mixture which can be heated to around 500 °C, but need an advanced control system to prevent the salt to crystallize at around 200 °C. [4] [5].

## 2 Parabolic trough and other concentrating solar power technologies

In the parabolic trough type CSP plant the solar irradiation is concentrated by parabolic curved, trough-shaped reflectors onto a receiver pipe running along the inside of the curved surface. The medium in the receiver pipes is heated by the concentrated solar energy and used to produce steam in a Rankine cycle. The mirrors are typically placed in parallel rows along a north to south axis to be aligned towards the sun. A tracking system angles the mirrors to minimize the incidence angle from the solar beams. Trough systems can incorporate thermal storage. Many currently operating systems are hybrids meaning they can be supplementary fired with an alternative fuel (often natural gas) when the solar irradiation and heat storage is not enough to run the plant. A typical parabolic trough plant can produce 50 MW to 100 MW of electrical power. One of the largest operating CSP plants today, the Shams 1, is of parabolic trough type. It has a power output of 100 MW and is located in the Abu Dhabi Emirate. [4] [5]

The linear Fresnel system works in the same way as the parabolic trough with another collector and mirror design. The absorber is elevated with several mirrors mounted under the absorber tube. A separate tracking device gives the mirrors high flexibility to track the movement of the sun. This system has a lower investment and operation cost than the parabolic trough system. The major disadvantage is the lower solar to electricity efficiency [8].

Power tower systems use one central receiver mounted on top of a tower. A large amount mirrors, so called heliostats, are placed around the tower and track the sun in two axes. The THF is heated to rather high temperature and is used to produce steam in a Rankine cycle. Recently molten nitrate has been introduced which is also the most common medium used in the thermal storage, eliminating the need for a heat exchanger between the thermal heating fluid and the thermal storage fluid [6].

The parabolic dish system utilizes a large two axis parabolic mirror concentrating the incoming irradiation on to a receiver in the mirror focal point. The receiver is typically a heat powered motor meaning that the absorbed heat is used directly in the receiver to produce electricity. The setup has been realized in plants producing up to 5 MW of electricity.

### 3 Reference system

The most common and mature technology for thermal solar power is the parabolic trough design with indirect two-tank thermal storage capability [9], and chosen as the subject of this study. In order to model the system correctly regarding incoming solar irradiation a specific location on earth is needed. The Andasol power plant in Aldeire y La Calahorra, Spain, was chosen as reference system because the availability of performance data and plant design parameters. Technical specifications of the Andasol power plant are presented in Table 1 below [11].

Plant name	Andasol-I and Andasol-II
Plant location	Aldeire y La Calahorra, Spain
Plant type	Parabolic trough
Start date	June 1, 2009
Receiver type	Schott PRT-70
Sun tracking	One axis in north-south direction
Collector type	Flabeg RP-3
Thermal heating fluid type	Dowtherm A
Turbine type	Siemens SST-700 50MW steam turbine
Thermal heat storage type	Two-tank indirect with molten solar salt

Table 1 Andasol power plant specification

The thermal heating fluid used in Andasol-I and Andasol-II are of the type Dowtherm A. The system modeled will use another type of THF manufactured by Eastman Chemical Company with product name Therminol VP-1. Therminol is commonly used in concentrating solar power plants today [12]. Also, more technical data is available about the Therminol heat fluid than the Dowtherm type.

### 4 Modeling the solar power plant

The different system components described in section one will be implemented in Dymola. There are no solar power specific components present in available Modelica libraries today. After model implementation of the components an evaluation will be made against available data. Furthermore, when the different components are working properly they will be connected to a system model that will be compared against performance data given by the operator of the reference system.

#### 4.1 Media models

Both the THF circulated through the receivers and the fluid used in the thermal heat storage need to be implemented in Modelica for use in Dymola. A sim-

plified temperature dependent medium model is developed where thermodynamic state is interpolated from a table. The THF called Therminol is a clear, transparent synthetic oil made of an eutectic mixture of 73.5 % diphenyl oxide and 26.5 % biphenyl. The oil has one of the highest thermal stabilities of all organic heat transfer fluids and is stable in liquid phase between 12 °C and 400 °C. This makes it ideal for use in CSP applications [13].

The fluid used in the thermal heating storage is a mixture of 60 %  $NaNO_3$  and 40 %  $KNO_3$  by weight often referred to as solar salt. Solar salt is used because of its thermodynamic properties such as high heat capacity, high density, relatively low cost and low vapor pressure. The low vapor pressure makes the salt storage easy because no pressurized tanks are needed. Another favorable feature of solar salt is the high temperature stability and liquid phase up to 560 °C. The downside is that it has a rather high melting point starting to crystallize at 238 °C. This means that special care must be taken to prevent the salt from freezing causing major damage to pipes, pumps and heat exchangers [14]. The thermodynamic properties of solar salt are implemented in the same way as the THF (Therminol).

#### 4.2 Sun model

A set of different equations is needed to calculate the direct solar irradiation onto a surface, in this case a solar collector assembly, for a specific date, time and location on earth.

The term solar time is used when calculating the angles that are needed to determine how much direct radiation will hit a collector, and differs from the local time on earth. The difference in minutes can be expressed as follows [15]:

$$\text{solar time} - \text{local time} = 4 \cdot (L_{st} - L_{loc}) + E \quad (1)$$

Where  $L_{st}$  is the standard meridian for the local time zone,  $L_{loc}$  is the longitude of the location in degrees west and E is the equation of time.

Equation of time is expressed as:

$$E = 229.2 \cdot (0.000075 + 0.001868 \cdot \cos B - 0.032077 \cdot \sin B - 0.014615 \cdot \cos 2B - 0.04089 \cdot \sin 2B) \quad (2)$$

Where

$$B = (n - 1) \cdot \frac{360}{365} \quad (3)$$

And n = day of the year [15].

The angle of incidence of direct solar radiation onto a north to south axis tracking collector that is used at the Andasol plant can be calculated as follows [15]:

$$\cos \theta = (\cos \theta_z^2 + \cos^2 \delta^2 \cdot \sin \omega^2)^{0.5} \quad (4)$$

Where  $\delta$  is the declination, the angular position of the sun at solar noon [15].

$$\delta = 23.45 \cdot \sin\left(360 \frac{284+n}{365}\right) \quad (5)$$

$\omega$  is the hour angle, the angular displacement of the sun east or west of the local meridian due to rotation of the earth on its axis at 15° per hour [16].

$$\omega = (t_{sol} - 12) \cdot 15 \quad (6)$$

$\theta_z$  is the zenith angle, the angle of incidence of beam radiation on a horizontal surface [15].

$$\theta_z = \cos \phi \cdot \cos \delta \cdot \cos \omega + \sin \phi \cdot \sin \delta \quad (7)$$

Where  $\phi$  is the latitude.

The incidence angle is the angular difference  $\theta$  between the normal to the aperture and the actual solar irradiation that can be seen in Figure 1. When the direct beam radiation is not normal to the plane of the collector aperture there is a loss of direct beam radiation that scale with the cosines of the angle  $\theta$ .

Figure 1 A graphical interpretation of the angle between the aperture normal and the solar irradiation [16].

### 4.3 Collector model

The collector is a mirror shaped as a half cylindrical parabolic reflector focusing the incoming solar irradiation onto the absorber pipe. There are numerous equations to describe the geometry of the mirror and the image, distribution of solar radiation flux across the focus, it produces. It is assumed that the collector design already is optimized which gives the parameters that should be provided to the collector model in Dymola. The parameters of interest are the optical efficiency and collector aperture width and length.

The aperture width is the trough width and the total aperture area is the length of the collector times the aperture width. The total aperture area gives the total amount of solar irradiation that can be concentrated onto the receiver.

There are several models for the mirror loss that have to be taken into account. In this model a single parameter called optical efficiency,  $\eta_{opt}$ , is introduced to describe the total mirror efficiency. The different losses included in this parameter are listed in Table 2 below [16].

Tracking error	Inability of the collector to perfectly orient along the tracking angle. Twisting of the collector about the lengthwise axis.	$\eta_{track}$
Geometry defects	Poor alignment of the mirror modules.	$\eta_{geo}$
Mirror soiling	Dirt or soiling on the reflective surface that decreases the reflected amount of solar irradiation onto the absorber pipe.	$\eta_{soil}$
General error	Any other loss not covered by previous categories.	$\eta_{gen}$

Table 2 List of mirror losses.

This gives the optical efficiency:

$$\eta_{opt} = \eta_{track} \cdot \eta_{geo} \cdot \eta_{soil} \cdot \eta_{gen} \quad (8)$$

This efficiency term is multiplied with the total radiation incidence on the collector calculated earlier in the sun model and the total aperture area which gives the amount of incoming, reflected solar irradiation onto the receiver.

$$\dot{Q}_{receiver} = I_{field} \cdot A_{tot,aperture} \cdot \eta_{opt} \quad [W] \quad (9)$$

### 4.4 Receiver model

The amount of heat absorbed by the THF in the receiver model considers the amount lost due to radiation and convection to the surroundings. The radiation and convection losses, either natural in case in no wind or forced in case of wind, are heat transferred from the outer glass envelope of the receiver. Because of the long receiver length, in the Andasol case almost 90000 m, the temperature and heat losses will vary along the absorber axis. In this case the model is discretized i.e. the absorber pipe is divided in n number of segments. The heat transfer equations are then solved in each segment summing up to the total heat transfer. By doing this a much more accurate model is obtained as discussed in several studies on the subject [17]. The receiver can be represented as a thermal resistant network as shown in Figure 3. The temperatures denoted in the equations that follow are marked in Figure 2 and Figure 3.

The absorbed energy in the receiver pipe is modeled with a standard conduction heat transfer model for a metal wall already available in Modelon Base Library (MBL). It is assumed that the pipe is made out of standard carbon steel. The heat transferred through the metal wall is then absorbed by the THF by convection in a pipe model also already available in MBL.

Figure 2 Measurements and heat flow in receiver.

Figure 3 Receiver model represented as a thermal resistance network.

The outer surface in commercial absorbers is coated with special materials to decrease reflection from the surface. In the parameter settings for the receiver the surface emissivity of the pipe can be set to a value representing the current coating material.

From the pipe surface both convection and radiation occurs in the vacuum gap between the outer glass envelope and the pipe. The convection is modeled with a standard convective heat transfer model developed by Modelon. When this gap is under vacuum the convective heat transfer mechanism is molecular conduction between molecules. If the vacuum is lost for example by a crack in the glass cover the heat transfer mechanism is free convection [18]. It is assumed that vacuum is always present in the gap for this model and that the heat transfer coefficient for the vacuum of air is  $k_{c,gap} = 0.0001115 \text{ W/m}^2\text{K}$  [17]. The heat transfer coefficient is provided as a model parameter for the user which means that simulations with different vacuum properties or vacuum with different gases other than air can be made.

$$\dot{Q}_{gap,conv} = k_{c,gap} \cdot D_3 \cdot \pi \cdot L_{rec} \cdot (T_3 - T_4) \quad (10)$$

There were no models for radiation present in any Modelica library which had to be developed and based on following expressions:

$$\dot{Q}_{gap,rad} = \pi \cdot D_3 \cdot L_{rec} \cdot \gamma_{gap,rad} \cdot (T_3 - T_4) \quad (11)$$

$$\gamma_{gap,rad} = \sigma \cdot (T_3^2 - T_4^2) \cdot \frac{T_3 + T_4}{\frac{1}{\epsilon_3} + \frac{D_3}{D_4} \cdot \left(\frac{1}{\epsilon_4} - 1\right)} \quad (12)$$

Several assumptions were made in deriving this equation but the errors caused are relatively small [17]. The glass envelope is implemented as a heat transfer model including wall material with constant parameters developed by Modelon. The user needs to provide data for the glass material such as density, specific heat capacity and thermal conductivity. Most receiver glass envelopes are made out of borosilicate glass that has a very low coefficient of thermal expansion. This makes them resistant to thermal shock that is crucial in CSP applications [23].

Most of the solar irradiation concentrated onto the receiver is utilized by the THF but the receiver glass envelope also absorbs some heat. This raises the glass surface temperature and creates a temperature difference to the ambient. The amount of heat absorbed by the glass can be expressed as follows [19]:

$$\dot{Q}_{env,abs} = \dot{Q}_{receiver} \cdot \frac{\alpha_{env}}{\tau_{env} \cdot \alpha_{abs}} \quad (13)$$

Some of the heat transferred through the glass envelope is lost by radiation due to temperature differences between the glass and the sky. Convective heat transfer also occurs and is either natural or forced depending on if there is wind or not.

The radiation loss can be expressed as follows when assuming the glass envelope to be a small convex gray body surrounded by a large black body that represents the sky [17]:

$$\dot{Q}_{env,rad} = \sigma \cdot \pi \cdot D_4 \cdot L_{rec} \cdot (T_5^4 - T_{sky}^4) \quad (14)$$

The sky temperature can be assumed to be 8 degrees lower than the ambient temperature [20].

The convection from the outer surface of the glass envelope can be expressed as follows:

$$\dot{Q}_{env,conv} = h_{amb} \cdot \pi \cdot D_4 \cdot L_{rec} \cdot (T_5 - T_{amb}) \quad (15)$$

Where  $h_{amb}$  is the convective heat transfer coefficient to ambient.

For natural convection (no wind) the heat transfer function can be expressed as follows [17]:

$$h_{amb,nowind} = \overline{Nu} \cdot \frac{k_{56}}{D_4} \quad (16)$$

Where the Nusselt number can be calculated using a correlation developed by Churchill and Chu for a long isothermal horizontal cylinder [17].

All thermodynamic properties are calculated at the mean temperature between the envelope surface and the ambient temperature  $T_{56} = \frac{T_5 + T_{amb}}{2}$

Forced convection heat transfer will occur at windy conditions and is calculated in the same way as for natural convection but the Nusselt number will instead be estimated with Zhukauskas' correlation for external forced convection flow normal to an isothermal cylinder as follows from [17].

When the heat loss by radiation and convection from the envelope is known, and the same for the vacuum gap, the amount of heat absorbed by the thermal heating fluid is known:

$$\dot{Q}_{oil,conv} = \dot{Q}_{absorber} - \dot{Q}_{gap,rad} - \dot{Q}_{gap,conv} \quad (17)$$

$$\dot{Q}_{gap,rad} + \dot{Q}_{gap,conv} = \dot{Q}_{env,rad} + \dot{Q}_{env,conv} - \dot{Q}_{env,abs} \quad (18)$$

#### 4.5 Thermal storage model

The thermal storage task is to supply extra heat to the plant when the solar irradiation is below a certain value. In this case the outlet temperature of the THF from the collector field cannot reach the desired value of 393 °C, the design point temperature for the Andasol power plant. This is when the thermal storage instead is used heating the thermal heating fluid to 373 °C. It is not possible to reach the design point temperature because of losses in the heat exchanger between the thermal oil and the solar salt.

The collector field for the Andasol power plant is over-sized in order to be able to produce heat for both charging the thermal storage and the power cycle during the whole day and not only when the insolation is peaking in the middle of the day. With no thermal storage the collector field size could be reduced with approximately 40 %. After a couple of hours when the thermal storage is completely charged too much heat is absorbed just for the power cycle and a part of the collector field is intentionally defocused [20].

The heat from the THF is transferred to the solar salt via a heat exchanger with a 10 °C pinch point. When the solar salt is used to heat up the THF the system is reversed and the thermal fluid is heated up via the same heat exchanger. The THF will then reach an outlet temperature 10 °C below the solar salt inlet temperature. It is assumed that the thermal storage tanks are well insulated and no heat loss occurs.

The charging of the solar salt is made by tapping off a part of the heated THF from the collector field and redirecting this to the heat exchanger between the thermal oil and the solar salt. The mass flow rate of the thermal fluid through the heat exchanger is given by a simple energy balance and the fact that the minimum mass flow rate to the power cycle is known.

The discharging of heat from the thermal storage is a bit more complicated. The collector field is shut off via valves creating a new loop for the THF that runs through the thermal storage and then directly to the power cycle. This isolates the main THF pump creating the need for a secondary pump which is only used when discharging the thermal storage. The mass flow rate of this pump is calculated for the power cycle THF inlet temperature of 373 °C. The user can set the threshold value of incoming solar irradiation, the minimum amount of incoming solar irradiation where the system switches to run on the thermal storage. Under all simulations in this paper the value of 400 W/m<sup>2</sup> is used which means that the system will switch over to run on the thermal storage when the DNI is less than this value. The value has been chosen after testing the model and is not calculated.

#### 4.6 Rankine cycle model

The power cycle including boiler, steam turbine, generator and condenser is simply modeled. The Rankine power cycle model consists of a single heat exchanger where the THF flows on the primary side and the water boiled to steam on the secondary side. The water is supplied from a source and dumped in a sink meaning that there are no models for turbine, generator or condenser. By using this approach the thermal inertia of the otherwise big boiler is not accounted for. This means that the system modeled in Dymola will react too fast to changes in incoming thermal fluid temperature.

## 5 Modelica implementation

The Modelica language for dynamic simulations is ideal for CSP applications. The solar irradiation equations are time dependent and easily calculated after implementation in Modelica. There are different plant operating modes depending on solar insolation, amount of heat stored in the thermal storage and other events that has to be taken into account when the plant is simulated. There are also several modes the plant has to switch between in order to produce optimal amount of electricity to the grid. This kind of dynamics combined with automatic control, which Modelica is well suited for, makes it possible to test and simulate plant performance and behavior in a fine resolution. The downside with Modelica is a rather high threshold for new users.

The system model consists of Modelica implementation of the main components described and connecting them using system controller, see Figure 4.

- Sun model based on 15-minutes time series weather data on a file from a location close to Andasol plant in Spain
- Collector model consisting of own implementations of heat resistance and mirror models, and base classes (pipe and wall models) from Liquid Cooling Library (LCL) and Thermal Power Library (TPL)
- Thermal heat storage model implemented with own models combined with efficiency based heat exchanger model from MBL
- Simplified Rankine cycle solely consisting of source and sink terms and the same base class heat exchanger model from MBL
- Additionally a pump like component from LCL (setFlowRate) and an expansion volume component from MBL used for the thermal oil circuit.
- Thermal heating fluid (Therminol) implemented as table based media template class from LCL
- System controller for controlling mainly thermal heat storage as well as flow rate in the thermal oil and Rankine cycle circuits
- A summary record for key parameters and results

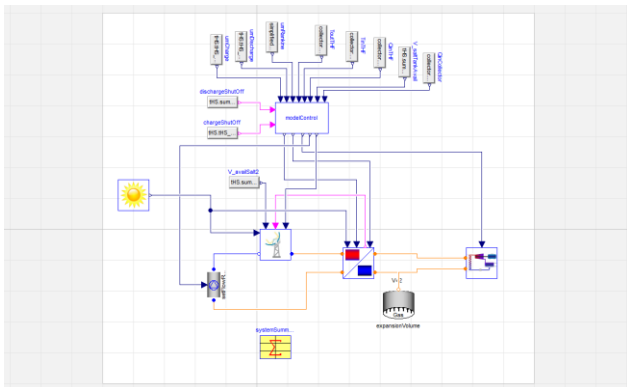

Figure 4 System model as in the Dymola Modeling view

## 6 Verification of system model

To verify the system performance a comparison with the Andasol I parabolic trough power plant is carried out with the same design parameters provided by the plant operator [22]. The goal is to match efficiencies from different parts of the system with them from the Andasol power plant. The thermal storage will not be used in this test, neither for heating up the salt nor to heat up the thermal fluid. They are left out from the simulation due to efficiency calculations that will turn out wrong if heat is added or subtracted from the

system. The performance numbers given by Andasol are based on an average typical weather year. To match the incoming solar irradiation a median value of the yearly incoming solar irradiation for a typical meteorological year were used as input to the system model and the specific simulation day was set to day no. 92 and the time to 10 AM. This represents a median value of the solar position.

Efficiency	Andasol	System model
Solar field – solar irradiance to steam	43 %	42.6 %
Rankine – steam to electricity	38.8 %	38.8 %
System – solar irradiance to electricity	16 %	16.5 %

Table 3 Results from system model validation.

As shown in Table 3 the values from the system model align well with plant data indicating a correct implementation of the system model. However, the Rankine efficiency is the whole cycle efficiency but in the system model only a simplified Rankine cycle is used. Therefore the same efficiency provided by Andasol was used to calculate the amount of electricity produced by the system model.

## 7 Results from test cases

In this section two different simulations from a clear and a partly clouded summer day respectively will be shown. By studying the behavior of the system model under these conditions, understanding of how the system handles solar irradiation variations can be gained. Information about system performance during a single day and how the system handles low values of solar insolation can also be obtained.

### 7.1 Simulation of a typical clear summer day

Flabeg, the manufacturer of the solar collector assemblies for the Andasol power plant is demonstrating the performance of the plant for a typical clear summer day in Figure 5. This figure serves as a benchmark and gives a hint of how the system model in Dymola should behave under similar conditions. The system model is set up to run on day 189 i.e. 8th of July, with the simulation starting at 4 AM and running for 24 hours. The results are presented in Figure 6 below.

As can be seen the simulation in Dymola is a bit more irregular than the presented graph from Flabeg, for instance some very sharp curves. The most obvious reason for this is that the graph of Figure 5 is a computer rendering and not based on actual calculations, which is the case for the other graphs.

Figure 5 Insolation and heat flow to and from different system parts of the Andasol power plant [21].

Figure 6 Heat flow to and from different system parts in the system model in Dymola.

There is a problem with the automatic control circuit causing the fluctuations in the beginning of the simulation in Figure 6. This could be avoided if the control parameters were to be optimized.

### 7.2 Partly clouded typical summer day

How the system behaves during a day which is partly clouded is investigated next with a custom set of solar data parsed to the system based on the data from the typical clear summer day, day no. 189. The incoming solar irradiation during the simulation is shown in Figure 7. The sudden drop in incoming solar irradiation is supposed to mimic a big cloud moving over the solar power plant. After three hours the cloud has passed and the solar irradiation goes back up again until the end of the day. The system results are shown in Figure 8.

At first the system behaves as in the clear summer day case shown in Figure 6 but when the sun is blocked by the cloud the thermal storage starts to discharge heat and the power plant can continue deliver power to the grid.

Figure 7 Direct normal insolation for the partly clouded day simulation.

Figure 8 Heat flow from and to different system parts for the partly clouded day simulation in Dymola.

When the cloud passes three hours later the system switches back to run on heated thermal oil from the collector field until the sun sets. Because of the blocking of the sun the thermal storage is not fully charged when the irradiation disappears and the system can only run on the thermal storage for just little under four hours. Another control strategy may be desirable in this case depending on the price fluctuation of electricity. If the price is higher in the evening, which it usually is, the system should not start to discharge heat from the thermal storage during the day. Instead the power cycle could be shut off or put at low load during these hours. The power cycle could then go back up and deliver maximum electrical power in the evening while utilizing the energy contained in the thermal storage.

## 8 Discussion

The goal with this paper was to successfully model and simulate a concentrating solar power plant of a parabolic trough type and compare results with data found in literature. Parabolic trough is the most common technology with a huge potential to deliver large amount of environmental friendly electricity.

In order to model other types of CSP plants the current models may be redesigned rather easily for a linear Fresnel system. However, this is not the case for the central receiver solar tower design and the parabolic dish type.

The simulation results (numbers) presented may not be very useful in its current form but the models developed can be used for research and future plant analysis and development. There is some old code already existing for dynamic simulations of parabolic trough plants in other simulation tools. These tools do not offer as high degree of flexibility as the models developed for Dymola. The Modelica models can easily be altered and customized for a specific plant design and shortens the project lead time in the design and verification project phases where simulation is important. If systems can be modeled with a high degree of accuracy the time from project start to plant startup can be shortened and the plant performance predicted on an early stage. New system design can be tested and evaluated in an early stage in Dymola and less physical prototype tests have to be done which is much more cost effective and leads to cheaper plant development cost.

The verification done on the solar and collector models and on the system model as a whole, shows good results, which is an indicator that a correct implementation of the loss models has been made. The collector and sun models are considered to be implemented adequately but the thermal storage model needs more work because of the simplifications.

No complete Rankine cycle was implemented which is a drawback but the overall results presented show strong similarities with manufacturer data.

The fast switching between modes, charging and discharging of the thermal storage, and certain irregular behavior could be avoided with better automatic control with parameters optimized for each simulation depending on how much solar irradiation hits the collector during the day. The effects of this dynamics have to be studied more carefully to gain knowledge of which control parameters to modify.

# Testing Power Plant Control Systems in Modelica

Kilian Link<sup>a</sup>, Leo Gall<sup>b</sup>

Julien Bonifay<sup>a</sup>, Matthias Buggert<sup>a</sup>

<sup>a</sup>Siemens AG, Energy Sector, Erlangen, Germany

<sup>b</sup>Bausch-Gall GmbH, Munich, Germany

## Abstract

This paper describes the status and findings of the development of a Modelica based test system for power plant controls. The development is part of the ITEA2 project MODRIO which has the main goal to improve the operation of plants by utilizing modeling, simulation and optimization techniques.

The control test application shown in this paper demonstrates the usability of Modelica to run comprehensive tests for plant controllers involving large parts of the physical plant and the control system. However it highlights the need for further development, in areas such as: the test system, the discrete part of the models, the Modelica language, Modelica Association standards such as FMI and ModelicaXML and the tool support for these.

*Keywords: SCADA; DCS; ModelicaXML; MODRIO; Controller Test*

## 1 Introduction

Flexibility in operation of power plants becomes more and more important. This trend started in the nineties of the last century due to the opening of the energy markets world wide. The growing part of renewable energy production and their positive discrimination to be dispatched accelerated the evolution of the remaining fossil power plants. Therefore demand for control quality of these plants increased.

Power plants are controlled by distributed control systems (DCS) [6]. This article focuses on the Siemens DCS SPPA-T3000, see [3] for more details. However, most of the results are transferable to all up to date DCSs.

The goal of the development presented here is to allow the easy testing of controllers for power plants developed in a DCS such as SPPA-T3000 at every

control engineer's desk. Therefore the effort to run these tests needs to be acceptable and iterative improvement of the controls needs to be supported. Having such a tool available offers some great benefits:

- Tests on the real plant shall be avoided, since these are:
  - Expensive, due to cost of fuel and loss of profit.
  - Dangerous, since they might cause damages.
  - Limited with respect to the number of tests and the allowed operating range.
- Speeds up the development of improved controllers.
- Will improve the quality and enable systematic quality assurance (QA).

During the requirements engineering phase it became apparent that users, i.e. the control engineers, consider using a test system for very different tasks and in all different phases of a project. This means that the system under development needs to cover different aspects such as early test of concepts on the one hand and regression testing for maintenance of existing control standards on the other. Apparently, this needs high flexibility on the modeling and simulation for the plant model in order to cover all different kinds of physical effects of the plant in an appropriate level of detail.

An agile software development approach was chosen for this project, because the control engineers, modeling experts and software developers had the chance to team up for this development. Having a working prototype early on, turned out to be very useful.

Everything afore mentioned, lead in the direction of a fully Modelica based approach, at least for the fast development of a prototype. Due to the urgent need for control testing in a running project this fully Modelica based prototype has than be applied to a

real life example which highlighted some important advantages of the Modelica solution:

1. No special support of the DCS (besides already existing export features, see section 3).
2. Comprehensive insight in the control and plant model.
3. No real-time requirement.
4. No need to develop interfaces, e.g. to a virtualized control system such as SPPA-S3000 [2].
5. Only a Modelica tool needed for deployment.

The major disadvantage is that this approach introduces a new source for bugs: The Modelica model of the control system (see section 3). Compared to the advantages mentioned above this seems to be acceptable.

## 2 Background

### 2.1 SPPA-T3000

SPPA-T3000 is a Siemens DCS system of the latest generation. Like most of its competitors the communication back bone is the IEC Fieldbus standard. It offers integrated functionality for plant operation (including HMI), Alarming, Data Archives, Engineering of the controls, Diagnostics for optimized plant maintenance and interfaces for field device communication [3]. It is notable that the online runtime system of SPPA-T3000 still consists of programmable logic controllers (PLCs), i.e. the SIMATIC S7. But even so the power plant control needs to be run on a few of these PLCs for performance reasons, the DCS system still provides a global namespace for all signals.

The global namespace for all signals introduces a motivation for systematic naming. In power plants the KKS (Power Plant Classification System) system is still commonly used, although newer standards like RDP-PP based on EN 81346 are available. Typically the plant model is more general and therefore less strictly named. Disregarding which of the mentioned naming standards are used for the control system, the interface to the plant model needs to be taken into consideration for the design of a control test system for power plants.

### 2.2 SiemensPower

The Modelica library SiemensPower is used for dynamic simulations throughout the entire lifetime of a power plant: from conception to decommissioning.

The primary target is to provide information on dynamic behavior of a plant to verify the feasibility of process concepts and control strategies.

Validation of operating and safety procedures as well as tests of control concepts before implementation on real plants is performed, using SiemensPower models.

Key features of SiemensPower are:

- Wide range of component models especially for combined cycle power plants.
- Control package to implement real plant control in simulation models that allows parsing of controls from SPPA-T3000.
- High performance TTSE (Tabular Taylor Series Expansion) water/steam function.

In the context of this paper, all equations describing the dynamics of the plant and of controls are implemented in SiemensPower.

## 3 Bringing the Control System into Modelica

This section describes how functional block diagrams are automatically transferred from SPPA-T3000 to a controller model in Modelica which can be simulated together with the plant model. Figure 1 shows the two steps of exporting and converting functional block diagrams.

First, the control engineer has to define a set of functional block diagrams which are to be tested. This subset of the full-plant control system is then exported from SPPA-T3000 into an XML file describing the diagram layout, connections and parameter settings.

Second, the XML output is translated into a Modelica package containing one model for each functional block diagram and a top-level class containing all open controller inputs. Therefore a customized T3000-Modelica parser has been developed. During the conversion, the graphical layout of block diagrams is preserved as much as possible in order to allow analyzing and changing the control layout in the same style as in SPPA-T3000. But there are limitations for blocks with conditional inputs. For example, T3000 icons are automatically adapted in height, according to the number of activated input connectors. Unfortunately in current Modelica, the means of adapting icons and connectors according to parameter settings are very limited.

Figure 1: Process from SPPA-T3000 XML to Modelica

The parsed controller package contains the layout, hierarchy and parameterization of control blocks as Modelica instances, but lacks the actual equations. All relevant blocks have been re-implemented in Modelica, similar to the approach of [1]. There is an option to use purely discrete equations or continuous equations as much as possible. Re-implementing all controller equations and integrating them into the component library SiemensPower was a considerable effort. This work has already been initiated for earlier projects, as there was a need for real-world control blocks in dynamic simulation studies. The validation work of all control blocks is still ongoing.

The global name space of SPPA-T3000 (see section 2.1) is replicated by the connection to an outer expandable connector (bus). Therefore, the parsed functional block diagrams do not have input/output connectors on the top level, instead they are connected via bus signals in KKS naming scheme.

Due to extensive bus usage, the T3000-Modelica parser can avoid generating a lot of connect equations through the model hierarchy. Furthermore changes in the control layout are facilitated as all signals can be retrieved from bus at any level, just as in the authoring tool SPPA-T3000. Due to the high number of bus instances in the model, compiling was not possible. The reasons were memory and performance limitations during translation. This has been solved by using the inner/outer concept of Modelica.

## 4 Plant Model

The overall combined cycle power plant and its district heating system has been modeled based on the in-house Modelica library SiemensPower.

### 4.1 Description of Plant Model

For this prototype the control of a district heating system of a combined cycle plant (CCPP) was investigated. The district heating system uses steam from steam turbine extractions in order to heat the water that will be supplied for district heating. The main function of the controller is to control the supply temperature of the water by means of several valves in the plant. Figure 2 shows a simplified schema of the model.

The model of the CCPP serves as dynamic and consistent boundary conditions for the district heating system. It was therefore reduced to a minimal level of detail. The gas turbine is a steady state model based on tables, the steam turbine sections are modelled using Stodola’s equation and a constant isentropic efficiency and the heat recovery steam generator is a lumped time delay model as proposed by VDI 3508.

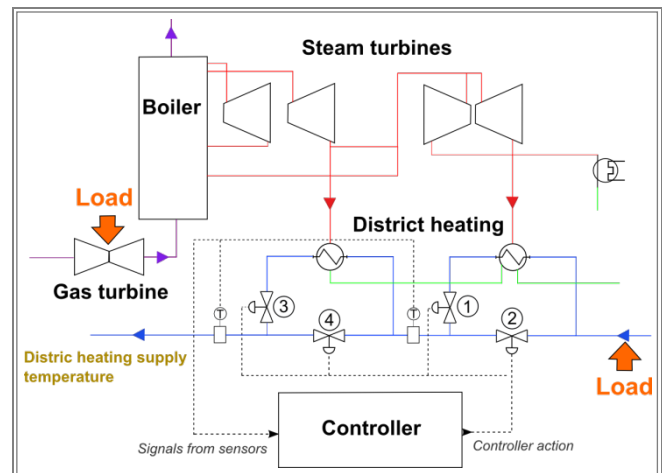

Figure 2: Simplified schema of the overall plant model with its controller

### 4.2 Components of District Heating System

A district heating system has long piping connections which can be longer than 100 meters, thus leading to large delays in the transport of enthalpy. To model this accurately while avoiding a huge number of elements in the discretized pipes, transmission line pipe models with spatial distribution for the enthalpy are used.

In the transmission line the enthalpy is delayed with a time  $\tau$ , solution of the following equation:

$$\text{Length of pipe} = \int_{t-\tau}^t \text{velocity}(t) dt$$

The controlled butterfly valves are modelled according to valve pressure loss correlation using a zeta (pressure loss coefficient) characteristic curve as function of opening angle:

$$\begin{aligned} \text{mass flow} &= \frac{\text{cross sectional area} \times \sqrt{2 \times \text{pressure difference} \times \text{density}}}{\text{zeta}(\text{angle})} \\ \text{massflow} &= \frac{\text{crosssectionalarea} \times \sqrt{2 \times \text{pressuredifference} \times \text{density}}}{\text{zeta}(\text{angle})} \\ \text{crosssectionalarea} &\times \frac{\sqrt{2 \times \text{pressuredifference} \times \text{density}}}{\text{zeta}(\text{angle})} \end{aligned}$$

To have realistic temperature transients, the heat exchange surfaces and especially the condensing heater need also to be correctly modeled. Hence, specific heat correlations for one and two phase flows are used [7].

Other important parts of the plant for a reliable controller test are the sensors. Due to the delay of enthalpy transport in the connection pipe, the exact position of the sensors is crucial. Further time delay within the sensors themselves must be also considered.

### 4.3 Size of Model

To improve the performance of the plant model an effort has been made to reduce the size of the non linear systems of equations at its maximum. This has been principally achieved by increasing the amount of continuous states, where appropriate. No system with higher amount of unknowns than 1 are left after manipulation of the non linear systems by the Modelica simulation tool (Dymola).

The plant model has around 464 continuous states and 4739 time-varying variables.

After adding the controller, the model keeps the same amount of continuous states as all controller variables are discrete and has in total 17095 time-varying variables.

## 5 Connecting Plant Model and Control System

A Test Unit is a Modelica model which instantiates one version of the plant model as well as the controller model (System under Test).

Figure 3 shows the current approach for signal handling. Besides connecting controller and plant model, the Test Unit is used for adding boundary conditions. Test Cases are then created by extending the Test Unit and adding disturbances and changing parameters. A benefit of storing all Test Cases in the Modelica package hierarchy is having one single source of information during simulation and testing.

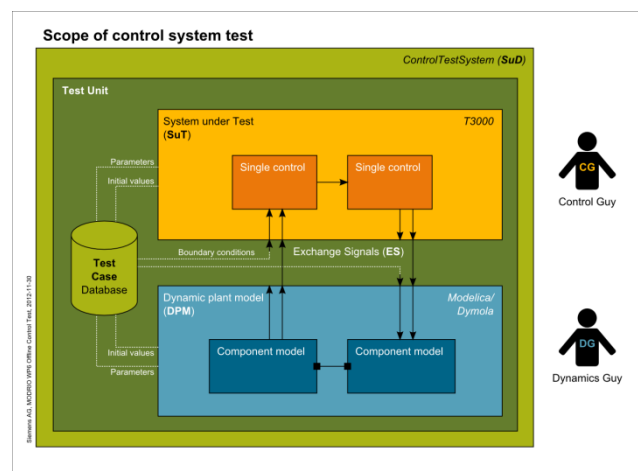

Figure 3: Test Unit with plant model and controller

The tested functional block diagrams usually depend on hundreds of Boolean and Real signals from the power plant control system. Therefore, setting appropriate boundary conditions is only possible in cooperation between control developers and dynamic simulation engineers. When connecting the models, additional unit conversions are necessary. The controllers work with non-SI units, which are adapted to different customer requests around the world. In order to avoid errors from manually converting units, an automated conversion of units is planned. The support through tools and the Modelica language for handling of non-SI units and factors could be improved (e.g. %).

Due to the chosen package structure, the controller can be updated (re-parsed) without requiring changes to the Test Unit, as long as no new boundary conditions are required. This enables efficient testing of various controller revisions.

## 6 Simulation

### 6.1 Performance Issues

The performance of plant model in open loop is very acceptable with a computation time considerably shorter than real time. Also, the computation of the discrete control signals at each one of its cycle time needs only an insignificant amount of computing resources. However, for the complete Test Unit, the time events generated at each cycle time of the control as well as the way how these time events are handled by the DAE solver dramatically deteriorate the performance of the plant model.

If it is not possible to avoid the generation of events at each control cycle time, one solution to improve the performance is by simply increasing the cycle time in order to reduce the amount of events. The cycle time in the DCS can typically go down to 100 ms. A cycle time of 400 ms can be chosen for the models, which greatly improves the performance. However, small instabilities in control actions can be noticed with this higher cycle time.

Another way to improve simulation performance is to change the DAE solver settings and the way it handles events. The Dassel solver starts for example its iteration after an event with the minimal step size, thus worsening the performance. While this can be modified for the Dassel solver in Dymola by manipulating the `dsin.txt` file, there is unfortunately a general lack of possibilities to influence solver settings in a user-friendly way.

An alternative attempt was to use FMI for Co-Simulation by packaging the controller in a FMU. This would offer the possibility to use two different solvers, a fixed step size solver (e.g. Euler) for the controller and a variable step size solver (e.g. Dassel) for the plant model. Due to the large size of the control model in terms of block instances (23000 in total) and amount of parameters, the simulation of the FMU in Dymola was unfortunately unsuccessful.

### 6.2 Results and Validation

A first validation test has been performed comparing the model behavior with measurement data from a real plant.

Boundaries of the model are set according to the measurements. As the model is covering the overall plant only few boundaries are needed. The necessary boundaries are the gas turbine load, the district heating load, and the set point for the district heating supply temperature.

The validation shows that the behavior of the model fits very well to the plant behavior. For instance, this can be observed for the valve openings on Figure 4.

Figure 4: Comparison of real plant and model for the valve openings

## 7 Conclusion

This paper shows that the simulation based test of control systems in Modelica is possible for industrial use cases.

The self-contained simulation setup revealed interesting benefits. First of all, absolutely no changes to the authoring tool (SPPA-T3000) were necessary. Secondly, the tested output file of SPPA-T3000 could be the same as used on the real plant.

Even if the Functional Mock-Up Interface (FMI) is “en vogue” in industrial applications, the tool dependencies are much lower with our self-contained simulation model in Modelica. We can avoid a complex co-simulation setup for testing and are open to fast changes on the plant model and controller as well as Test Cases. All parts of the model retain their hierarchical structure and can be investigated deeply during testing. This helps control engineers not only to work with but also to trust in the simulation based testing procedure.

On the downside, we are reaching the limits of what current Modelica tools can handle in terms of number of signals and simulation performance. And of course there is substantial maintenance effort in regards to SiemensPower library and the T3000-Modelica parser in order to provide a stable control test system for in-house users.

## 8 Outlook

Encouraged by the success of the existing prototype the development of the control test system will be continued. Naturally the prototype needs to be improved with respect to many aspects and the most severe shall be mentioned here.

First of all, the controller part is a fully time discrete model which is modeled using existing Modelica elements such as “when” clauses and “pre()”. Besides the sampling rate or cycle time being defined for the global scope, i.e. contrary to the real DCS all controllers run on the same cycle time. This simplification did not limit the capabilities of the prototype for the particular case. However, it is a strong limitation in general. Note, the limitation is not on the export of SPPA-T3000 or the parsing to Modelica, but on the modeling of the functional controller blocks. It is evident that Modelica’s new synchronous features [4] will help to improve the situation. Both, on the modeling part utilizing clocks and sampled systems as well as on the simulation part guaranteeing deterministic behavior.

Another missing part to allow model based control development is the backwards parsing to SPPA-T3000. This step is needed to close the cycle in case modifications to the controller have been implemented during testing in Modelica. Again, the development of this feature might be backed up by a recent Modelica Association development, namely ModelicaXML. If this is standardized and supported by Modelica tools it might be a big step in the right direction. Then, the remaining task to transform one standardized XML format into another standardized XML format will be of very limited effort.

## Acknowledgements

# Vehicle Thermal Management – A Case Study in Web-Based Engineering Analysis

Michael Tiller  
Xogeny Inc., USA  
michael.tiller@xogeny.com

## Abstract

Modelica has proven to be a compelling technology for creating sophisticated multi-domain models. It provides modern language features to promote model reuse and maximize developer productivity. These capabilities are backed up by proven simulation performance. More recently, the Functional Mockup Interface standard (FMI) has created an avenue for these models to be exported outside the model development environment as Functional Mockup Units (FMUs).

In this paper, we explore one possible way to utilize models that have been exported as FMUs. Specifically, we discuss how to incorporate these models into a web-based engineering analysis application that is designed to be accessible to non-expert users. Our goal is to show the important role that web and cloud based approaches can have in magnifying the impact of modeling activities across the enterprise.

We consider a specific engineering model and discuss exactly how we have transformed the model to make it accessible as a web-based application. This includes a discussion of the input and output data associated with the model as well as how a web based deployment (backed by cloud based services) can provide unique features compared to more conventional methods of model deployment.

**Keywords:** *FMI, cloud, web, HTML5, JavaScript*

## 1 Background

### 1.1 “Start the Revolution Without Me”

At the dawn of the world wide web, web servers served up static content (ordinary files) and web browsers rendered that content. What was remarkable about the web at this point was the ability to mix graphics and text using HTML and to hyperlink between pages. As the web matured, servers started to switch from serving static files to assembling content on a per request basis.

Up until 1998, the role of the web browser was simply to render this content produced by web servers. But in 1998, the “Web 2.0” revolution began. A big part of this revolution was the idea that the browser should become an application platform. Although at this point it wasn’t clear what technologies would ultimately win out for “executing” content through the web (Flash, Javascript or a variety of proprietary plugins), it was clear that a browser was no longer just for rendering hypertext.

Since 1998, the changes in the web browser platform have been nothing short of astounding. In fact, most users of these web browsers are probably not even aware of all the capabilities that have not only been added to web browsers but also standardized across browsers. Modern web browsers don’t just render hypertext, they can render vector graphics through SVG, detailed three dimensional scenes through WebGL, a wide variety of open ended rendering capabilities through canvas widgets and feature ever improving styling options through CSS. Along the way, the HTML specification has improved as well.

Behind the scenes, cloud based technologies are advancing by leaps and bounds. Every day new tools

and technologies emerge for supporting web-based applications. For example, there are now so many high-quality free options for databases that it is almost impossible to keep track of them. But this is true in nearly every area of web and cloud based technologies from Javascript frameworks to virtualization technologies.

The ubiquity of distributed computing resources is fundamentally changing the way we think about programming these large scale systems to make them more scalable and fault tolerant. This, in turn, has changed the way we think about programming. New languages and programming metaphors (*e.g.*, channels in Go[1][2], the `core.async` library in Clojure[3], actors in Akka[4] and promises[5]) are emerging to help us abstract away the behind the scenes complexity associated with these new distributed computing paradigms.

## 1.2 Engineering 2.0

But what does this mean for engineering? Almost nothing. While most engineers personal lives have been impacted somewhat by web based applications like Facebook, Twitter, Evernote, etc. their professional lives are still largely centered around applications, computing resources and storage tied to their local desktop. Simply put, the tools and capabilities in engineering are far from keeping pace with the proven technologies in other areas that have emerged over the last two decades.

Part of this effect is driven by the fact that engineering tools tend to be large and monolithic. This has resulted, in part, from industrial customers who approach adoption of engineering tools with a long list of requirements. This tends to foster a monolithic approach which, in an ironic twist, probably ends up hurting these customers in the long run.

One of the reasons that the technology industry seems to be better served by recent advances is that they are a more aggregated market. Engineering companies often attempt to differentiate themselves through what they feel are unique or innovative processes. The result is that their requirements are all slightly different from each other. This, in turn, means that vendors can rarely make a product that has broad market appeal in engineering. This leads to the situation that vendors often cannot justify sig-

nificant development resources or reinvestment because they are, ultimately, addressing a niche market. Moving forward, engineering and industrial companies need to collaborate more to drive standards and common best practices. In this way, more resources can be brought to bear on the problems that they all share.

While the web has evolved well beyond “web 2.0”, engineering is still waiting for the impact of those technologies to create an “engineering 2.0” revolution. Until then, engineering applications will remain largely centered around the desktop and subject to the same computing and storage limitations they always have and collaboration will be limited to “SharePoint” sites or network shared drives.

## 1.3 Xogeny

Xogeny was started to attack this problem head on. Xogeny is a new company with no legacy software to support. Everything we do starts with modern, proven technologies. There are countless technologies out there developed by technology giants like Google and Amazon that are simply there for the taking. Xogeny’s mission is to help build the bridges necessary to make these technologies accessible for engineering applications.

The first step in this process was to develop a platform to easily distribute simulation of FMUs to the cloud. We call this platform FMQ.

# 2 Representative Model

## 2.1 Vehicle Thermal Management

For the remainder of this paper, we will be discussing a Modelica model used to study vehicle thermal management. This model was developed by Modelon[6]<sup>1</sup> **without any prior consideration given to using it with the FMQ platform.**

The model itself is very sophisticated and includes detailed models of several different aspects of the vehicle. This model is used to simulate the thermal

---

<sup>1</sup>The author wish to thank Modelon for their participation in this case study and express his sincere appreciation for their support.

response of many individual components and subsystem during a prescribed drive cycle. Such analyses are important when optimizing system level efficiency to ensure that components are not oversized for their purpose and that control strategies are effective in managing thermal loads without reaching unacceptably high temperatures in components.

## 2.2 Model Compilation

The model itself was written in Modelica. As part of the normal modeling process (unrelated to any specific application involving FMQ), a considerable amount of engineering information was captured. For example, most parameters in this model include a description, physical units as well as minimum and maximum parameter values. Modelica makes associating such information with the model quite easy.

This Modelica code is then compiled into an Functional Mockup Unit (FMU) that conforms to the Functional Mockup Interface (FMI) specification[7]. One important thing to understand about this process of converting Modelica into an FMU is that much of the engineering information discussed previously is propagated into the FMU. So the descriptions, physical types and limits of parameters are available via the `modelDescription.xml` file in the FMU.

The FMI specification translates Modelica parameter values and solution variables into “flattened” names. This means that while the original Modelica model was hierarchical, the parameters and variables contained in the FMU are essentially just a simple list (not a tree structure) with fully qualified names that effectively indicate their location within the model instance hierarchy. The consequence of this is that organizational information from the Modelica model is only partially preserved (via the names).

## 2.3 Input and Output Data

As mentioned previously, variable names convey information about the relative positions of variables within the model hierarchy, but their organization within the FMU is flat. The parameters (input data) we are interested in characterize several different subsystems in the vehicle. These can be organized roughly into parameters related to the heat exchang-

ers, the powertrain and the chassis. Each of these different categories contains information about both the physical characteristics of components but also various control strategy calibration parameters as well. Also, some of these categories may have so many parameters associated with them that they necessitate further hierarchical organization. So, for example, the data associated with the heat exchangers is further broken down into information about stack geometry, fan control and scale factors.

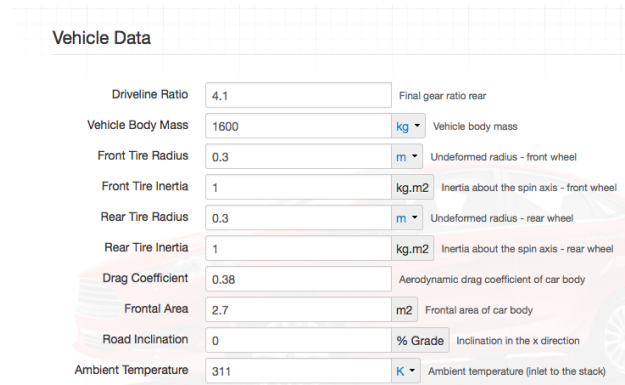

Figure 1: Input data panel

In addition to input data, there is also the question of what kinds of results can be generated from the FMU. In the case of this model, there are an enormous number of variables that are evaluated when the FMU is simulated. We won't attempt to list them all here, but the set of output variables consists of nearly any kind of information you might be interested in when exploring vehicle thermal management. As we will discuss shortly, we will only use a handful of these results. But it is worth noting that the FMQ platform itself is capable of computing and extracting whatever signals we need.

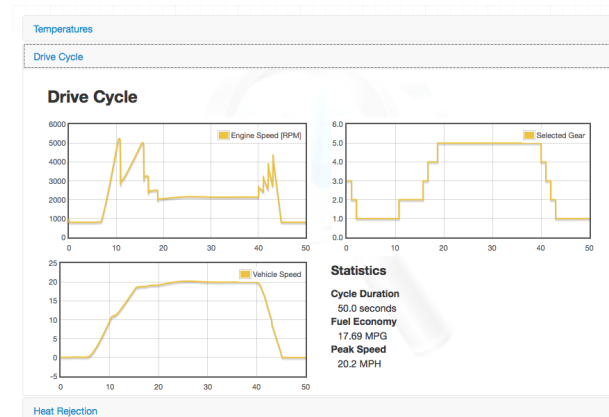

Figure 2: Output Report

### 3 Supporting Non-Experts

Before jumping into a discussion about web-based engineering analysis, it is worth taking some time to discuss **why** a web-based analysis tool is useful. The first thing to clarify is that this paper is not about web-based **development** tools. In other words, these tools are not designed for the creating Modelica models. The process of model development is a complex process and requires a sophisticated user interface. While creating a web-based development platform is a very interesting topic, it is not the topic of this paper. As such, for the purposes of this paper we assume that models are developed in an existing model development environment. The question we are focusing on is how to make these models accessible to non-developers or **non-experts in general**. So let us spend a little time considering a workflow that involves non-expert users.

Consider the following scenario. You are a software developer. You are writing software that you want lots of people to use. You work very hard developing the software and now you are ready to let other people use it. Imagine if circumstances required that instead of simply installing a compiled version of your code, users of your software had to buy all of your development tools (*e.g.*, Visual Studio), find a way to get the source code to your application, and then build your software for themselves.

If your “user” was an ordinary consumer (and not an open source hacker), this approach would be a complete disaster. Until recently if you were a Modelica developer, this would have been the only way to distribute your models **and** the compiler that your users would require could potentially be rather expensive. Fortunately, with the emergence of the FMI standard, we have an open and widely format for distributing models.

As a result, potential model “consumers” no longer have to compile the models themselves using expensive model development tools and their associated traps and pitfalls. However, simply having an FMU is not a complete solution for deploying models to non-expert users. There is still the issue of adding an appropriate graphical user interface. It is also important to recognize that non-expert users require an interface that is relatively straight-forward to use and warn users about potential mistakes. Such an application will typically expose a limited set of input and

output data. This data should be organized in a way that is intuitive to the user. Finally, an application developed for non-expert users must focus on addressing the specific questions of that user. If this means masking some or even most of the underlying models general capabilities, then so be it.

There is an (often uncaptured) return on investment for such efforts. Many model developers are forced to spend at least some of their time justifying the resources they consume for model development (in the form of time, expensive tools, etc). This concept of model deployment (*i.e.*, having an easy path for getting analyses leveraging your models into the hands of non-experts) is one potential way to demonstrate the need for model development resources. If model developers have an easy means to deploy models to end users and, as a result, turn those non-expert users into enthusiastic customers, then they have an opportunity to create a “pull” effect for their models. This can potentially lead to greater demand from the organizations that use those models. In such cases, this can lead to a virtuous cycle where the model developers can more easily justify their resource demands and, ideally, this increased demand will allow them to focus more resource on model development.

It is worth noting that non-expert users are generally interested in performing some kind of analysis. A model may be central to this analysis, but the analysis often involves more than just a single simulation of a single model. In a sense, a model is simply a complex function (*i.e.*, you give it data and it returns data). Creating and application and an high quality user experience involves much more than providing people with a function. We have deliberately used the term web-based engineering *analysis* applications because we think it is important to explicitly recognize that these applications must be prepared to support the complete analysis, not just part of it. Leveraging one or more models, a typical analysis will involve an optimization, a sensitivity study, a Monte-Carlo analysis or some other numerical procedure.

### 4 Web-Based Deployment

Given the requirements for non-expert users and the representative vehicle thermal management model previously discussed, the remaining question

is what should be the medium for model deployment.

## 4.1 Desktop Limitations

Given the case previously made for deploying models to non-expert users, one approach could be to develop desktop based analysis tools that are distributed to end users with the necessary models embedded in them. Indeed, one could argue that this is the conventional choice. But this approach has several important drawbacks.

The first issue to consider is data management. A tool that runs on a desktop has many inherent limitations. Typically, results files are simply written to a user's desktop and managing the results is left up to them. In some cases, running an analysis simply overwrites any previous analyses (making it very easy to lose data). A desktop environment makes it hard to collaborate with others because sharing results means sharing results files which are not easily shared when they are locked up in a desktop environment. Email and shared network drives are one way to address these issues, but they still involve a lot of manual work and discipline by users.

Another issue with the desktop is limited computing power. What if your analysis deals with uncertainty and requires a Monte-Carlo approach to simulating models. Or, what if you want to perform a large scale DOE or sensitivity study. There many types of analyses that could require hundreds, thousands or even more individual simulations. For even a high-end desktop environment, this could mean long wait times for analysts and this only aggravates the data management problem previously discussed.

In most organizations, a desktop application also means involvement with IT. The application has to be installed on the user's desktop and then updated when new releases come out. Getting the necessary IT resources to support installation across desktops is logistical aspect that must be dealt with and another drain on corporate resources.

## 4.2 Web-Based Client

To address many of these limitations, Xogeny has developed a set of tools for building web-based engineering analysis applications. These tools extract

information from FMUs and build a high-quality, intuitive user interface using this information.

As mentioned before, these FMUs frequently come from Modelica tools. As such, they include lots of useful information that can be automatically incorporated into the user interface. So, for example, such a web application can automatically incorporate logic to warn users about parameter values that are outside the expected limits. The nice thing about how these applications are built is that if the FMUs are updated, the information captured in them (parameters descriptions, default values, physical units, upper and lower limits) can be automatically incorporated into the application.

One might assume that a web browser is not an appropriate context for engineering applications because engineering applications require rich user interfaces with support for plotting, complex diagrams, detailed human machine interfaces or 3D animation. However, modern browsers have all this in the form of HTML5 support. Widely used web browsers like Firefox and Chrome can do all of these things seamlessly and without the need for any plugins.

A web-based application is easy to deploy and update because all that work can be done centrally once for all users. This reduces the impact on both the end user and the IT infrastructure to support installation and maintenance at the desktop. In fact, "installation" is typically as simple as circulating a URL to potential users. Furthermore, it is much easier to track usage and restrict access using a web-based approach.

In the case of the vehicle thermal management application, the web application can be found at the following URL<sup>2</sup>:

<http://vtm.demos.xogeny.com>

This user interface demonstrates that a high quality HTML5 user interface can be synthesized from information contained in an FMU. Such an interface can incorporate the necessary business logic to support non-expert users and operate in a way that is intuitive for most users.

But in order for this application to function, it must

<sup>2</sup>The "simulation" capabilities of the public web application have been removed. The results presented are actual simulate results, but they are simply injected rather than simulated. As a result, they are not affected by the parameter values in the UI.

be able to perform simulations. A web-browser generally has very limited access to the user’s desktop (certainly not enough to execute a simulation). So how does this interface perform the simulations required for the analysis? When the web application is compiled, support for simulation is compiled in through the `fmq.js` Javascript library. This library provides a native Javascript interface to the FMQ platforms cloud-based simulation capability. We’ll return to the simulation side shortly.

One last thing to note about the web-based user interface is the presence of a “History” view. This functionality is enabled by the **data management** features provided by FMQ. This view presents the user with a graphical history of their interactions and includes a tree structure of the different data sets that the user has either saved, simulated or is currently working with. It visualizes the relationships between each data set (which ones were derived from which). Hovering over a given version provides a summary of differences between that dataset and its parent dataset. All of this data is collected automatically and passively (*i.e.*, the user doesn’t have to do anything explicit or manually). Because this information is stored centrally, it would be easy to generate hyperlinks associated with each dataset visualized in the “History” view to share with colleagues. This kind of hyperlinking is the essence of the web but, unfortunately, it is not widely supported in the context of engineering tools.

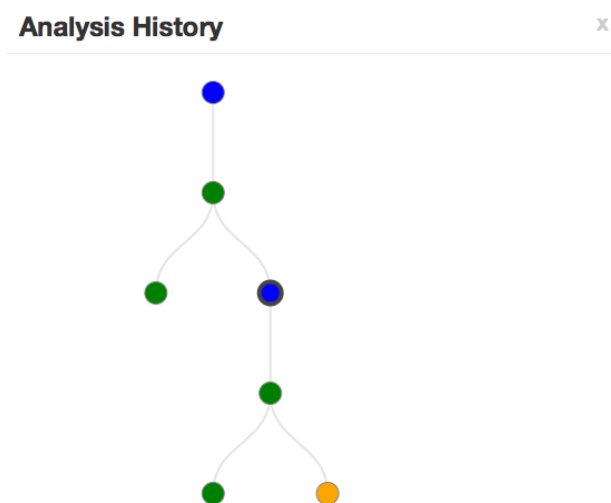

Figure 3: Visualization of data history

### 4.3 Cloud-Based Services

The central component of the FMQ platform (currently) is the ability to simulate an FMU. In this process, the FMU is registered in advance with the system and a RESTful web services API is used to request simulations involving specific parameter sets. This RESTful service can be accessed directly (to support large scale batch processing of FMU simulations) by making programmatic web requests or via a web-browser. For the web-based use case discussed in this paper, a special high-level Javascript library was developed that leverages the low-level RESTful API behind the scenes.

In addition to batch processing, the FMQ platform is capable of supporting interactive simulations. There are two sides to this interactivity. The first is the ability to stream simulation results interactively as the simulation is running. This means that clients can be asynchronously updated when new simulation results are generated. But it also means that the client can interactively feed **input** signals to the simulation while it is running as well. The result is the ability to create web-applications where the user manipulates the model and the model responds interactively.

Simulation results can be handled in several ways. We already discussed the ability to stream simulation results to the client as they are generated. In many cases, it may be preferable to simply wait until the simulation is complete and then provide the trajectory for key variables to the application. There are other cases where the web-based application may not have an immediate need for simulation results but it might wish to access them later. Finally, some types of analyses may generate large binary files as a by-product of the analysis (*e.g.*, a “meld” file from a simulation[8]). In those cases, the application may wish to access such artifacts. The FMQ platform supports all of these different use cases.

The FMQ services provide complete accountability for all data being processed. What this means is that for every analysis request being made, there is a record of the input data to the analysis and of all data generated from the analysis. Furthermore, the relationships between the job requests, job data, results and binary artifacts are all represented through FMQs Hypermedia API[9]. This provides a comprehensive approach to data management.

One final topic worth discussing is security. One of

the main concerns with any cloud-based solution is the security of the data. An important aspect of security is understanding exactly what “threat” is at issue and what techniques can be used to mitigate or eliminate those threats. A full discussion of such threats is beyond the scope of this paper but we are happy to discuss this topic. But it should be noted that the FMQ software is not tied to any particular platform or provider. As such, many of these security concerns can be addressed by **running the FMQ software on a computing cluster within the customer’s own internal network.**

## 5 Conclusion

This paper presents a representative engineering model and shows how that model can be shaped into an intuitive user interface with sufficient business logic and guidance to be used by a non-expert user. Such an application can directly leverage information already available from the FMU. The application can utilize an array of technologies already available in HTML5 to provide plotting, 3D rendering, sophisticated reports and human machine interfaces.

But more importantly, by leverage the capabilities already being actively developed and supported around web and cloud-based technologies, we can **improve** the engineering process providing better data management, greater opportunities for collaboration and data sharing as well as richer views of the engineering data and process by aggregating information that be automatically and passively collected through simple use of the application.

Ultimately, the goal of this work is to underscore the importance of model development. By providing an avenue for model developers to deploy their models to more users, we hope to create a positive feedback loop that will emphasize the value of model development and model-based system engineering that will, in turn, provide greater resources to model developers for creating high-quality, high-fidelity and high-impact engineering models.

This effort is really just the beginning. The FMI initiative helped to unify previously fragmented potential markets. The adoption of FMI has just started the process of building an eco-system around the FMI standard. FMQ is simply one example of how we can leverage the power of web and cloud based

resources and standardization to help drive improvements in the engineering world.

## Abstract

There are many different commonly used file formats for storing time series data. Most of these file formats are designed with the assumption that the file itself will be locally available to the software that will be reading or writing the data stored in them. While this assumption is an excellent one for desktop based tools with direct access to disk drives capable of moving virtually instantaneously around from sector to sector, there are a growing number of applications for which local access is not necessarily available. For these applications, we've initiated the recon project to develop more suitable formats.

With the emergence of web and cloud based modeling and simulation technologies, the time has come to explore file formats specifically optimized for non-desktop applications. In this paper, we present a new set of file formats that are specifically designed for web and cloud based approaches. This paper reviews the key requirements for web and cloud enabled applications and then presents a specification for two file formats that address those requirements.

When considering the various use cases that drove our requirements, we recognized that two different file formats were actually required. The first format, the `wall` format, is optimized for writing. The other format, the `mold` format, is optimized for reading over a network (*i.e.*, minimizing the number of reads and bytes read). We will discuss the layout of each of these formats and describe the use cases for which they are most appropriate.

In the open tradition of the Modelica Association, the authors have made specifications and implementations for these formats available as open source libraries with the hope that they will benefit the community as a whole.

**Keywords:** *Modelica, FMI, simulation results, cloud, web, open source*

## 1 Introduction

Several groups have examined the issue of standardized file formats[1, 2] in the context of Modelica. In keeping with the principles of the Modelica Association, an ideal choice would be a production ready format that is open source and cross-platform. With these requirements in mind, most people consider HDF5 a natural choice. There are already open source implementations and the file format has been widely used. In fact, it has even been adopted by The MathWorks for use in MATLAB.

But HDF5 has some practical drawbacks. The first is that it is not truly cross-platform. The reference implementation of HDF5 is written in C. The implementation is primarily targeted for use within C, C++ or Fortran applications. While there are various libraries available for reading HDF5 on the Java platform[3], they are incomplete and awkward to use.

Another issue with HDF5 is that for simple time-series data it is over engineered. HDF5 is feature rich, of that there is no question, but these features come at the cost of complexity. This is why you see very few implementations outside of the reference implementation. Furthermore, the file format makes extensive use of “seek” operations and assumes they are relatively inexpensive. This assumption is reasonable if you are able to communicate directly with the hard drive that the files are stored on, but it isn't reasonable when these files are only available through the network.

There are, of course, many standards for encoding data in web or cloud based environments. The most popular formats, by far, are Javascript Object Notation (or JSON, for short) and XML. There are other approaches as well like Google Protocol Buffers[4], Avro[5] and Thrift[6]. Different approaches have different goals. Some define schemas to add a level static checking. Others exist mainly to compress the data being transmitted. Finally, others exist to introduce a layer of interoperability with RPC frameworks or “big data” tools like Hadoop[7] and

Storm[8].

So where does that leave us? Should we adopt the tried and true standards from the engineering world and simply live with their lack of interoperability with important platforms like Java or Javascript and poor performance when accessed remotely? Or, should we adapt tools from the “big data” world, that were developed for quite different use cases, to work in the engineering world.

In some sense we’ve chosen a compromise. As we will see shortly, the `wall` and `meld` formats are fundamentally derived from the `msgpack`[9] specification. This gives us excellent cross platform compatibility. But `msgpack` is simply a serialization protocol. To address some of our more important concerns, to be discussed shortly, we needed to design a format the imposed additional structure on top of `msgpack`. So in this sense, we’ve created a set of original file formats that leverage open standards, like `msgpack`, but re-purpose them for modeling and simulation applications.

## 2 Goals

After independently reviewing various file formats, the authors were not happy with the existing options for web and cloud based modeling and simulation. The `recon` project started as a discussion about requirements. For our applications, the following requirements were identified:

### 2.1 Requirement 1 - Adding Data

Simulations are constantly producing additional data. For this reason, adding new data to an existing file is an operation performed many times during a simulation. For this reason, adding data to an existing file should be fast and easy. The key thing is to avoid having to rewrite previous data or, even worse, move data around within the file. For this reason, the ideal solution is to have the ability to simply append new data at the end of the file.

### 2.2 Requirement 2 - Minimizing I/O

In web and cloud based applications, it is not always practical to download the complete set of results for a simulation into the browser environment. There are many use cases where it would be best to be able to access results “on demand”. In these environments, such requests for data will be done via HTTP[10].

However, each of these requests will come with far greater latency than a simple request to read from a disk drive and far less bandwidth. As such, we would want to minimize the number of such requests and the amount of data necessary to transmit in each request. This means we need a way to “cluster” the data we are interested in so as to minimize both the number of requests required and the amount of data in each response.

### 2.3 Requirement 3 - Cross Platform Support

The file formats developed as part of the `recon` project are targeted at web and cloud based applications. Client side web programming is dominated by Javascript. On the other hand, server side programming is done in a wide variety of languages (*e.g.*, Java, Python, Javascript). Meanwhile, numerical analyses such as simulation are typically done in languages like C, C++ and FORTRAN. For this reason, it should be possible to implement libraries in all of these languages for generating and extracting simulation results.

### 2.4 Requirement 4 - Aliasing

One of the common patterns in component-oriented modeling approaches like Modelica is that many variables end up with exactly the same solution trajectories. When storing simulation results from such tools, it is useful to recognize that considerable disk space can be saved by recognizing the fact that these variables all share a common underlying solution trajectory. Typically, the data for each unique solution trajectory is stored once and each variable is simply a reference to the underlying solution trajectory. Even more storage can be saved by recognizing that some trajectories are related to other trajectories by very simple transformations (*e.g.*, a simple sign change). For this reason, it is very useful if these kinds of relationships are directly represented in the file format itself.

### 2.5 Requirement 5 - Data Types

When dealing with simulation results that come from the solution of differential equations, the main type of result is a solution trajectory. In these cases, both the dependent and independent variables are typically represented as floating point numbers.

But these are not the only types of data a simulation or other numerical analysis might yield. From the Modelica world, we might easily have results that are either reals, integers, booleans or strings (since these are all fundamental built-in types in Modelica). But why not hierarchical data structures (as represented by records in Modelica) as well?

## 2.6 Requirement 6 - Metadata

One issue with data files is that if you don't provide a means for associating metadata with entities in the file, the metadata will **become** entities in the file. For this reason, we deemed it important that metadata should be treated in a "first-class" way. Specifically, it should be possible to associate metadata with the file as a whole and with data structures in the file all the way down to individual signals. This would allow tools to persist other important information, beyond the solution, in these data files. For example, information about common plots or plotting options, descriptions of the signals, units or display units could all be managed in a structured way without being confused with data and without needing to be a formal part of the file format specification.

## 2.7 Requirement 7 - Hierarchy

Many tools create structures that are hierarchical. In the Modelica world, we have deep hierarchies of instances in simulated models. We also have hierarchies for packages and the definitions contained in them. So it is important that a file format can represent these hierarchies in some way.

In our experience, trying to organize results according to an instance hierarchy creates quite a bit of complexity. While tools could exploit some of the previous requirements (primarily 5 and 6) to achieve a hierarchical representation, we've found that simply encoding hierarchy in the names of variables (e.g., `car.engine.crankshaft.tau`) is typically sufficient and can avoid considerable complexity.

## 2.8 Requirement 8 - Easy Translation

Even though our goal is to have a format that is well suited to web and cloud based applications, it should also be capable of representing the kinds of simulation results we interact with in a desktop environment. For this reason, one of our requirements was the ability to translate data in the "dsres" format into

the recon formats. Such a translation should preserve all data and metadata normally associated with the "dsres" format. Furthermore, the resulting recon files should be approximately the same size as the original "dsres" file.

# 3 Approach

## 3.1 Reading vs. Writing

In reviewing these requirements, the main design challenge was trying to reconcile requirements 1 and 2. Implementing requirement 1 typically involves the need to write data out one row at a time, where each row represents the values of all the variables for successive solution times. As such, the solution values for any particular *variable* are widely spaced. However, requirement 2 requires us to be able to extract a given variable with a minimum number of I/O operations. In other words, requirement 1 typically results in data being fragmented while requirement 2 depends on that data being clustered together.

Our solution to this design problem was to design two file formats. The first, the `wa11` format, is designed for writing. Not only does it make adding data fast and efficient, it also supports, unlike the `dsres` approach, adding data for multiple tables at once. In practice, this means that if you have variables in your simulation that are partitioned such that they have different independent variables (as with the new clock semantics in Modelica 3.3), this format supports writing out new data for any of these variables. In other words, you can add results that may have completely different time bases. You can also include results from multiple simulations and use the metadata features to associate the specific parameter sets with each table.

The other format, the `me1d` format, is optimized for reading. Specifically, it is optimized for requirement 2. For an ideal format, it should be possible to extract a single result trajectory in a single read. This would act to minimize the impact of latency. Furthermore, the bytes read should contain only data associated with the desired signal. This would minimize the impact of limited bandwidth. As we will discuss shortly, the `me1d` file manages to achieve these performance characteristics for all but the first signal read.

Our expectation is that tools will write data out (during simulation) in the `wa11` format. Tools may choose to keep the data in this format. For platforms

where network access is not a requirement, the write optimized nature of the `wall` format will probably be adequate for both reading and writing. However for cases where data will be read over a network, we expect that tools will, upon completing a simulation, rewrite their data into the `me1d` format.

### 3.2 Serialization

There are really two aspects to each `recon` format. The first is the structure of the file (where different pieces of information reside in the file, something we'll discuss in Section 4) and the other is how the actual data is represented.

Obviously, the data is represented as individual bytes. So we must define the process by which multi-byte pieces of information (*e.g.*, floating point numbers) are “serialized” into bytes. One of the implicit goals of this project was to make a file format that was easy to read and write. Since serializing and deserializing data was a big part of the implementation, we could make the implementation much easier if we leveraged existing standards for serialization and deserialization.

One of the interesting things about coming from the web and cloud based application side is the ubiquity of JSON notation. While the Javascript language itself has many “unusual” semantics, the syntax and semantics around serialization and deserialization are surprisingly simple and intuitive. Unlike XML, for example, writing a parser for JSON and then mapping into a native language representation is surprisingly easy and widely supported.

However, JSON is a textual representation. The problem with a textual representation is the additional overhead of having to parse and interpret the text and convert, without any loss of precision, into a binary representation. For this reason, we didn't consider JSON by itself a practical approach to serialization and deserialization.

While we wanted to avoid the parsing aspect of JSON, the JSON data model[11] is well suited to our purposes and many different groups have attempted to create a binary representation that follows the JSON data model. So our initial approach was to consider BSON [12] which is a binary format that is formally specified and widely implemented because it is one of the cornerstones of the MongoDB database[13].

Unfortunately, the BSON serialization scheme has a significant drawback. The way it serializes arrays is very space inefficient. This is because JSON itself

supports sparse indexing of arrays. As a result, a serialization must include, for each value in the array, the index as well. This adds significant overhead. There is no way to specify that all elements in the array are sequential. As such, there is no way to avoid this significant penalty.

Fortunately, our reference implementation in Python[14] had a clean separation between the serialization scheme and the structural aspects. This made it very easy for us to experiment with other serialization techniques. We investigated other similar serialization schemes like Smile[15], BJSON[16] and UBJSON[17]. However, none of them seemed to have a critical mass behind them. Indeed, there doesn't seem to be a consensus in the JSON community on how to serialize JSON in a binary form.

As part of our investigation, we also looked at `msgpack`. It turned out that, like BSON, `msgpack` was formally specified and implemented for a wide variety of platforms[9]. Furthermore, in testing `msgpack`, we found that it had much better storage efficiency compared to BSON. So, in the end, we moved forward using the `msgpack` serialization scheme.

The `msgpack` approach had a couple of unanticipated benefits. In `msgpack`, floating point numbers can be encoded in either single or double precision representations. Also, the specification identifies and formally specifies several different optimizations to minimize the number of bytes required to store short integers or short strings. The underlying “types” permitted in this format map very easily into the JSON format which, in turn, means that it maps well into the native data types common across all the languages we are interested in. Finally, the `msgpack` serialization scheme includes an extension mechanism for including additional data types beyond those in the specification. While we don't have any immediate use for these extensions, it is nice to have that feature if we ever find that `msgpack`'s serialization is too constraining.

## 4 Specification

With the motivation behind us, let's turn to the actual specification of these formats. In this section we will describe the layout of both the `wall` format and the `me1d` format. As mentioned in the previous section, the serialization is done using `msgpack`. So we will focus mainly on the layout of data within the file. When describing the actual data being stored we will

use JSON notation to document the data with the implicit understanding that this data will be serialized and deserialized using `msgpack`.

Before we get into the specifications for each of these formats, it will be useful to discuss a few topics that are relevant to both formats. For example, what exactly are we storing in these file formats? Both formats support the storing of tables and objects. Tables are, as the name implies, a structure for storing tabular data. It is worth noting that there are no restrictions on what kind of data can be stored in a table except those imposed by the underlying `msgpack` format (which are very few). This means tables can mix integers, floats, doubles, longs, short ints, strings, booleans and even objects across different columns in the same table.

In addition to tables, we can register objects to be stored in our results file. These are essentially free-format pieces of data. The objects can be used to create arbitrarily deeply nested data structures that mix all varieties of data. Once again, the only limitations are those imposed by `msgpack` and/or the source language.

When storing tables and objects in a file, they must be referred to by names. The same namespace is used for both objects and tables (in other words, you cannot have a table with the same name as an object). It also means that no two tables and no two objects can share the same name either. The columns of each table are also named and no two columns within the same table can share the same name. But there is no such restriction between columns in different tables (or fields in different objects, for that matter).

Finally, it is worth noting that certain pieces of data are optional. In those cases, we have consistently followed a policy of leaving out both the key and the value. In other words, it is not sufficient to simply associate a null value with a key. **Both the key and the value must be removed** if there is no value provided. The guiding principle here is that parsers should not have to do excessive amounts of null value checking.

With that background out of the way, let's proceed with our explanation of the two file formats.

## 4.1 Wall Format

Recall that the `wall` format is optimized for writing and that this, in turn, means being able to easily add data. You can think of the `wall` format as being similar to a brick wall where each brick (new piece of data) is staggered with respect to others. As you will

see, we are **not** storing information in homogenous arrays and this means that we cannot predict the index of data simply based on information about which row or column it is in. Also note that it is possible to have data from two different tables interleaved between each other. This allows us to add data with two distinct time bases. But it makes the location of data even more difficult to predict. However, remember that the `wall` format is optimized for writing, not reading and that if network access is required then tools will typically rewrite their data into the `meld` format.

### 4.1.1 Leading Bytes

Each `wall` file starts with the following sequence of bytes:

```
0x72 0x65 0x63 0x6f 0x6e 0x3a 0x77
0x61 0x6c 0x6c 0x3a 0x76 0x30 0x31
```

This is a hex encoding of the ASCII string `recon:wall:v01`. This allows us to identify whether this is a `recon wall` file and, if so, what version of the specification should be applied.

The next four bytes are a binary encoding of the length of the header. This encoding is done in so-called "network byte order" (big-endian). The byte encoding of the length is not considered part of the header (*i.e.*, the length indicated doesn't include the 4 bytes that encode the length).

### 4.1.2 Header

Once the length of the header is known, the bytes for the header are read in. These bytes are assumed to have been serialized in `msgpack` format so we must next unpack (deserialize) these bytes. Once unpacked, the header should contain the following information:

```
{
  "fmeta": {<file-level metadata>},
  "tabs": {
    "<table name>": {<table data>}
  },
  "objs": {
    "<object name>": {<object metadata>}
  }
}
```

The "fmeta" key is associated with the value for any file level metadata. This metadata is, itself, represented in our notation here as an object in JSON but will be encoded as a map in `msgpack`. The "tabs"

key is associated with a value that maps the names of tables to table data. The format of this table data is as follows:

```
{
  "tmeta": {<table-level metadata>},
  "sigs": [<list of signals>],
  "als": {
    "<aliasname>": {
      "s": <base signal name>,
      "t": <transform string> // OPTIONAL
    }
  },
  "vmeta": {
    "<varname>": {
      <variable-level metadata>
    } // OPTIONAL
  }
}
```

The "tmeta" key is associated with metadata (again, represented as a msgpack map) but this time it is metadata associated with the table. In addition, we have the "sigs" key which represents an ordered list of signals. A signal represents an actual solution trajectory and the order is important because the order in this list indicates the order in which the data will be stored in successive rows (to be discussed shortly).

The "als" key represents any aliases present in the table. Again, this is a msgpack map where the name of the alias is the key. There are two essential pieces of information associated with each of the aliases. The first, stored under the "s" key (which stands for "signal") is the name of the base signal that this alias is based on. The "t" key is used to represent the transformation that should be applied to the base signal to compute the value of the alias signal. Note that this transformation is **optional**. The possible values will be described shortly in 4.3.

Finally we have the "vmeta" key, which is a map where the keys are the names of variables (*i.e.*, both signals and aliases) and the values are any metadata (again, stored as a msgpack map) associated with the named variable. Note that keys are only present in the "vmeta" map if there is metadata associated with that variable.

Returning to the header level entries, the "objs" key is associated with a value which is, in turn, a msgpack map. Each key in that map represents an object name and the value associated with those object name keys represents the metadata associated with the named object.

### 4.1.3 Entries

Following the header, the remainder of the file consists of "entries". Each entry is preceded by 4 bytes in network byte order indicating the length of the entry (again, the length indicated does not include the 4 bytes used to represent the length). All entries are encoded maps in msgpack format. There are two types of possible entries and there are no rules about which can be present (*i.e.*, they can appear in any order and be interleaved).

The first type is a "row entry" which details a new row for a specified table. The format of a row entry is as follows:

```
{
  "<table name>": [<list of signal values>]
}
```

where the table name must be a key in the "tabs" map found in the header and the order of values in the list of signal values must correspond to the order defined by the list associated with the "sigs" key value within that table.

The other entry type is a "field entry". These represent updates to the values of fields in objects and have the following format:

```
{
  "<object name>": {
    "<field name>": <field value>,
    "<field name>": <field value>
  }
}
```

Note that the header does not specify which fields are present in the object. This can only be determined by processing all the field entries and incorporating fields as they are given values. The complete value for a given object is determined by processing all field entries associated with that object in the order they appear in the wall file. The complete value is then simply the final value after all processing is completed. One consequence of this is that it is therefore possible to have the values of individual fields change while writing the file.

### 4.1.4 Wall Format Summary

The following outline attempts to summarize all the details presented so far:

```
// ID
0x72 0x65 0x63 0x6f 0x6e 0x3a 0x77
0x61 0x6c 0x6c 0x3a 0x76 0x30 0x31
```

```
// Header length, network order
0x?? 0x?? 0x?? 0x??
{
  "fmeta": {<file-level metadata>},
  "tabs": {
    <table name>: {
      "tmeta": {<table-level metadata>},
      "sigs": [<list of signals>],
      "als": {
        <aliasname>: {
          "s": <base signal name>,
          "t": <transform string> // OPTIONAL
        }
      },
    },
    "vmeta": {
      <varname>: {
        <variable-level metadata>
      } // OPTIONAL
    }
  },
  "objs": {
    <objname>: {<object metadata>}
  }
}

// Followed by zero or more entries
// which can be either...

// ...field entries...
0x?? 0x?? 0x?? 0x?? // entry length
{
  <object name>: {
    <field name>: <field value>,
    <field name>: <field value>
  },
}

// ...or row entries
0x?? 0x?? 0x?? 0x?? // entry length
{
  <table name>: [<list of signal values>]
}

```

where all maps are encoded in msgpack.

## 4.2 Meld Format

### 4.2.1 Leading Bytes

Each meld file starts with the following sequence of bytes:

```
0x72 0x65 0x63 0x6f 0x6e 0x3a 0x6d
0x65 0x6c 0x64 0x3a 0x76 0x30 0x31
```

This is a hex encoding of the ASCII string `recon:meld:v01`. This allows us to identify whether this is a recon meld file and, if so, what version of the specification should be applied.

The next four bytes are a binary encoding of the length of the header. This encoding is done in so-called “network byte order” (big-endian).

### 4.2.2 Header

Once the length of the header is known, the bytes for the header are read in. These bytes are assumed to have been serialized in msgpack format so we must next unpack these bytes. Once unpacked, the header should contain the following information:

```
{
  "fmeta": {<file-level metadata>},
  "tabs": {
    "<table name>": <table data>
  },
  "objs": {
    "<object name>": <object data>
  },
  "comp": true|false // Compression flag
}
```

This is very similar to the wall format presented in Section 4.1. Again, we see file level metadata exactly as it is used in the wall format. We also have the “tabs” and “objs” keys, also present in the wall format but with an important distinction which is that the values that follows them have a different format, as we shall see shortly.

But we also have a new key, the “comp” key, which isn’t present at all in the wall format. The value associated with the “comp” key indicates whether the remainder of the file (after the header) is not just encoded (using msgpack) but also compressed. If the value associated with the “comp” key is true, then all remaining msgpack encodings present in the file after the header are compressed using bz2[18] compression.

For reasons that will become obvious, the data for tables and objects is different in the meld header than in the wall header. In a meld file, the table data has the following format:

```
{
  "tmeta": {<table level metadata>},
  "vars": <list of variable names>,
  "toff": {
    "<varname>": {
      "i": <index of variable data>,
      "l": <length of variable data>,
      "t": <transform string> // OPTIONAL
    }
  },
  "vmeta": {
    "<varname>": {
      <variable level metadata>
    }
  }
}
```

```

    } // OPTIONAL
  }
}

```

The "tmeta" is, again, the table level metadata. Similarly, the "vmeta" key is associated with variable level metadata which is a map where the variable name is the key (again, only present if there is metadata associated with the specified variable) and the associated value is the variable level metadata.

The "vars" key is associated with an ordered list of the variables present in the file. The "toff" key is associated with a map that specifies important information about the location of the variables within the file. It is the "toff" data that makes it easy for us to extract individual signals. The "i" key is associated with the starting byte, within the file (starting from 0), of the data associated with the variable and the "l" key is associated with the length of that data. The optional "t" key defines the transformation, if any, to be applied to the variable data (see Section 4.3 for more details).

Returning to the header data, the object data associated with the "objs" key has the following format in a meld file:

```

{
  "ometa": {<object level metadata>},
  "i": <index of object data>,
  "l": <length of object data>
}

```

The "ometa" key is associated with the metadata of the associated object. The "i" and "l" keys are used just as they are within tables, to define the index and length, respectively, of the object data within the file.

#### 4.2.3 Variable Data

As discussed in Section 4.2.2, both variables (conceptually, columns in tables) and objects have an offset and a length provided in the header. In the case of a variable, the data that is extracted from that location in the file will be a **list** of values in msgpack format. The values in that list represent the values for the specified solution variables (first row first, last row last). In the case of an object, the data that is extracted from that location in the file will be a **map** where the keys in the map represent the fields present in the object and the values associated with those keys are the field values.

#### 4.2.4 Header Size

It is worth pointing out that when writing the file, the exact length of the header (when encoded in msgpack format) cannot be known *a priori* (we shall explain why, shortly). For this reason, a collection of bytes representing the largest possible size must be reserved for the header. The size of the header depends on the number of tables and objects as well as the number of signals in each table so it important that all of this information is known before determining the maximum number of bytes required to represent the header.

However, when the final version of the header is written out (once the location of all the data can be determined), its size may be less than originally anticipated. This is a result of the msgpack format's aggressive compression of small integers. For this reason, there may be a few unused bytes present between the end of the header and the first variable or object data in the file. While it is true that a few bytes will be wasted as a result, it really only means that msgpack's aggressive optimizations will be wasted in this case (and this case only).

#### 4.2.5 Meld Format Summary

The following outline attempts to summarize all the details presented so far:

```

// ID
0x72 0x65 0x63 0x6f 0x6e 0x3a 0x6d
0x65 0x6c 0x64 0x3a 0x76 0x30 0x31
// Header length, network order
0x?? 0x?? 0x?? 0x??
{
  "fmeta": {<file-level metadata>},
  "tabs": {
    "<table name>": {
      "tmeta": {<table level metadata>},
      "vars": <list of variable names>,
      "toff": {
        "<varname>": {
          "i": <index of variable data>,
          "l": <length of variable data>,
          "t": <transform string> // OPTIONAL
        }
      },
      "vmeta": {
        "<varname>": {
          <variable level metadata>
        } // OPTIONAL
      }
    }
  },
  "objs": {
    "<object name>": {
      "ometa": {<object level metadata>},
      "i": <index of object data>,

```

```

    "l": <length of object data>
  }
},
"comp": true|false // Compression flag
}

// Followed by any padding
// resulting from header shrinkage

// Followed by zero or more blocks
// of msgpacked data representing
// either vectors or objects whose
// offsets and lengths are specified
// in the header)

```

### 4.3 Transformations

In the previous sections, there were several mentions of a so-called “transform string”. This is an optional piece of information associated with an alias (in the case of the `wall` format) or a variable (in the case of the `meld` format). It defines the transformation, if any, that must be performed over some base data in order to retrieve the true value of the referenced data. There are presently only two allowed transformation types that are supported by the `recon` formats.

The first transformation type is the “inverse” transformation. This transformation is indicated when the transform string has a value of `"inv"`. The impact of the inverse transformation depends on the data type. For numeric data types, the inverse transformation causes the data to have its sign inverted. For boolean data, the inverse transformation applies a logical not operation to the data. With this simple transform alone, it is possible to avoid storing a significant amount of data.

The other transform type is the “affine” transform. This transformation is indicated when the transform string has a value of `"aff(s,o)"`, where `s` represents a scale factor and `o` represents an offset value. In the presence of this transformation, all **numeric** values in the base data should be multiplied by the scale factor, `s`, and then added to the offset value, `o`. As one reviewer of this paper noted, unit transforms are almost always affine in nature. This means that the affine transformation permits results to be stored in many different physical units without taking up any appreciable additional storage.

No transform should be applied to the data if:

- No transform string is present
- The transform string is unrecognized/cannot be parsed

- The transform does not apply to the underlying data type (e.g., applying the affine transformation to a Boolean value)
- There was an kind of error or exception when attempting to apply the transformation

In all but the first case, the tool or environment is strongly encourage to provide an error message alerting the user. Tools are also free to treat all but the first of these conditions as an error and suppress access to the alias data.

## 5 Discussion

### 5.1 Use Case

Although it is implicit in the requirements listed in Section 2, it is worth elaborating a bit more on the specific use case that drove these requirements.

For web and cloud based simulation, the bulk of the computational work is done remotely. In cloud services, there is an effect sometimes called “data gravity” which dictates that to improve overall throughput, the computing platforms tends to gravitate to where the data is stored (*i.e.*, the same service provider or at least ones that are connected with low latency, high bandwidth connections).

So if one seeks an optimal configuration where the computing and storage are well connected, it is easy to store the complete simulation results without any significant concerns for latency or bandwidth.

The complication comes from having to access that data via a “normal” network connection. A typical use case (and the one that we imagined while formulating our requirements) is one where a web application, running in a web browser, needs to display simulation results. The question then is how could such an application make effective use of simulations results generated “in the cloud”?

One approach to this could be for the web browser to download the complete simulation results. Without consideration for web and cloud based applications, such results might very likely be stored in formats like HDF5 or MATLAB version 4 format. The first problem is that these formats are not well supported in a Javascript environment. In fact, the authors are not aware of a single Javascript implementation that can read either format.

Even if you had Javascript implementations for these formats, this approach would necessitate having to download the entire file into some kind of “in

memory” representation to be parsed. This is because these formats do not provide a simple way to extract the required data via a few simple reads.

The other approach, the one we’ve taken for the recon project, is to use a format (of our own design, the me1d format) that is designed for remote access. Given access to header information (more on this in a moment), we can extract a single table column or single object with a single read. Furthermore, we can use the HTTP Range header to specify exactly which range of bytes we require. In this way, we only have to endure the latency of a single network request and we avoid transmitting any extraneous data which minimizes the impact of bandwidth limitations.

Note the previous paragraph presumes we already have the header information from the files. The worst case scenario for getting header information is to make two additional (one time only) network requests. The first request would be for the first 18 bytes (again, utilizing the Range header) to establish the size of the header. The next request would be to read the binary header data which includes information about the locations of all table columns and objects. Once these two requests have been made, the client would be able to access any object or column with only one additional request.

One of the things we’ve tried to do in this project is avoid solving problems that have already been solved. This was the motivation behind the use of msgpack, but we are also assuming that most network requests for data will be made using HTTP. This is a safe assumption given the ubiquitous nature of HTTP (or HTTPS, for that matter). But if we assume that requests are made via HTTP we also gain the additional benefits of caching.

Most networks are already equipped to efficiently handle caching transparently. Of course, within a given application, we might maintain a cache of headers for different results files that we may be interested in. But what about multiple users accessing these results across the same network? As it turns out, once one user accesses the file, it is quite likely that the header information will be stored in a caching proxy between the users network and the storage provider. This is a caching scenario that we cannot address within an application, but nevertheless, it is very likely that in such a multi-user environment the existing network proxies would transparently act to improve overall performance and enhance the user experience.

## 5.2 Metadata

As discussed throughout Section 4, the wall and meld formats have extensive support for metadata. This provides a clean mechanisms for including metadata in files without the need to mix it in or conflate it with actual data. Furthermore, metadata is supported for a wide range of entities represented in the file.

There are many potential applications for such metadata. For example, file level metadata can be used to store useful information such as who ran a simulation, what particular model they ran, what modifications (if any) were applied to the model or even a complete listing of all the parameter values that were used to simulate the model. In addition, general experimental data could also be stored in the results file.

Metadata at the signal level could be used to specify not just descriptions of those variables along with their physical units but, could also be used to include other attributes like start values, nominal values, *etc.*,

In summary, the recon formats make metadata a first class citizen within the file formats and this opens the door to many very useful applications involving metadata.

## 5.3 Performance

It is worth taking a moment to discuss the actual performance of this approach vs. existing approaches. As a baseline, we have generated a “representative results file” by simulating the R3 robot example from the Modelica Standard Library. This results file, produced by Dymola and written in the “dsres” format, will serve as our baseline.

The first issue we will examine is space efficiency. The baseline results take up 3,069,623 bytes of storage (for the storage options we selected). When stored in the me1d format **without compression** those same results take up 3,169,994 bytes. Note that this translation process from the dsres format to the me1d format preserves variable names and description strings as well as numerical trajectories. This means the me1d format is only 3.3% larger than the corresponding dsres file. If we enable compression, the me1d file is only 2,787,467 bytes which means it is almost 10% smaller than the dsres file.

So, in terms of storage, the me1d format is quite comparable to the dsres format. At first, this may seem counter-intuitive since we know, from our earlier discussion of msgpack, that arrays of floating

point numbers incur an extra byte for storage. However, the dsres format cannot store strings very efficiently and that long descriptions will result in enormous amounts of padding. So it would appear that, on net, these two effects cancel each other out. However, one advantage that the me1d format has that the dsres format doesn't (and an advantage that is not capitalized on in these benchmarks at all) is the wider range of alias transformations. In particular, it is possible to relate two signals via an affine transformation with the me1d format. Unfortunately, we do yet have any data on the potential savings this might offer.

Another benchmark worth considering is the time it takes to extract one particular trajectory from a results file. For extracting results from a dsres file, we used the `scipy.io.loadmat` function to load the `data_2` matrix and then extracted the 0<sup>th</sup> column (Time). In other words,

```
mat = loadmat("tests/fullRobot.mat")
T2 = mat["data_2"]
time = T2[0,:]
```

Running this script 5 times gave the following times (in milliseconds): 18.111, 18.143, 20.076, 19.309, 21.773 for an average time of 19.482 milliseconds.

In the case of the me1d file, we opened the results file, created a `MeldReader` object to read it, extracted the `data_2` table (called T2 in the translated file) and then extracted the data associated with the Time signal. That code looks as follows,

```
with open("dsres_robot.m1d", "rb") as fp:
    meld = MeldReader(fp)
    dt = meld.read_table("T2")
    time = dt.data("Time")
```

Running this script 5 times gave the following times (again, in milliseconds): 17.260, 18.074, 16.882, 14.608, 14.572 for an average time of 16.280 milliseconds.

It is worth noting the SciPy implementation is very mature and utilizes numpy internally. So one would expect excellent performance from that implementation. Nevertheless, extracting data based in the me1d format was over 15% faster on average.

The last benchmark will be reading multiple signals. In fact, our benchmark in this case will be to extract all transient signals into a Python dictionary. We will do this again for both formats. We used the following script to extract the same signals from the dsres file format:

```
ret = {}
mf = dymat.DyMatFile("tests/fullRobot.mat")
for signal in mf.names(2):
    ret[signal] = mf.data(signal)
ret["Time"] = mf.abscissa(2)
```

This code uses the `dymat` library which, in turn, leverages SciPy and numpy. Running this code 5 times gave the following execution times (in milliseconds): 519.50, 495.38, 483.60, 476.69 and 481.15 for an average execution time of 491.26 milliseconds.

The script for performing this benchmark using the me1d format looks as follows:

```
ret = {}
with open("dsres_robot.m1d", "rb") as fp:
    meld = MeldReader(fp)
    dt = meld.read_table("T2")
    for signal in dt.signals():
        ret[signal] = dt.data(signal)
```

Running this script 5 times, we record execution times (in milliseconds) of: 246.34, 240.66, 225.58, 224.22, 222.65 for an average of 231.89 milliseconds (over 50% faster compared to the dsres version of the benchmark).

In fairness, it is worth pointing out that we generally expect simulation tools to write output results in the wall format first and then convert them into the me1d format. As such, they will incur some penalty as a one-time cost when regenerating their results in the me1d format and this penalty is not taken into account here. Furthermore, this benchmark doesn't include any writing performance benchmarks (primarily because we have not connected any of these codes to actual simulation tools to measure write performance).

In summary, we do not have any benchmarks that compare write performance. But in terms of storage efficiency, the me1d file format was only 3% larger when compared to our baseline results in dsres format. On the other hand, in terms of read performance, the me1d format was between 15 and 50% faster depending on the amount of data to be read.

## 5.4 Implementations

As already mentioned, there is a reference implementation of both the wall and me1d formats already available in Python[14]. There are also implementations available for both C[19] and Java[20].

In addition, the wall format is also now supported by OpenModelica as of r18784. The implementation of the wall format required 408 lines

of code to implement in OpenModelica (this includes implementation of all necessary msgpack operations, *i.e.*, no external libraries are used to implement msgpack functionality) while the implementation of the “dsres” format uses 656 lines of code.

## 6 Conclusion

In conclusion, the recon file formats support many important features:

1. **easy to implement on a wide range of platforms** - An open source reference implementation is available in Python with implementations in C and Java already planned.
2. **efficient disk and network access** - These formats have been optimized for efficient network performance. But as the benchmarks show, these formats also perform very well for when results are stored locally on hard disks.
3. **first-class metadata** - With metadata available at all structural levels, results files can embed metadata in a clean and practical way. This has the potential to open up many new and interesting applications.
4. **tables containing mixed data types** - All data types are given equal treatment within the recon formats. As a result, it is possible to embed a wide variety of data and still maintain all the other benefits associated with these formats.
5. **richer alias transformations** - The recon formats support not only the common “inverse” transform, but a richer set of affine transformations. This could lead to further space efficiencies.
6. **efficient treatment of strings** - MATLAB version 4 files are very inefficient for storing collections of strings. By using msgpack for serialization, we get very efficient handling of string data.
7. **ability to store objects/structures** - Not all data is tabular. For example, parameter data used as input to simulations is more naturally represented as an object. There are many other examples of potential applications that need to represent data as objects. The recon formats even allow these objects to be embedded within tables.

The recon formats provide all these benefits without any significant compromise in storage efficiency.

# IDOS - (also) a Web Based Tool for Calibrating Modelica Models\*

Radoslaw Pytlak    Tomasz Tarnawski

Warsaw Technical University, Institute of Automatic Control and Robotics  
ul. Sw Andrzeja Boboli 8, 02-525 Warsaw

## Abstract

This paper presents a newly deployed server, IDOS, an online-accessible environment providing the service of solving optimal control problems. Development and deployment of the Interactive Dynamic Optimization Server is a result of projects funded by NCBiR (National Center for Research and Development). One of the outcomes of the project was a modeling language (Dynamic Optimization Modeling Language, DOML) providing a uniform format for defining dynamic optimization problems. DOML is an extension of Modelica language and hence, not only a user can specify his problem in the way he does in Modelica but also (more importantly, for the purpose of this paper) models created in Modelica for simulation purposes can be easily transferred to DOML for solving their related optimization problems. In particular, Modelica models can be calibrated with the help of our server. The paper tries to illustrate the point in depth. It presents the workings of the server and reviews the scope of solvers implemented, focusing especially on those that can be used for calibrating Modelica models. Special attention is devoted to an algorithm using adjoint equations for evaluating sensitivities of model equations with respect to parameters and to calibrating models described by higher index DAEs.

*Keywords: dynamic optimization; optimal control; model calibration*

## 1 Introduction

The paper describes computing environment IDOS accessed by Internet and created for solving opti-

mal control problems. The IDOS server is equipped with its Dynamic Optimization Modeling Language (DOML) for defining optimal control problems. The DOML format provides a mean for describing an optimal control problem in slightly extended Modelica syntax. It is very similar to Optimica ([1],[2]) and in fact its implementation is based on the JModelica.org Optimica compiler, although a number of features proposed in DOML set it apart from Optimica (these are described in detail in the accompanying paper [24]).

The IDOS server was created to provide means for solving optimal control problems by essentially different solvers such as: multiple shooting methods; methods based on *a priori* discretization of systems equations and then transforming the problem to a large-scale nonlinear programming problems; methods which use adjoint equations in order to evaluate reduced gradients of functionals defining the problem. From the beginning we have followed the idea that the server should enable a strategy of chaining of solvers—starting with some solver to get a rough approximation to the optimal control solution and then proceeding further with another solver which completes the solution process by giving an accurate solution to the problem. Having this in mind we knew from the beginning that the server should have as many different solvers as possible. Since all these solvers were to be invoked from the DOML script this approach enabled us to provide quite precise requirements for the dynamic optimization language. In the paper [24] we describe how that approach has been materialized in the form of new constructs put into the Modelica framework.

In the following sections the paper briefly describes the IDOS server by paying much attention to the types of optimal control problems which are supported by the server. Then we describe in some details numerical procedures which are avail-

\*The work presented in the paper has been partially supported by NCBiR grants: R02-0009-06, PBS1/A7/6/2012

able at the IDOS server and which can be used to calibrate various Modelica type problems. These solvers constitute a subset of all solvers available at IDOS which are also mentioned in the paper.

## 2 The IDOS server

The main task of the IDOS platform ([20],[19],[21],[26]) is to manage the processes of solving the dynamic optimization problems. Number of tasks that can be solved over a period of time depends on the server CPU. When its computing power is insufficient, optimization task are queued to be executed when the server resources are released. The solving process on IDOS is build of the general steps: 1) define the optimization problem using dedicated language (DOML, Dynamic Optimization Modeling Language); 2) submit the problem to IDOS platform; 3) interpret obtained results.

During the design process of the IDOS platform the following assumptions were made: 1) the primary goal of the system is to allow users to define, calculate and view results of optimization tasks; 2) all functions of the system will be available remotely via the Internet, without the need to install dedicated software on the user's machine. Different tools used to developed web applications will be used to fulfill this task; 3) the system is designed to manage several types of optimization libraries; 4) the system design is modular so it can be expanded and launched in stages (for example we can extend the system by adding computation servers or implementing support for newly developed numeric libraries); 5) the system should include user management module (registration, login). Each user should be able to define, calculate their own optimization tasks (within own account on the IDOS platform); 6) the results of optimization calculations shall be presented in a universal, unified form.

Each submitted optimization problem is processed in a pipeline fashion, beginning with a task data collection from a database and ending with storing the results. After a task is stored in a database and its status set as ready problem is located by a Data Base Adapter daemon (a process continuously running on the server). Next prepared task is analyzed by the DOML Compiler and in result C++ source code is generated (or compilation errors are reported if the submitted definition

was faulty). In the following step a C++ code is compiled. The final binary file is built on the base of optimization libraries stored on the IDOS server. The last step is the execution of the build binaries. When the job is finished, results are stored in the Central Archive database. If some error appeared its description is stored in the Central Configuration Database and the status of a task is set as failed. The optimization results are stored in uniquely named XML files. The name and location of each such file is stored in a central database.

## 3 Solvers implemented and libraries used

The IDOS server has been built to solve primarily the following optimal control problem

$$\min_u \phi(x(t_f)) \tag{1}$$

subject to the constraints:

$$F(\dot{x}, x, u, t) = 0 \text{ a.e. } t \in T = [0, t_f] \tag{2}$$

$$q(x(t), t) \leq 0, t \in T \tag{3}$$

$$h_i^1(x(t_k)) = 0, i \in E \tag{4}$$

$$h_j^2(x(t_k)) \leq 0, j \in I \tag{5}$$

$$u(t) \in \Omega \text{ a.e. } t \in T. \tag{6}$$

In general we assume that the structural index of equations (2) does not exceed three ([16]). If differential–algebraic equations in the above problem reduce to ODEs then more general problems (with respect to constraints) can be handled by the server.

At the moment the IDOS server can handle control problems described with ordinary equations and differential–algebraic equations but the incorporation into the IDOS solvers for problems with partial differential equations is also under way.

The IDOS server enables solving optimal control problems by using essentially different methods:

- a) based on an *a priori* discretization of systems equations–optimal control problem is then transformed to a large scale nonlinear programming problem;
- b) based on numerical methods for integrating system equations with variable stepsizes–reduced gradients are then evaluated with the help of the corresponding adjoint equations;

- c) based on shooting methods applied to differential equations derived from necessary optimality conditions for optimal control problems;
- d) based on adjoint equations for problems described by higher index differential–algebraic equations;
- e) based on Mixed Integer Programming algorithms for optimal control problems with ordinary differential equations in which some control variables take only integer values.

Obviously, not all solvers can be used on the every problem. Their applicability is briefly discussed below.

### 3.1 Optimal control problems described by ODEs

As far as optimal control problems described by ODEs are concerned essentially three different approaches to solving them are applied.

**In the first approach** system equations are discretized *a priori* (with respect to time) and in effect replaced by nonlinear algebraic equations. As a result, a large scale nonlinear programming problem (NLP) is solved. The main library used in this case is the OLADO package ([3]) which contains a wide range of optimization solvers, mostly based on some version of the SQP algorithm. Furthermore, in the OLADO package three different interior point QP solvers are available: procedure which implements Mehrotra’s primal-dual predictor-corrector method [13]; procedure based on the Mehrotra’s algorithm modified by R. Franke [6]; and the procedure which applies the Gondzio’s multiple centrality correctors variant of the primal-dual interior-point method for convex QP [8].

The IDOS server is also equipped with sparse nonlinear optimization HQP solver and its OMUSES interfaces to ODEs integrators ([7]). In particular, the HQP solver is linked with: procedures employing Euler, or simple Runge–Kutta fourth order rules (RK4); GRK4 procedure of Rosenbrock’s type ([11]); DOPRI5 procedure based on explicit Runge–Kutta scheme due to Dormand and Prince ([10]); IMP procedure which uses the implicit midpoint rule ([11]); SDIRK procedure based on singly diagonally implicit Runge–Kutta formula ([11]) and

with ODETS procedure which uses Taylor’s expansion of ODEs derived from ADOL–C driver routine `forodec`.

**The second approach** ‘preserves’ the continuous time of the optimal control problem to be solved. It means that during numerical treatment the system’s equations are integrated by a procedure with variable stepsizes. Since state variables are not decision variables the problem is considered in the, so called, reduced space, i.e. all functionals defining the problem are functionals of control variables only—gradients of these functionals, required by an optimization procedure, are evaluated with the help of the adjoint equations which are consistent with the system equations.

Essentially, there are two procedures on the IDOS server which follow this approach. In the first one, system equations are integrated by procedures from the `cvodes` part of the SUNDIALS package ([22]), also adjoint equations are integrated by procedures from the `cvodes`. Iteration of the optimization procedure is performed by IPOPT ([25]). In the second procedure, implicit Runge–Kutta method is employed for system equations integration and adjoint equations are evaluated in accordance with the discretization of ODEs by the integration procedure. In this case optimization is performed by the SQP method which applies an active set strategy ([17]). The procedure described in [17] was designed to cope efficiently with control problems with state constraints.

**The third approach** to optimal control problems with ODEs deals with multiple shooting methods. At the moment within the IDOS server an indirect shooting method based on Oberle’s code ([14]) is implemented.

### 3.2 Optimal control problems described by DAEs

The server currently offers two procedures for solving optimal control problems with DAEs. The first one is aimed at problems whose differential–algebraic equations have index one. It is based on the implicit Runge–Kutta integration procedure but adopted to index one DAEs in the semi-explicit form ([17]). The optimization engine used here is the SQP procedure which uses an active set strategy in corresponding QP subproblems (a range–space variant of it).

The second procedure carries out the unique approach to optimal control problems with higher

index DAEs described in [18]. The approach does not require the system to be transformed from DAEs to ODEs (through differentiation, with respect to time, of selected algebraic equations). Instead, the constructed procedure employs an implicit Runge–Kutta method for system equations integration. We use Radau IIA method as implemented in [11] (see also [9]). Reduced gradients are evaluated on the basis of adjoint equations defined for discretized (by the integration procedure) system equations. The procedure uses the algorithm for consistent initialization of system equations and for that purpose the method based the Pantelides’ algorithm ([15]) and the `kinsol` procedure from the SUNDIALS package was implemented. To our knowledge, it is the first successfully implemented procedure for solving optimal control problems described by higher index DAEs which does not need transformation of the DAEs to the underlying ODEs.

### 3.3 Optimal control problems with integer valued controls

For the moment, optimal control problems with integer valued controls solved at the IDOS server can only have ordinary differential equations. For these problems we used BONMIN package (see e.g. [4], [5]). It has been integrated with the OLADO library and with the procedures based on the `cvodes` procedures from SUNDIALS package.

Table 1 summarizes to some extent the solvers structure of the IDOS server — in fact it is much more complex since, for instance, procedures such as `cvodes`, or BONMIN contain themselves a number of essentially different methods which can be accessed by setting their parameters. Furthermore, the server employs ADOL–C package for performing automatic differentiation and OpenBLAS package for linear algebra operations.

The code developed for the server is meant as open source<sup>1</sup> (most of the libraries used by the server are open-source, as well, see Table 1), hence one could deploy own instances of IDOS server, at least in principle. The experience teaches, however, that installation, configuration and maintenance of all required packages is in itself far from trivial. For that reason, at this point there is no dedicated distribution package for automated in-

## 4 Estimation of models parameters

Suppose that we have the dynamic model with parameters  $p$ :

$$\dot{x}(t) = f(x(t), t, p), \quad t \in [0, t_f], \quad x(0) = x_0. \quad (7)$$

which solution  $x^p$  is dependent on parameters  $p$ . It is often the case that such model describes a real life, observable phenomenon but the exact values of its parameters are unknown. Then, they could be approximated by solving nonlinear least squares problem:

$$\min_p \sum_{k=1}^N [(x_l(t_k) - x_l^e(t_k))^2] \quad (8)$$

subject to the constraints (7), where  $x_l^e$  is an empirical (measured) trajectory.

Since  $x$  is a function of parameters  $p$ , the problem can be stated as

$$\min_p \left[ F(p) = \sum_{k=1}^N (x_l^p(t_k) - x_l^e(t_k))^2 \right] \quad (9)$$

That problem can be solved by nonlinear programming techniques provided that we can evaluate gradients of  $F(p)$ . In particular, we can apply the Gauss–Newton algorithm (see section 5) to problem (9) taking advantage of the least–squares structure of its objective function.

The gradient of the functional  $F(p)$  may be evaluated with the help of adjoint equations if we observe that  $F(p)$  is composed of  $N$  functions  $F^k(p)$ :

$$F^k(p) = (x_l^p(t_k) - x_l^e(t_k))^2$$

where  $x^p$  is the solution to the equations (7).

The gradient of  $F^k(p)$  is given by the formula:

$$\nabla F^k(p) = \int_0^{t_k} f_p(x(t), t, p)^T q_k(t) dt \quad (10)$$

where  $q_k$  is the solution to the adjoint equations

$$\begin{aligned} q_k(t_k) &= Q_k \\ \dot{q}_k(t) &= -f_x(x(t), t, p)^T q_k(t), \quad t \in [0, t_k). \end{aligned}$$

Here,

$$Q_k = \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 2(x_l(t_k) - x_l^e(t_k)) \\ 0 \\ \vdots \\ 0 \end{bmatrix}$$

Then  $\nabla F(p) = \sum_{k=1}^N \nabla F^k(p)$ .

Having objective function values and its gradients we can build an optimization procedure for model calibration. A general scheme for these procedure may look like stated below:

### General Calibration Procedure

1. Set initial values of parameters:  $p_1$  and set  $k = 1$ .
2. For parameters  $p_k$  calculate system trajectories  $x^{p_k}$  by numerically integrating system equations using, for example, procedure `cvoides` from SUNDIALS package. On that basis determine objective function value  $F(p_k)$  through values  $F^l(p_k)$ ,  $l = 1, \dots, N$ .
3. Having trajectories  $x^{p_k}$  and values  $F^l(p_k)$ ,  $l = 1, \dots, N$  solve adjoint equations (using, for example procedure `cvoides`), and determine  $\nabla F^l(p_k)$ ,  $l = 1, \dots, N$ s and  $\nabla F(p_k)$ .

4. Determine the direction of descent using some optimization procedure (for example, `Ipopt`).
5. Perform directional minimization with the help of optimization procedure to evaluate step size  $\alpha_k$ . Substitute  $p_{k+1} = p_k + \alpha_k d_k$ . increase  $k$  by one and go to Step 2).

## 5 Gauss–Newton method for the least squares problem

One approach to implementing the just-outlined general calibration procedure makes use of the Gauss–Newton method for solving nonlinear least squares problems. For the purpose of discussing it, consider the following optimization problem:

$$\min_{x \in \mathcal{R}^n} \left[ f(x) = \frac{1}{2} \|g(x)\|^2 = \frac{1}{2} \sum_{i=1}^m \|g_i(x)\|^2 \right] \quad (11)$$

where

$$g(x) = \begin{bmatrix} g_1(x) \\ g_2(x) \\ \vdots \\ g_m(x) \end{bmatrix}. \quad (12)$$

In this case, the gradient and the Hessian matrix of the objective function (11) are defined as follows:

$$\begin{aligned} \nabla f(x) &= \sum_{i=1}^m g_i(x) \nabla g_i(x) = J(x)^T g(x) \\ \nabla^2 f(x) &= \sum_{i=1}^m \nabla g_i(x) \nabla g_i(x) + \sum_{i=1}^m g_i(x) \nabla^2 g_i(x) \\ &= J(x)^T J(x) + \sum_{i=1}^m g_i(x) \nabla^2 g_i(x). \end{aligned}$$

Here,  $J(x)$  is the Jacobian matrix of the transformation matrix (12). Assuming that  $g_i(x) \nabla^2 g_i(x) \approx 0$  we can write

$$\nabla^2 f(x) \approx J(x)^T J(x).$$

The Gauss–Newton method minimizes, at every iteration, linearization of  $g$  at the point  $x_k$ :

$$\tilde{g}(x_k; x) = g(x_k) + J(x_k)(x - x_k).$$

The next point  $x_{k+1}$  is obtained by solving the problem

$$\min_{x \in \mathcal{R}^n} \frac{1}{2} \|\tilde{g}(x_k; x)\|^2.$$

Then

$$x_{k+1} = x_k - \left( J(x_k)^T J(x_k) \right)^{-1} J(x_k)^T g(x_k) \quad (13)$$

It is a descent method since

$$-J(x_k)^T g(x_k)$$

is a descent direction for the function  $\frac{1}{2} \|g(x_k)\|^2$ , because

$$\nabla \left( \frac{1}{2} \|g(x_k)\|^2 \right) = J(x_k)^T g(x_k)$$

and provided that

$$\left( J(x_k)^T J(x_k) \right) > 0$$

(it means matrix positiveness).

The outlined algorithm is most often applied with the modifications

$$x_{k+1} = x_k - \alpha_k \left( J(x_k)^T J(x_k) + \Delta_k \right)^T \times J(x_k)^T g(x_k), \quad (14)$$

where  $\alpha_k > 0$  is the result of the directional minimization, and  $\Delta_k$  is such diagonal matrix that

$$\left( J(x_k)^T J(x_k) + \Delta_k \right) > 0.$$

If the least squares problem is used to calibrate a model then on the basis of experimental data  $\{y_i, z_i\}_1^m$  we evaluate models parameters  $x$

$$z = h(y, x).$$

In this case models parameters are calculated by solving the optimization problem

$$\min_x \left[ f(x) = \frac{1}{2} \sum_{i=1}^m \|z_i - h(y_i, x)\|^2 \right].$$

The Gauss–Newton approach was implemented along the lines of the *General Calibration Procedure* presented in Section 4. In Step 4) of the procedure, the direction of descent  $d_k$  is determined

on the basis of vectors  $\nabla F^l(p_k)$ ,  $l = 1, \dots, N$  and  $\nabla F(p_k)$ . By referring to relations (13)–(14) we set

$$\begin{aligned} J(p_k) &= \begin{bmatrix} \nabla F^1(p_k) \\ \nabla F^2(p_k) \\ \vdots \\ \nabla F^N(p_k) \end{bmatrix} \\ H(p_k) &= J(p_k)^T J(p_k) \\ p_{k+1} &= p_k - \alpha_k [H(p_k)]^{-1} \nabla F(p_k). \end{aligned} \quad (15)$$

The formula (15) uses the stepsize  $\alpha_k$  which usually is evaluated with the help of sophisticated procedures. We decided not to build new optimization packages but to adopt existing ones therefore  $\alpha_k$  is determined according to Ipopt or RKNCON procedures. Similarly, scaling matrices  $H(p_k)$  are made nonsingular by procedures built-in Ipopt or RKNCON. For example, it can be done in Ipopt by ‘cheating’ the method eval-h with matrices  $H(p_k)$  instead of true Hessian matrices evaluated at  $p_k$ .

## 6 Estimation of parameters of higher index DAEs

The estimation procedure stated in Section 4 can also be adopted to higher index DAEs provided that numerical procedure presented in [18] is used. Suppose that our system equations are as follows:

$$F(\dot{x}(t), x(t), t, p), \quad t \in [0, t_f] \quad (16)$$

and, as before,  $p \in \mathcal{R}^m$  is the vector of unknown parameters.

When the integration scheme from [11] is extended to implicit equations then we will arrive at equations

$$F(x'_i(k+1), x(k) + h(k) \sum_{j=1}^s a_{ij} x'_j(k+1), t_k + c_i h(k), p) = 0, \quad (17)$$

$$x(k+1) - x(k) + h(k) \sum_{i=1}^s b_i x'_i(k+1) = 0, \quad (18)$$

$i = 1, \dots, s$  and they represent the dynamics of a discrete time control system.

In order to define state equations we introduce the state vector  $X(k)$ :

$$X(k) = \begin{bmatrix} x'_1(k) \\ \vdots \\ x'_s(k) \\ x(k) \end{bmatrix}, \quad (19)$$

then equations (17)–(18) become

$$\tilde{F}(X(k+1), X(k), k, p) = 0. \quad (20)$$

Here,  $X(k) \in \mathcal{R}^{(s+1)n}$ ,  $\tilde{F} : \mathcal{R}^{(s+1)n} \times \mathcal{R}^{(s+1)n} \times \{0, \dots, N-1\} \times \mathcal{R}^m \rightarrow \mathcal{R}^{(s+1)n}$ .

System (20) is fully implicit discrete time and, under some nonsingularity assumption, can be expressed as explicit. If the Jacobian of  $\hat{F}$  with respect to  $X(k+1)$ , denoted by  $\tilde{F}_{X+}$ , exists and is nonsingular for all  $k = 0, \dots, N-1$ , then from the Implicit Function Theorem there exists unique function  $\varphi$  such that

$$X(k+1) = \varphi(X(k), k, p) \quad (21)$$

and

$$\tilde{F}(\varphi(X(k), k, p), X(k), k, p) = 0, \quad (22)$$

for  $k = 0, \dots, N-1$ . Under differentiability assumptions imposed on  $F$  the function  $\varphi$  is differentiable with respect to  $X(k)$  and  $p$  which means that we can write

$$\begin{aligned} \tilde{F}_{X+}(k)\varphi_X(k) + \tilde{F}_X(k) &= 0 \Rightarrow \\ \varphi_X(k) &= -[\tilde{F}_{X+}(k)]^{-1} \tilde{F}_X(k) \end{aligned} \quad (23)$$

$$\begin{aligned} \tilde{F}_{X+}(k)\varphi_p(k) + \tilde{F}_p(k) &= 0 \Rightarrow \\ \varphi_p(k) &= -[\tilde{F}_{X+}(k)]^{-1} \tilde{F}_p(k). \end{aligned} \quad (24)$$

$\tilde{F}_{X+}(k)$ ,  $\tilde{F}_X(k)$ ,  $\tilde{F}_p(k)$  are evaluated at  $(X(k+1), X(k), k, p)$  and  $\varphi_X(k)$ ,  $\varphi_p$  at  $(X(k), k, p)$ .

If we consider optimal control problem with the objective function

$$\hat{F}^0(p) = (x_l^p(t) - x_l^e(t))^2 \quad (25)$$

then the gradient of it can be calculated by referring to adjoint equations for the functional (25) and the system (21).

The adjoint equations for the functional (25) and the system (21) are considered, for example, in [17]:

$$p(t) = Q_t \quad (26)$$

$$p(k) = \varphi_X(k)^T p(k+1), \quad (27)$$

$k = 0, \dots, t-1$  and

$$Q_t = \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 2(x_l^p(t) - x_l^e(t)) \\ 0 \\ \vdots \\ 0 \end{bmatrix}.$$

Notice that vector  $Q_t$  has dimension  $(n+1) \times s$ .

Then adjoint variables  $p$  are the means for the gradient evaluation according to the formula

$$\hat{F}_p^0(p) = \sum_{k=1}^{t-1} \varphi_p(k)^T p(k+1). \quad (28)$$

Using (23)–(24) the adjoint equations (27) and the formula (28) can be expressed without the knowledge of  $\varphi$ :

$$\begin{aligned} p(k) &= -\tilde{F}_X(k)^T [\tilde{F}_{X+}(k)]^{-T} p(k+1) \\ \hat{F}_p^0(p) &= -\sum_{k=1}^{s-1} \tilde{F}_p(k)^T [\tilde{F}_{X+}(k)]^{-T} p(k+1). \end{aligned}$$

Fortunately, the calculation of  $[\tilde{F}_{X+}(k)]^{-1}$  can be avoided with the help of additional variable  $r$  which is the solution to the linear equations

$$\tilde{F}_{X+}(k)^T r(k+1) = p(k+1). \quad (29)$$

Then the adjoint equations become

$$p(k) = -\tilde{F}_X(k)^T r(k+1) \quad (30)$$

$$\hat{F}_p^0(p) = -\sum_{k=1}^{s-1} \tilde{F}_p(k)^T r(k+1). \quad (31)$$

Eventually we have the viable formula for the gradient of  $\hat{F}(p)$  provided that matrices  $\tilde{F}_{X+}(k)$  are nonsingular and equations (29) can be solved efficiently.

Important observation is that matrices  $\tilde{F}_{X+}(k)$  are **nonsingular** even for index three problems provided that  $h(k)$  are sufficiently small—see [18] for details. Therefore, for many higher index DAEs we have a valid technique for computing gradients of  $\hat{F}^0(p)$ . The evaluation of adjoint equations requires solving linear equations with matrices which have to be evaluated (and factorized) anyway while numerically integrating system equations.

The estimation procedure discussed in this section requires the program for consistent initialization at initial time. That program consists of two steps.

### Consistent Initialization Procedure

1. In the first step new equations have to be determined by differentiating some equations with respect to time.
2. In the second step the extended set of equations is solved, at initial time, to get initial values of original equations.

In our approach Step 1) of *Consistent Initialization Procedure* is carried out on the basis of a graph based algorithm proposed by Pantelides ([15]). The algorithm finds the minimal subset of equations which need to be differentiated.

Next symbolic differentiation is performed. A good enough tool with symbolic differentiation module is an open source computer algebra system Maxima ([23]) which is descendant of Macsyma, the computer algebra system developed in the late 1960s at MIT. In the next section we show that we start solving optimal control problems by stating them in the DOML environment. In that case the first step in the symbolic differentiation is a conversion of the equations defined in the DOML format to the Maxima form. Then, the Maxima library is invoked and as a result differentiated equations are returned to the system console.

Eventually, in Step 2) of *Consistent Initialization Procedure*, the set of nonlinear (in general) algebraic equations is solved by using the KINSOL solver from the SUNDIALS package ([12]) (alternatively the Ipopt solver can be applied-[25]).

Summing up, the IDOS server is equipped, for the moment, with optimization procedures which either use quasi-Newton approximations of Hessian matrices (if Ipopt or RKNON are used without modifications), or their Gauss-Newton approximations. They are based on adjoint equation evaluations and can be applied to models described by ODEs or higher index DAEs. Procedures for models calibration based on *a priori* discretization of systems equations are under development.

## 7 Examples

**Example 1** The first example is the chemical kinetics model available as SUNDIALS example. The equations of the reaction rates are as follows:

$$\begin{aligned} \dot{x}_1 &= -p_1x_1 + p_2x_2x_3 \\ \dot{x}_2 &= p_1x_1 - p_2x_2x_3 - p_3x_2^2 \\ \dot{x}_3 &= p_3x_3^2 \end{aligned}$$

The models transcription in Modelica is shown on Listing 1. The corresponding DOML file for the model calibration is presented on Listing 2. It defines the reference trajectory through the spline function of degree 1. All three parameters there are decision variables.

When  $p_1 = 0.04$ ,  $p_2 = 1.e7$  and  $p_3 = 3e7$  we have the SUNDIALS example and we call the model with

```

package Roberts
  model Roberts_model(startTime=0.0,
                      finalTime=1.0 )
    parameter Real p1 = 0.04;
    parameter Real p2 = 1e4;
    parameter Real p3 = 3e7;
    Real x1(start = 1.0);
    Real x2(start = 0.0);
    Real x3(start = 0.0);
  equation
    der(x1) + p1*x1 - p2*x2*x3 = 0;
    der(x2) - p1*x1 + p2*x2*x3 + p3*x2*x2 = 0;
    der(x3) - p3*x2*x2 = 0;
  end Roberts_model;
end Roberts;

```

Listing 1: Roberts model in Modelica

Figure 1: The calibration of Roberts model.

```

package Roberts
  import I = Modelica.DOML.Inputs;
  optimization Roberts_opt(startTime=0.0,
                           finalTime=1.0 )
    minimize AccErr = err(finalTime);
    I.Spline x1r(startTime = startTime,
                 finalTime = finalTime, degree=1,
                 table=[0.0, 0.6;8e6, 0.3; 16e6, 0.2;
                        24e6,0.1;32e6,0.01;40e6,0.0;4.0e7,0.0]);
    parameter Real p1(free=true,
                      initialGuess=0.04, min=0.0, max=10.0);
    parameter Real p2(free=true,
                      initialGuess=1e4, min=0.0, max=10.0);
    parameter Real p3(free=true,
                      initialGuess=3e7, min=0.0, max=10.0);
    input Real x1e(free=false) = x1r.y;
    Real x1(start = 1.0);
    Real x2(start = 0.0);
    Real x3(start = 0.0);
    Real err(start = 0.0);

    annotation(solver="nlsq_cvodes", Steps="5",
              RTOL_tolerance="1.0e-6");
  equation
    der(x1) + p1*x1 - p2*x2*x3 = 0;
    der(x2) - p1*x1 + p2*x2*x3 + p3*x2*x2 = 0;
    der(x3) - p3*x2*x2 = 0;
    der(err) = (x1-x1e)^2;
  end Roberts_opt;
end Roberts;

```

Listing 2: Calibrating Roberts model

Figure 2: The calibration of the extended SIR model.

these parameters as the nominal model (its trajectories are denoted as  $x_N$  in Figure 1). However, when the model was adjusted to the reference trajectory for  $x_1$ :  $(0.0, 0.6)$ ,  $(8e6, 0.3)$ ,  $(16e6, 0.2)$ ,  $(24e6, 0.1)$ ,  $(32e6, 0.01)$ ,  $(40e6, 0.0)$ ,  $(4.0e7, 0.0)$  models parameters were changed to  $p_1 = 1e - 3$  (we assumed that lower bound for the parameter  $p_1$  is  $1e - 3$ ),  $p_2 = 2.1986e4$  and  $p_3$  to  $3.0e7$ . Also trajectories of the model changed—they are shown on Fig. 1.

**Example 2** The second example is related to the model of food borne diseases. The equations of the evolution of three populations:  $S$  (Susceptible population),  $I$  (Infected population),  $R$  (Recovered population) and the equation of the pathogen concentration evolution are given below.

$$\begin{aligned}\dot{S} &= -p_3(B/(B+p_2))S - ((p_4p_5)/p_8)SI - \\ &\quad p_1S + p_1p_8 \\ \dot{I} &= p_3(B/(B+p_2))S + ((p_4p_5)/p_8)SI - p_1I \\ \dot{R} &= p_1I - p_6R \\ \dot{B} &= p_7I - p_5B.\end{aligned}$$

The model has eight parameters, all of them are decision variables in our calibration problem. In addition we assume that initial pathogen concentration,  $B(0)$ , must be determined. The trajectories of the calibrated model are shown on Fig. 2.

## 8 Conclusions

The IDOS server is still a prototype. Although it is operational its widespread use can be hampered by the limited computing resources which are currently allocated to the server. Furthermore, adding a new solver to the server is not as simple as it should be. We plan to alleviate these problems in the near future.

# Client-side Modelica powered by Python or JavaScript

Rüdiger Franke, ABB, Germany – Ruediger.Franke@de.abb.com

## Abstract

Modelica is primarily supported by simulation environments for the treatment of equation based models and model libraries. As of today Modelica is rarely used for the exchange of engineering data, visualization or interactive computing, even though the Modelica language offers a lot of interesting features for such applications.

This paper investigates the potential of lightweight Modelica tools that run directly in scripting or web clients. Two Modelica parsers have been implemented in the popular client-side languages Python and JavaScript.

The Modelica parser in Python is extended with a backend translating algorithmic Modelica definitions to Python. This gives access to existing Python packages from scripted Modelica. It also enables the interactive debugging of algorithmic Modelica code.

The Modelica parser in JavaScript offers a generic backend interface. The paper demonstrates two applications. First a simple analysis tool for Modelica packages running from the command line is demonstrated. The true potential of JavaScript is the embedding of engineering data as Modelica code with HTML5 documents and their processing on the client side, e.g. in Web browsers. The paper shows a Modelica text editor and parameter GUI generator running in a web browser.

*Keywords: Modelica, scripting, interactive computing, data exchange, Lex, Yacc, Python, JavaScript, jQuery, HTML5.*

## 1 Introduction

Today's Modelica simulation environments act as servers that offer proprietary client interfaces, basing on Modelica Script, COM, or CORBA, for instance. There has been no success in standardizing Modelica client interfaces so far. XML has been selected for tool coupling in the FMI standard.

Major advantages of XML are that it is both: human and machine readable. XML parsers are readily available. The major drawbacks of XML are its very

basic syntax, making it bulky and hard to read for humans. The semantics still needs to be defined.

This paper investigates the use of Modelica itself as interface language. Modelica is human and machine readable as well. The major advantages of Modelica are its more compact, richer syntax. The semantics is already standardized, tailored for modeling and simulation, including:

- rich syntax for high-level definitions, like packages, classes, records, enumerations, doc strings, and physical units;
- modification syntax for predefined classes that is comparable to XML documents for XML schemata;
- convenient formulation of matrix expressions, statements and functions;
- embedded graphical representation;
- embedded HTML documentation;
- embedded version management;
- enable automatic generation of graphical user interfaces out of Modelica definitions.

The features are unique in their combination and could directly be exploited without the need to define some new XML schema first.

The drawback is that parsing Modelica by machines is not as simple as parsing XML. But a Modelica parser neither is a miracle since the concrete syntax is specified and tools like Lex and Yacc exist.

## 2 MoiPy – Modelica in Python

MoiPy is intended to bridge the gap between the powerful Modelica language and convenient scripting. This is done by adding a thin syntactic layer on top of the existing scripting language Python, translating between Modelica and Python, and by using the NumPy package for scientific computing.

MoiPy is not an alternative to other Modelica tools; it is an optional addition. MoiPy allows staying in the Modelica world even if the simulation environment at hand has only limited support for model-based applications or scripting.

## 2.1 Implementation overview

MoiPy implements the Modelica syntax (Modelica 3.3 specification, Appendix B; see [1]) using Python Lex-Yacc. PLY provides Lex and Yacc entirely in Python, including extensive error checking and logging. The syntax specification can directly be executed. A parser table is generated on demand and cached in the background.

Of course the execution speed is slower, compared to a parser explicitly generated and readily compiled. This is why MoiPy only reads Modelica files as needed.

The parser produces an abstract syntax tree (AST). Each node of the tree is a Python object. The AST reduces the concrete syntax for simpler further processing. For instance, a `class_definition` is represented as object of `ClassDefinition`. The attributes of `class_prefixes`, `class_specifier` and `composition` appear directly in the `ClassDefinition`. The elements and sections of the composition are further reduced into one `elementList`, one `initialEquationList` / `initialStatementList` and one `equationList` / `statementList`.

An exemplary rule reads:

```
def p_annotation(p):
    ''' annotation : ANNOTATION \
        class_modification '''
    p[0] = Annotation(
        classModification = p[2],
        track = Track(p, 1))
```

The syntax rule is specified in the documentation string of a Python function that implements the respective production. A new object of the class `Annotation` is created in the example. The second argument tracks the location in the Modelica code.

The class definition objects have the common method `toPython` that generates Python code from the Modelica definitions. The `toPython` method of `PrimaryUnsignedNumber`, for instance, constructs a predefined `Real` or `Integer` object that adds attributes like `min`, `max` and `unit` to the value itself. Note that the Python code generation only covers the algorithmic part of the Modelica language, i.e. a subset of all possible class definitions:

- Modelica packages are treated as Python modules
- Modelica functions are translated to Python functions
- Modelica records are translated to Python classes

- Modelica enumerations are translated to Python objects

Moreover expressions and statements are covered:

- Modelica expressions are evaluated as Python expressions
- Modelica arrays are treated as NumPy arrays
- Modelica builtin functions are forwarded to Python functions
- Modelica statements are executed as Python statements

## 2.2 Extended Modelica syntax for scripting

MoiPy attempts to stay as close as possible to Modelica, using the same rules as specified in the Modelica concrete syntax and without introducing any new keywords. Two extensions are needed for scripting though: support for commands and use of variables without declaration on the top-level scope.

The Modelica concrete syntax covers stored definitions in the form of class definitions. MoiPy additionally accepts commands on the top-level scope that are Modelica expressions, statements or import clauses.

In Modelica each variable must be declared before use. MoiPy follows this rule inside class definitions. Also on the top-level scope assignments like:

```
v := {1,2,3}
```

are declaration errors if `v` has not been declared before. On the top-level scope, outside class definitions, it is allowed though to implicitly declare a variable by defining it equal to an existing object. For instance:

```
v = {1,2,3}
```

defines `v` to be the vector `{1, 2, 3}`. Afterwards

```
v := {4,5,6}
```

assigns a new value to the existing vector `v`,

```
v := "a string"
```

is an error, whereas

```
v = "a string"
```

(re)defines `v` to be a string.

MoiPy uses the file extension `.moi` to distinguish interpreted script files from regular Modelica definitions.

## 2.3 Basic uses

Start MoiPy with

```
python moi.py
```

A parser table for Modelica is generated when called the first time. Afterwards the `moi>>` command prompt appears.

Do some matrix calculations, e.g.:

```
moi>> A = [1,2;3,4]
moi>> b = {1,1}
moi>> A*b
```

or matrix concatenations:

```
moi>> [A,b]
moi>> [A; transpose([b])]
```

Call a Modelica function from Python:

```
moi>> t = 0:0.01:1
moi>> y = Modelica.Math.sin(
...     2*Modelica.Constants.pi*t)
```

This will look for the Modelica definitions under `MOIPYPATH`, load the files `Modelica/Math/package.mo` and `Modelica/Constants.mo`, translate the function `sin` and the constant `pi` to Python, call the function, and assign the result to the vector `y`. Note that the function call is vectorized automatically.

## 2.4 Enhance Modelica with Python

Python offers many interesting modules, such as Numpy, SciPy and matplotlib. MoiPy enables to access them from Modelica. Type:

```
moi>> import Plt = matplotlib.pyplot
```

MoiPy attempts to find a Modelica definition first. As `matplotlib` is not found in Modelica, the import gets forwarded to Python and found there, provided you have `matplotlib` installed. Type:

```
moi>> Plt.plot(t, y, "ro");
moi>> Plt.title(
...     "pyplot for Modelica");
moi>> Plt.show();
```

A plot window pops up; see Figure 1.

Figure 1: pyplot generated from Modelica

## 2.5 Access Modelica from Python

MoiPy translates Modelica definitions to Python. This means that the translated definitions may also be called from Python directly. When started in interactive mode:

```
python -i moi.py
```

and done some Modelica scripting, e.g.:

```
moi>> import
...     Modelica.SIunits.Conversions.*
moi>> from_degF(70)
```

one may leave MoiPy with `Ctrl-D` (`Ctrl-C` under Windows). A Python command prompt appears. Type:

```
>>> from_degF(70)
```

to directly call the translated Python function. One may switch back to Modelica with:

```
>>> moipy()
```

## 2.6 Advanced Modelica functions

`Modelica.Media` defines more advanced functions. They serve as example for 3D plotting and for debugging in the subsequent section. Take the example:

```
moi>> Modelica.Media.Water.
...     IF97_Utility.h_pT(1e5, 300);
```

In order to evaluate the function for the specific enthalpy, MoiPy needs to load 7 Modelica files and translate 19 functions as well as 7 data records out of 13 packages in MSL 3.2.1. The parsing of the files takes a few seconds. Once loaded and translated, subsequent calls go fluently.

```

moi>> p = linspace(1, 300, 30)
moi>> T = linspace(0, 600, 30);
moi>> (pp, TT) =
... numpy.meshgrid(p, T);
moi>> hh = Modelica.Media.Water.
... IF97_Utilityies.h_pT(
... pp * 1e5,
... TT .+ 273.15);

```

This evaluates the function `h_pT` at  $30 \times 30 = 900$  grid points. See also `examples/mplot3dDemo.moi` resp. call it:

```
moi>> import examples.mplot3dDemo
```

A wireframe plot should pop up; see Figure 2.

Figure 2: Wireframe plot for `IF97_Utilityies.h_pT`

## 2.7 Debugging of Modelica functions

Python offers the extensible debugger `pdb`. This is exploited by `MoiPy` to transform the debugger outputs to the originating Modelica code. It uses the prompt (`modb`). This gives features like entering the debugger in case of errors, treating break points, stepping through Modelica code, walking up and down on the call stack and inspecting variables.

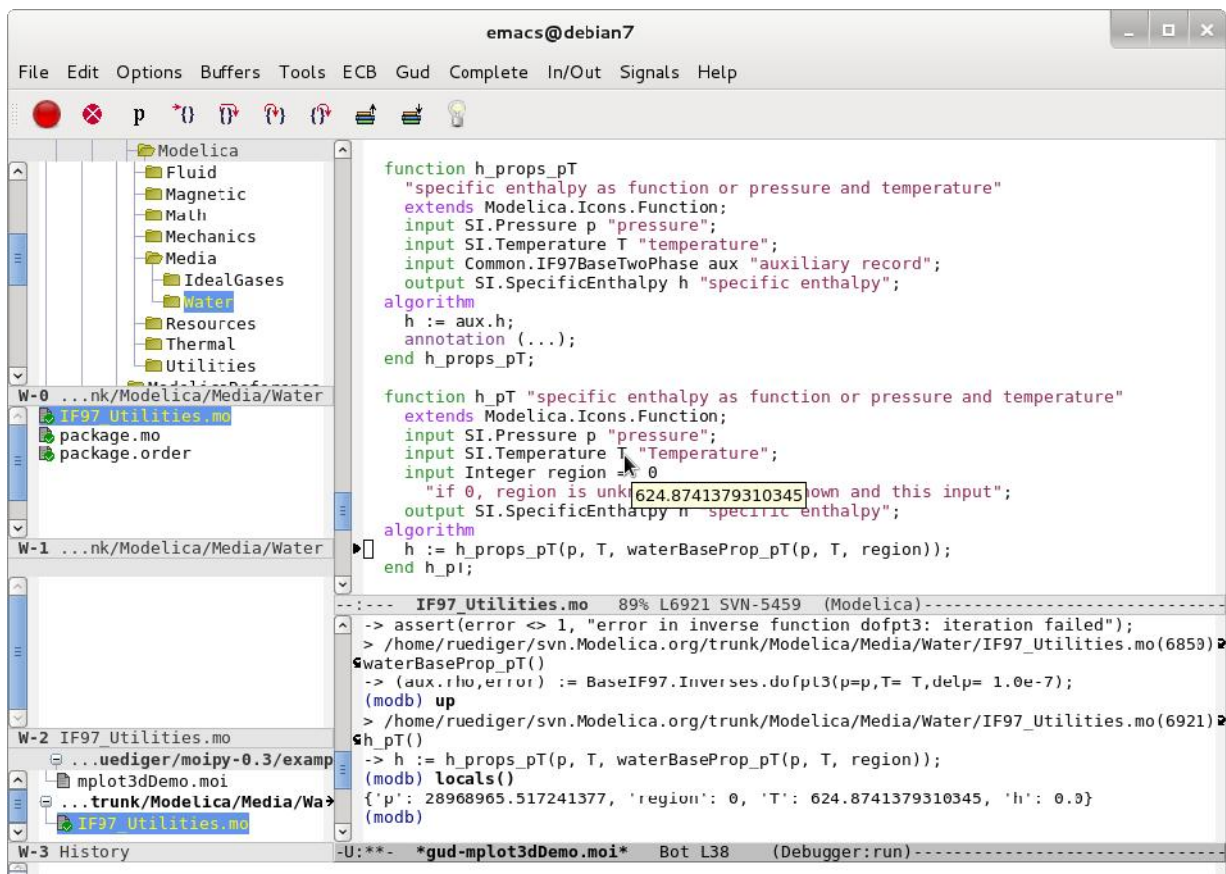

See also below for an example – the debugger shows an error in the `IF97_Utilityies.h_pT` function that was present prior to `r6066` around 290 bar and 350 °C – it has been fixed in `MSL 3.2.1`.

## 2.8 Integration with an IDE

An Integrated Development Environment (IDE) typically integrates several command line tools and can be extended to support new ones. shows Emacs running `modb` as example.

Several Emacs extensions have been loaded, such as Emacs Code Browser for the directory tree, SVN status and revision, besides Modelica mode for syntax highlighting and annotation folding. The Emacs debugger framework parses the output of `modb` and add a graphical user interface. Moreover it opens and shows the respective source file at the right position.

Figure 3: `MoiPy` in the GNU Emacs IDE

### 3 MoiJS – Modelica in JavaScript

Besides its convenient syntax for scientific computing, Modelica is strong in supporting graphical user interfaces. A Modelica model may contain annotations with flowsheet graphics and parameter dialogs, besides documentation – this is important for the specification and exchange of engineering data.

Graphical user interfaces are currently undergoing fundamental changes. Powerful, standardized GUI clients are running on virtually any device, exploiting HTML5 (HTML, CSS and JavaScript). What does this mean for a Modelica client?

Instead of dealing with proprietary server interfaces, events and callbacks, the client could receive a Modelica definition, parse it, build the user dialog, manage user interactions autonomously, and post back user inputs as Modelica definition or modification.

A Modelica parser in JavaScript is needed. Initially developed at Netscape almost 20 years ago, JavaScript grew to a multi-paradigm language covering functional, imperative and object-oriented programming. It gained a lot of momentum since the standardization of HTML5; see [3], the appearance of fast just-in-time compilers, development tools, powerful libraries, such as jQuery [4], and the adoption for server side programming as well, e.g. by Node.js [5].

#### 3.1 Implementation overview

MoiJS implements the Modelica syntax (Modelica 3.3 specification, Appendix B; see [1]) using Jison. Jison provides Flex and Bison (Lex and Yacc) in JavaScript; see [6]. The exemplary rule given in section 2.1 reads:

```

annotation:
  ANNOTATION class_modification
  {
    $$ = new Annotation(track(@$));
    $$ .classModification = $2;
  }
;

```

MoiJS generates a reduced AST as well. A significant difference to MoiPy is that JavaScript objects forming the nodes of the AST are based on prototypes. The prototypes can be extended later on. This means that arbitrary backends can be added without having to touch the original parser code (or requiring the parser to offer a specific plug-in architecture).

#### 3.2 Adding a backend

Assume all executable models of a Modelica library shall be identified, in order to automate testing. Figure 4 shows a MoiJS backend for this.

Figure 4: Exemplary MoiJS backend

```

// load Modelica parser as CommonJS module
var moparser = require("./moparser").parser;

// add method forModifier to each modification and annotation
moparser.Modification.prototype.forModifier =
moparser.Annotation.prototype.forModifier = function (name, callback) {
  (this.classModification || []).forEach(function(argument) {
    if (argument.name == name)
      callback(argument.modification);
  });
}

// add method logStopTime to each class_definition, calling forModifier
moparser.ClassDefinition.prototype.logStopTime = function(within) {
  var definition = this;
  // check for experiment StopTime annotation
  if (definition.annotation) {
    definition.annotation.forModifier("experiment", function(experiment) {
      experiment.forModifier("StopTime", function(modification) {
        console.log(within + "\n  " + definition.ident
          + "(StopTime=" + modification.expression.value + ");");
      });
    });
  }
}
// treat subclasses recursively
(definition.classDefinitionList || []).forEach(function(classDefinition) {
  classDefinition.logStopTime(within + "." + definition.ident);
});
}

```

It may appear confusing how to dive into the syntax tree. MoiJS closely follows the rules and names of the Modelica concrete syntax specification, in order to simplify the understanding. The capitalization is changed to camel style. If for instance the concrete syntax defines a class `modification`, then a class-Modification instance of `ClassModification` appears in the AST. The suffix `List` is used if curly braces find in the Modelica concrete syntax.

The syntax tree may also be explored in the JavaScript Object Notation (JSON) – see below.

The backend (and the parser) can be executed in Node.js that provides, besides a JavaScript runtime, a portable operating system interface through POSIX wrappers. An exemplary Modelica file is processed with:

```
var fs = require("fs");

fs.readFile("Modelica/StateGraph.mo",
  function(err, data) {
    if (err) throw err;
    // parse the file
    var ast =
      moparser.parse(data.toString());
    // call the new backend
    for (i in ast.classDefinitionList)
      ast.classDefinitionList[i]
        .logStopTime(ast.name || "");
  });
```

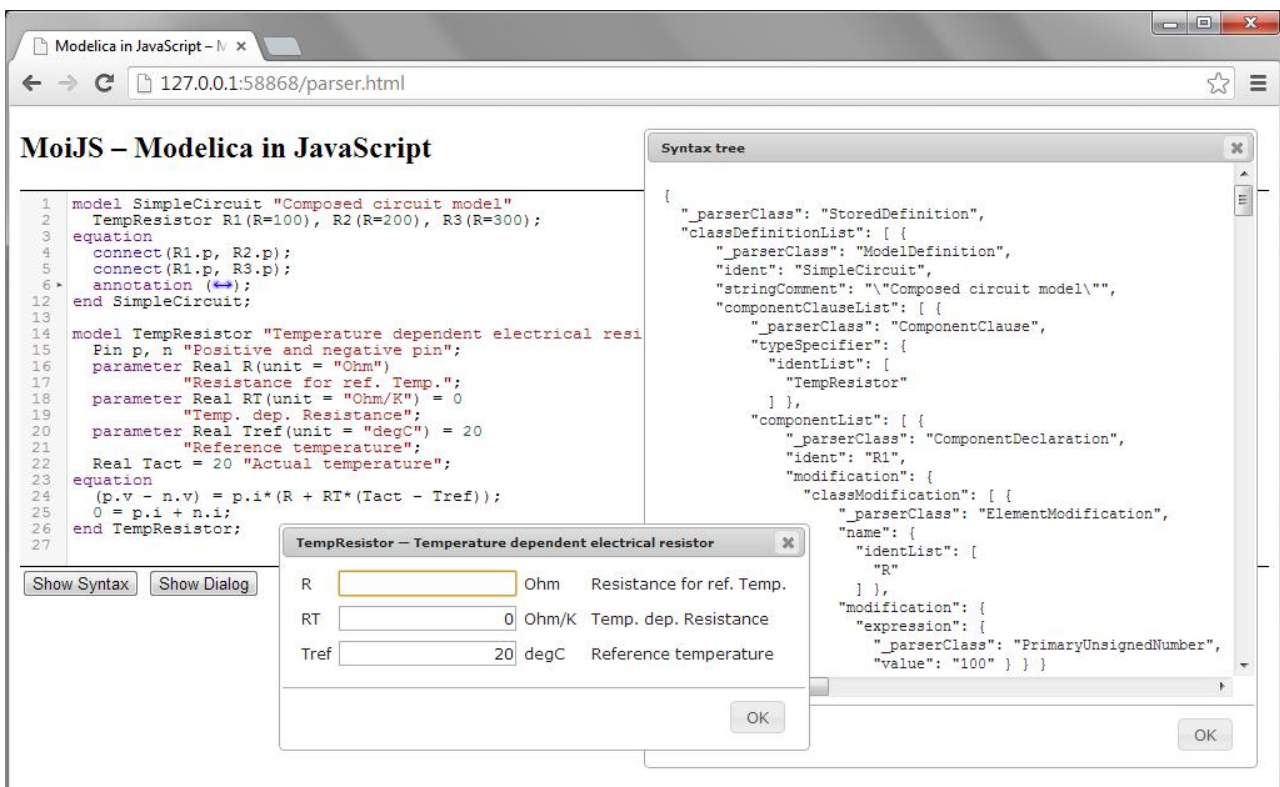

This produces the output:

```
Modelica.StateGraph.Examples.
  FirstExample(StopTime=5);
Modelica.StateGraph.Examples.
  FirstExample_Variant2(StopTime=5);
Modelica.StateGraph.Examples.
  FirstExample_Variant3(StopTime=5);
Modelica.StateGraph.Examples.
  ExecutionPaths(StopTime=15);
Modelica.StateGraph.Examples.
  ShowCompositeStep(StopTime=15);
Modelica.StateGraph.Examples.
  ShowExceptions(StopTime=20);
Modelica.StateGraph.Examples.
  ControlledTanks(StopTime=100);
```

### 3.3 Modelica in a Web browser

Having a Modelica parser in JavaScript, it is a small step to run it in a Web browser, using solely HTML5 standards. Figure 5 shows first results. The MoiJS lexer provides information for code coloring and annotation folding in an HTML textarea. The button “Show Syntax” invokes the MoiJS parser and shows the JSON representation of the resulting syntax tree in a popup window. The button “Show Dialog” invokes a backend to generate a parameter dialog out of the syntax tree. The GUI has been implemented using the jQuery UI library [4].

Figure 5: Modelica in the Google Chrome browser

## 4 Caveats on the Modelica syntax

It is a pleasure to experience that the Modelica concrete syntax can be passed to a general-purpose parser generator, such as PLY or Jison, and something useful comes out. Nevertheless there find some things that might be improved.

### 4.1 Syntax of primary numbers

The Modelica syntax does generally not rely on the use of whitespaces. With one exception: a primary unsigned number may end with a dot and an arithmetic operator might begin with a dot; see also [1], section 10.6.6. The expression

```
2. + [1, 2; 3, 4]
```

is wrong, because the dimensions of the scalar “2.” and the array [1,2;3,4] do not match. The expression

```
2 . + [1, 2; 3, 4]
```

is fine. The additional space makes clear that the dot shall belong to the element-wise addition operator.

The Modelica syntax should be changed to not allow primary numbers ending with a dot. Generally a “2” without dot is fine, in particular because the Modelica division operator “/” is non-truncating, e.g. “1/2” gives 0.5 and not 0. If nevertheless a primary number shall be forced to be a Real, then one can add a 0 behind the dot, e.g. write “2.0”.

### 4.2 Expression syntax

The Modelica expression syntax defines operator precedence and associativity with grammar rules. This leads to very long productions. When a primary number is passed as function argument, for instance, then this primary goes through `factor`, `term`, `arithmetic_expression`, `relation`, `logical_factor`, `logical_term`, `logical_expression`, and `simple_expression`, to finally become an expression.

This is not only hard to read, but also slows down parsers. The expression syntax can alternatively be specified with all operators in one rule, i.e.

```
expr : primary
     | expr or expr
     | expr and expr
     | not expr
     | expr rel_op expr
     | expr add_op expr
     | add_op expr
     | expr mul_op expr
     | expr ("^" | ".^") expr
```

The operator precedence and associativity can be defined in a separate table.

Prec	Operators	Associativity
7	or	left
6	and	left
5	not	right
4	< <= == <> >= >	left
3	+ - .+ .-	left
2	* / .* ./	left
1	^ .^	right

MoiJS, for instance, parses the Modelica Standard Library, version 3.2.1, more than 20% faster with this handy expression syntax.

### 4.3 Syntax of embedded HTML documentation

Working with HTML5 one gets used to documents that contain multiple special-purpose syntaxes, like HTML for content, CSS for styling and JavaScript for behavior – and maybe Modelica for engineering physics. Looking ugly initially, the richer syntax finally helps to faster grasp the different facets of the document. Modern text editors support such documents with mixed modes.

Modelica models may contain embedded HTML documentation. Unfortunately the HTML code needs to be encoded into Modelica strings, meaning that all double quotes used inside the HTML documentation need to be escaped. A general purpose text editor cannot detect and highlight the HTML code.

It should be considered to switch the syntax of embedded HTML documentation from Modelica strings to regular HTML, i.e. allow double quotes up to the ending `</html>` tag. In the simplest case a new Modelica string delimiter could be introduced, like `"""` for multi-line strings in Python. This way the readability improves and the mixed mode support of modern text editors could be exploited.

## 5 Conclusions and Outlook

Today’s Modelica simulation environments offer proprietary client interfaces, basing on Modelica Script, COM or CORBA, besides more. Only XML has been considered as standardized interface format for tool coupling so far. The major drawbacks of XML are its clumsy syntax and that the semantics still needs to be defined.

This paper investigates the use of the Modelica language itself as interface format for client/server architectures and for model exchange, instead of XML. This offers the advantage of having the semantics already standardized. The price to pay is a Modelica parser on the client side. This price turns out to be affordable in modern scripting or Web environments.

Two Modelica parsers have been implemented: MoiPy in Python and MoiJS in JavaScript. Both use the same grammar rules, exploiting parser generators with Lex and Yacc functionality.

It is not the aim of client-side Modelica to compete with simulation environments. The focus is on additional tasks in model-based applications, like scripting, testing, documentation, visualization and graphical user interfaces.

Python is strong in scientific computing. Due to its rich syntax, including e.g. operator overloading, and available packages, such as NumPy, it was straightforward to add a Python backend to the MoiPy parser, resulting in a Modelica interpreter and debugger for algorithmic models.

JavaScript is strong in dynamic user interfaces and in connecting them to servers. This is the main motivation for MoiJS. This paper shows how Modelica code is processed either in a console application or in an HTML5 user interface running the same parser.

The availability of compatible JavaScript implementations by multiple vendors and fast just-in-time compilers being preinstalled on virtually any device make JavaScript attractive for more applications. Examples are HTML5 pages containing verbatim Modelica code that is evaluated on the client side, e.g. in a Web browser or in a modern mobile device.

MoiJS is extensible with new backends, exploiting the prototype based inheritance of JavaScript. MoiJS is available under the MIT license at <http://omuses.github.io/moijs>.

# Dynamic modelling of a Condenser with the ThermoSysPro Library

Baligh El Hefni      Daniel Bouskela

EDF R&D

6 quai Watier, 78401 Chatou Cedex, France  
baligh.el-hefni@edf.fr      daniel.bouskela@edf.fr

## Abstract

The condenser is an important device for the operation of power plants in particular for pressurized water reactors. Undesirable transients may lead to the automatic shutdown of the power plant.

To simulate the complex dynamic physical behaviour of the condenser, a dynamic model has been developed using Modelica. The component model is meant to be used for power plant modeling and simulation with the ThermoSysPro library developed by EDF and released under open source license.

The transient most unfavorable to keeping the integrity of the condenser vacuum is the loss of the cold source pumps followed by a turbine trip and a missed islanding (house load operation).

The objective is to study the evolution of the pressure of the condenser for this kind of transients. During the transient, the condenser pressure should be always less than  $5 \times 10^4$  Pa.

The present paper describes in detail the condenser model: hypothesis, governing equations, correlations and the test-case (structure of the test model, the parameterization data and the results of simulation).

## 1. Introduction

Modeling and simulation activities play a key role in the design phase and performance optimization of complex energy processes. It is also expected that they will play a significant role in the future for power plant maintenance and operation.

The potential of Modelica as a mean to efficiently describe thermodynamic models has been recognized for quite a while [1, 2], and has led to the initiative of developing an EDF library for power plant modeling within the ITEA 2 EUROSYSLIB project.

This library, called ThermoSysPro, aims at providing the most frequently used models of components for the 0D-1D static and dynamic modeling of thermodynamic systems, mainly for power plants, but also for other types of energy systems such as industrial processes, energy conversion systems, buildings etc. It involves disciplines such as thermal-hydraulics, combustion, neutronics and solar radiation (see instance [1 to 8]).

The ambition of the library is to cover all the phases of the plant lifecycle, from basic design to plant operation. This includes for instance system design, verification and validation of the instrumentation and control system, system diagnostics and plant monitoring. To that end, the library will be linked in the future to systems engineering via the modeling of systems properties (or requirements), and to the measurements made on the real process via state estimation techniques.

The present paper focuses on the dynamic modeling of the condenser: hypothesis, governing equations, correlations and the test-case (structure of the model, the parameterization data and the results of simulation).

## 2. Model of the condenser

### 2.1. General presentation of the condenser

The condenser is a **two-phase** shell-and-tube heat exchanger. The feedwater flows inside the tube bundle, while the steam and condensate flows outside of those tubes located inside the cavity. In the condenser, there are two zones: the desuperheating zone and the condensation zone.

The condensate of water heaters located upstream is injected into the condenser. During the injection, part of the condensate may vaporize due to the pressure drop. This phenomenon is known as flash.

Figure 1: fluid flow inside an condenser

## 2.2. Description of the condenser model

The **DynamicCondenser** model represents the dynamics of the thermo-hydraulic phenomena of the hot fluid inside the cavity and of the cooling fluid which flows through the tube bundle. In particular, the model features the thermal exchanges between the fluid in the cavity and the cooling fluid flowing through the tube bundle.

The condenser is considered as a vertical or horizontal cylindrical cavity (as schematized in Figure 1), containing a tube bundle with the feedwater inlet and outlet located on the end.

## 2.3. Components of the condenser

The model is divided into sub-models of three different types which are connected together to make the full model (see Figure 2):

- One **DynamicOnePhaseFlowPipe** model,
- One **HeatExchangerWall** model,
- One **TwoPhaseCavityOnePipe** model.

By reassembling the sub-models, any other configuration of the condenser can be modelled.

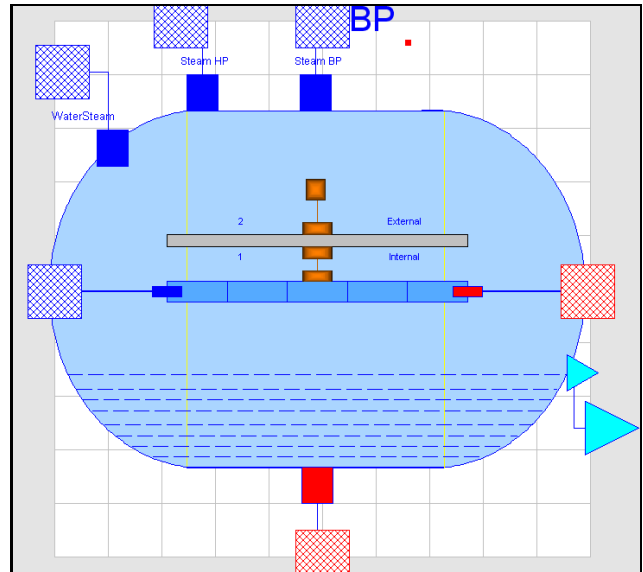

Figure 2: icon representation of the component model

The description of each sub-model is given in the following section. Each sub-model in the model can be recognized by looking at its icon (see Figures 3, 4 and 6).

## 3. Physics of the condenser

### 3.1. **DynamicOnePhaseFlowPipe** model

Figure 3: pipe model icon

The model of the fluid flow in a cylindrical conduit is based on the dynamic mass, energy, and momentum balance equations, which are originally given as 1-D partial differential equations. The original distributed-parameter model is first discretised by using the finite-volume method. The model is formulated in order to correctly handle possible flow reversal conditions.

### Assumptions

- Homogeneous fluid in each mesh cell (same velocity for the liquid and steam phases);
- 1-D modelling (using the finite-volume method);
- The accumulation is considered in each mesh cell;
- The inertia of the fluid is taken into account;
- The phenomenon of longitudinal heat conduction in the metal wall and in the fluid is neglected;
- The thermo-physical properties are calculated on the basis of the average pressure and enthalpy in each mesh cell.

### Mass balance equation

The mass balance equation in each cell is given by:

$$A \cdot \frac{d\rho_i}{dt} \cdot \Delta x = \dot{m}_{i-1i} - \dot{m}_{ii+1}$$

Taking the pressure and the specific enthalpy as state variables yields:

$$A \cdot \left[ \left( \frac{\partial \rho_i}{\partial P_i} \right)_h \cdot \frac{dP_i}{dt} + \left( \frac{\partial \rho_i}{\partial h_i} \right)_P \cdot \frac{dh_i}{dt} \right] \cdot \Delta x = \dot{m}_{i-1i} - \dot{m}_{ii+1}$$

### Energy balance equation

The energy balance equation in each cell is given by:

$$A \cdot \frac{d(\rho_i \cdot u_i)}{dt} \cdot \Delta x = \dot{m}_{i-1i} \cdot h_{i-1i} - \dot{m}_{ii+1} \cdot h_{ii+1} + \Delta W_i$$

with the specific internal energy given by:

$$u_i = h_i - \frac{P_i}{\rho_i}$$

Taking the pressure and the specific enthalpy as state variables yields:

$$A \cdot \left( \left( h_i \cdot \frac{\partial \rho_i}{\partial P_i} - 1 \right) \cdot \frac{dP_i}{dt} + \left( h_i \cdot \frac{\partial \rho_i}{\partial h_i} + \rho_i \right) \cdot \frac{dh_i}{dt} \right) \cdot \Delta x = \dot{m}_{i-1i} \cdot h_{i-1i} - \dot{m}_{ii+1} \cdot h_{ii+1} + \Delta W_i$$

$h_{i,i+1}$  is the specific enthalpy of the mass flow  $\dot{m}_{i,i+1}$  crossing the boundary between the cells  $i$  and  $i+1$ .  $h_{i,i+1}$  is related to the state variables  $h_i$  and  $h_{i+1}$  by:

$$h_{i,i+1} = \hat{s}(P_e) \cdot h_i + \hat{s}(-P_e) \cdot h_{i+1}$$

where  $P_e$  is the Peclet number and

$$\hat{s}(x) = \frac{1}{1 + e^{-\frac{x}{2}}} \quad (\text{see e.g. [10]}).$$

When neglecting diffusion, the Peclet number is infinite, and

$$h_{i,i+1} = s(\dot{m}_{i,i+1}) \cdot h_i + s(-\dot{m}_{i,i+1}) \cdot h_{i+1}$$

Where  $s$  is the step function:

$$s(x) = \begin{cases} 1 & \text{if } x > 0 \\ 0 & \text{if } x < 0 \end{cases}$$

This simplification is known as the upwind scheme.

### Momentum balance equation

The momentum balance equation in each cell is given by:

$$1/A \cdot \frac{d\dot{m}_{i,i+1}}{dt} \cdot \Delta x =$$

$$P_i - P_{i+1} - (\Delta P)_{i,i+1}^a - (\Delta P)_{i,i+1}^f - (\Delta P)_{i,i+1}^g$$

with respectively the acceleration, friction and gravity pressure losses given by:

$$(\Delta P)_{i,i+1}^a = \frac{1}{A^2} \cdot \dot{m}_{i,i+1} \cdot |\dot{m}_{i,i+1}| \cdot \left( \frac{1}{\rho_{i+1}} - \frac{1}{\rho_i} \right)$$

$$(\Delta P)_{i,i+1}^f = \zeta \cdot \frac{\Lambda_i \cdot \Delta x_h}{2 \cdot D \cdot A^2 \cdot \rho_i} \cdot \dot{m}_{i,i+1} \cdot |\dot{m}_{i,i+1}|$$

$$(\Delta P)_{i,i+1}^g = \rho_{i,i+1} \cdot g \cdot (z_{i+1} - z_i)$$

By default, the flow is considered turbulent (Reynolds number  $Re > 2300$ ).

The **Colebrook** correlation is used to compute  $\Lambda_i$ .

### Convective heat transfer within the tubes

The heat exchanged between the fluid and the wall is:

$$\Delta W(i) = h_c(i) \cdot \Delta S_2 \cdot (T_{w2}(i) - T(i))$$

### Convection heat transfer coefficient

The convection heat transfer coefficient  $h_c$  between the fluid and the wall is computed using the **Dittus-Boelter** correlation.

### 3.2. HeatExchangerWall model

Figure 4: wall model icon

The wall model describes the conductive heat flow through the wall of the tube bundle. The flow is positive when entering the tubes (going from side 2 to side 1 of the wall).

$$\Delta W_1(i) = \frac{2 \cdot \pi \cdot \lambda \cdot \Delta x(i) \cdot ntubes \cdot (T_w(i) - T_{w1}(i))}{\ln((e + D)/D)}$$

$$\Delta W_2(i) = \frac{2 \cdot \pi \cdot \lambda \cdot \Delta x(i) \cdot ntubes \cdot (T_{w2}(i) - T_w(i))}{\ln((2 \cdot e + D)/(e + D))}$$

$$\Delta M_w \cdot c_{pw} \cdot \frac{dT_w}{dt} = \Delta W_2(i) - \Delta W_1(i)$$

### 3.3. TwoPhaseCavityOnePipe model

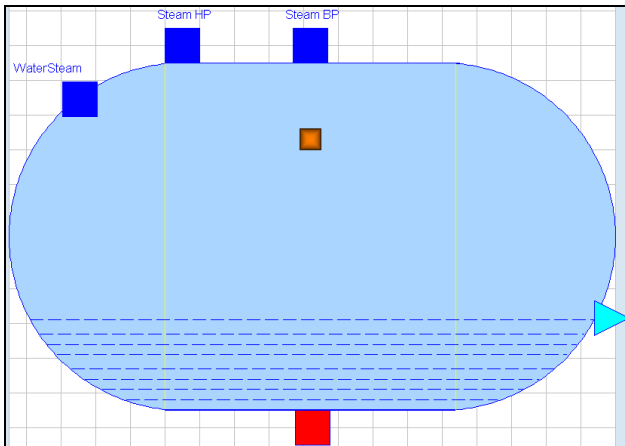

Figure 5: two-phase cavity model icon

The cavity is modelled as a non-adiabatic two-phase volume, with vertical or horizontal cylindrical geometry. The physical model is based on a non-equilibrium, two-phase formulation of the fluid balance equations with a control volume approach. The two phases are supposed to be isobaric and will be referred to as liquid zone and steam zone, respectively.

The model features the condensation flow of the steam phase into the liquid phase.

In most operating conditions, the liquid and steam phases in cavity are not necessarily in thermal equilibrium. The reasons are:

- The vapour may enter the cavity in a superheated state (the vapour temperature is then higher than the saturation temperature).
- The liquid may be subcooled by the incoming drain.

#### Assumptions

- Accumulation of mass and energy is considered. Heat exchange between the liquid and steam phases is considered.
- Heat exchange between the liquid or steam phases and the wall is considered.
- Heat exchange between the condenser and the external medium (ambient) is considered.
- Pressure losses are not taken into account in the cavity.
- The liquid and steam phases are not necessarily in thermal equilibrium.
- The liquid and steam phases are assumed to be permanently in pressure equilibrium.

#### State variables

The state variables of the system are:

- the mean pressure in the cavity,
- the specific enthalpy of the liquid phase,
- the specific enthalpy of the steam phase,
- the temperature of the wall,
- the volume of the liquid phase.

The volume of the steam phase is bound to the volume of the liquid phase by the following equation:

$$V_l + V_v = V$$

#### Mass balance equation in each phase

$$\frac{d(\rho_l \cdot V_l)}{dt} = -\dot{m}_l^o + (1 - x_{mv}) \cdot \dot{m}_{drain}^e + \dot{m}_{cond}$$

$$\frac{d(\rho_v \cdot V_v)}{dt} = \dot{m}_v^e + x_{mv} \cdot \dot{m}_{drain}^e - \dot{m}_{cond}$$

where  $\dot{m}_v^e$  is the mass flow of incoming vapor,  $\dot{m}_{drain}^e$  is the mass flow of the incoming condensate of the some water heaters,  $\dot{m}_l^o$  is the mass flow of outgoing condensate and  $\dot{m}_{cond}$  is the condensation flow inside the cavity.

**Condensation mass flow rate inside the cavity**

The evolution of the pressure in the condenser depends strongly upon the mass flow rate of condensation.

The classical equation used to calculate the condensation mass flow rate given in [8] is not correct to simulate the scenario "loss of the cold source pumps followed by a turbine trip and a missed islanding". The following new equation gives correct results:

$$\dot{m}_{cond\_1} = \frac{W_{1t} + W_{2t} + W_{vl} + W_{vp}}{h_v^{sat} - h_l^{sat}}$$

$$\dot{m}_{cond\_2} = (1 - x_e^v) \cdot \dot{m}_v^e$$

$$\dot{m}_{cond} = \dot{m}_{cond\_1} + \dot{m}_{cond\_2}$$

where  $\dot{m}_{cond\_1}$  is the mass flow rate of the steam condensed in the cavity and  $\dot{m}_{cond\_2}$  is the mass flow rate of the water contained in the wet steam at the cavity inlet.

**Energy balance equation in each phase**

The general form of the energy balance equation is given by:

$$\frac{d(\rho \cdot V \cdot u)}{dt} = \sum_e \dot{m}_e \cdot h_e + \sum_o \dot{m}_o \cdot h_o + \sum W$$

Taking the pressure and the specific enthalpy as state variables yields:

$$V_l \cdot \left[ \left( \frac{P}{\rho_l} \cdot \left( \frac{\partial \rho_l}{\partial P} \right)_h - 1 \right) \cdot \frac{dP}{dt} + \left( \frac{P}{\rho_l} \cdot \left( \frac{\partial \rho_l}{\partial h_l} \right)_p + \rho_l \right) \cdot \frac{dh_l}{dt} \right] =$$

$$-\dot{m}_l^o \cdot \left( h_l^o - \left( h_l - \frac{P}{\rho_l} \right) \right) + \dot{m}_{cond} \cdot \left( h_l^{sat} - \left( h_l - \frac{P}{\rho_l} \right) \right)$$

$$+ (1 - x_{mv}) \cdot \dot{m}_{drain}^e \cdot \left( h_{drain\_l}^e - \left( h_l - \frac{P}{\rho_l} \right) \right) + W_{vl} - W_{lw}$$

$$V_v \cdot \left[ \left( \frac{P}{\rho_v} \cdot \left( \frac{\partial \rho_v}{\partial P} \right)_h - 1 \right) \cdot \frac{dP}{dt} + \left( \frac{P}{\rho_v} \cdot \left( \frac{\partial \rho_v}{\partial h_v} \right)_p + \rho_v \right) \cdot \frac{dh_v}{dt} \right] =$$

$$\dot{m}_v^e \cdot \left( h_v^e - \left( h_v - \frac{P}{\rho_v} \right) \right) - \dot{m}_{cond} \cdot \left( h_l^{sat} - \left( h_v - \frac{P}{\rho_v} \right) \right)$$

$$+ x_{mv} \cdot \dot{m}_{drain}^e \cdot \left( h_{drain\_v}^e - \left( h_v - \frac{P}{\rho_v} \right) \right) - W_{vl} - W_{vw} - W_{1t}$$

**Energy accumulation at the wall**

$$M_w \cdot c_{pw} \cdot \frac{dT_w}{dt} = W_{lw} + W_{vw} - W_{wa}$$

**Heat exchange between the liquid and steam phases**

$$W_{vl} = K_{vl} \cdot A_{vl} \cdot (T_v - T_l)$$

**Heat exchange between the liquid or steam phases and the wall**

$$W_{lw} = K_{lw} \cdot A_{lw} \cdot (T_l - T_w)$$

$$W_{vw} = K_{vw} \cdot A_{vw} \cdot (T_v - T_w)$$

**Heat exchange between the condenser and the external medium**

$$W_{wa} = K_{wa} \cdot A_{wa} \cdot (T_w - T_a)$$

**Heat exchange between the liquid and the tube bundle 'Pipes'**

$$\Delta W_1(i) = \beta \cdot h_{conv}(i) \cdot \Delta S_{ext} \cdot (T_v - T_{w1}(i)) + W_{2t} / N$$

$$W_{1t} = \sum \Delta W_1(i)$$

**Total power exchanged for deheating, for  $h_v^e > h_v^{sat}$**

$$W_{2t} = \dot{m}_v^e \cdot (h_v^e - h_v^{sat})$$

**Heat transfer convection coefficients**

The **Nusselt** correlation is used to calculate the heat transfer coefficients  $h_{conv}$  between the steam and the outside wall of the tube bundle, in the condensation zone.

The heat transfer coefficient between the liquid and the wall ( $K_{lw}$ ), the heat transfer coefficient between the steam and the wall ( $K_{vw}$ ) and the heat transfer coefficient between the steam and the liquid ( $K_{vl}$ ) were calculated for flat wall.

## 4. Test-case of the condenser

### 4.1. Modelica model of the condenser

To simulate the complex dynamic physical behaviour in normal and dysfunctional conditions of the condenser model, a test model called “TestDynamicCondenser” has been developed by assembling the necessary components from the **ThermoSysPro** library (cf. Figure 6). The test model includes the level control system.

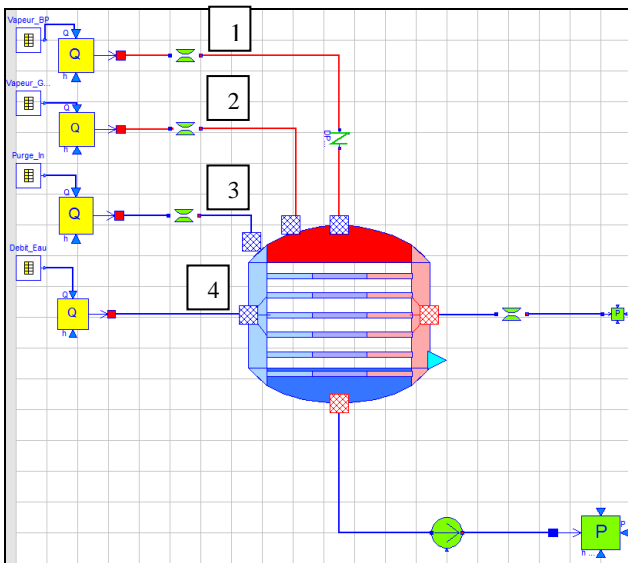

Figure 6: model of the condenser “TestDynamicCondenser”

### 4.2. Data implemented in the model

All geometrical data were provided to the model: tubes and exchangers lengths, diameters, volumes, corrective terms for the heat exchange coefficients, corrective terms for the pressure losses, etc. The plant characteristics are given in Figure 9 (cf. Appendix).

### 4.3. Calibration of the model

The calibration step consists in setting (blocking) the maximum number of thermodynamic variables to known measurement values. This method ensures that all needed performance parameters, size characteristics and output data can be computed.

For this model:

- setting (blocking) the cavity pressure to known measurement value and the value of corrective term of heat exchange coefficient between the cavity and pipes can be computed by model inversion,
- setting (blocking) the mass flow rate in the pump and the characteristics of the pump can be computed by model inversion (a polynomial coefficient)

### 4.4. Simulation scenario

In order to challenge the dynamic simulation capabilities of the model, a high amplitude transient "loss of the cold source pumps followed by a turbine trip and a missed islanding" is applied as a simulation scenario to the model. The purpose is to study the evolution of the pressure of the condenser for this type of transient. For this class of transients, the condenser pressure should always be less than  $5e4$  Pa (maximum pressure for the availability of the condenser).

This transient is used to check and validate the physics taken into account in the model and the numerical robustness of the model as it runs the condenser model into very different operating regimes. This allows to assess the validity and applicability range of the model equations, and the numerical robustness of the Modelica implementation when using Dymola.

### 4.5. Boundary conditions of the model

The boundary conditions of the model (scenario profiles) are presented in Figure 7.

Figure 7a: input mass flow rate of the steam

Others data of the model:

Enthalpy of the LP steam “1”	2416.6e3	J/kg
Enthalpy of the HP steam “2”	2759.6e3	J/kg

Enthalpy of the drain “3”	228.21e3	J/kg
Enthalpy of the feed water “4”	141.75e3	J/kg

Figure 7b: input mass flow rate of the feedwater

#### 4.6. Results of dynamic simulations

In order to cover the whole transient, the simulation time has been set at 75 seconds.

Simulation runs were done using Dymola 6.1 and Dymola 2012, with Dassl solver and with a tolerance = 0.0001. The simulation of the scenarios were mostly successful, with only one iteration variable to be fed manually.

The following phenomena are simulated:

- local condensation,
- swell and shrink effect in cavity,
- cavity water levels.

The model is able to compute:

- the mass flow rate of the condensate,
- the thermal power of the condenser and tubes,
- the distribution of pressure, temperature and specific enthalpy inside the tube bundle,
- the cavity water level and cavity pressure.

The results of the simulation runs are given in Figure 8. Figures 8a and 8b show the results obtained with Dymola. The simulation result demonstrates that the maximum pressure in the condenser is less than 5e4 Pa as required.

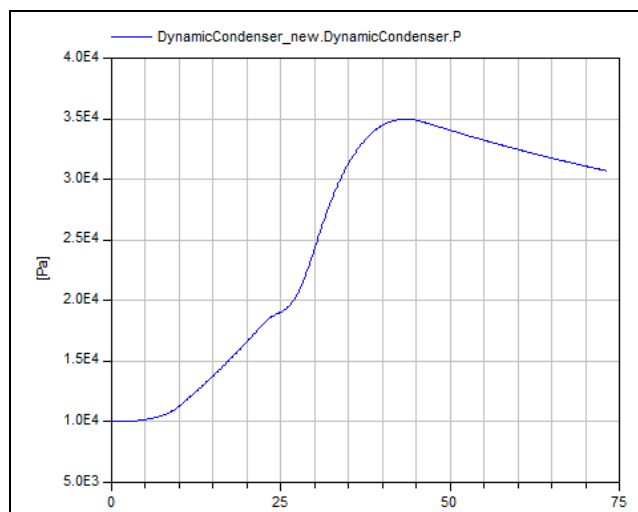

Figure 8a: evolution of the pressure inside the condenser

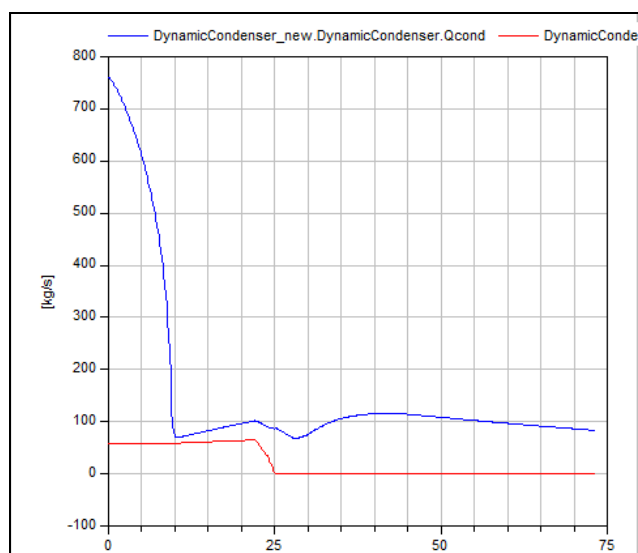

Figure 8b: evolution of the mass flow rate of the condensate ( $\dot{m}_{cond\_1}$ ,  $\dot{m}_{cond\_2}$ )

## 5. Conclusion

A new open source Modelica library called ‘ThermoSysPro’ has been developed within the framework of the ITEA 2 EUROSYS LIB project. This library has been mainly designed for the static and dynamic modeling of power plants, but can also be used for other energy systems such as industrial processes, buildings, etc. It is intended to be easily understood and extendable by the models developer.

A new dynamic model of a condenser has been developed using existing elements of ThermoSysPro.

To validate the model, the following difficult transient was simulated: loss of cold source pumps followed by a turbine trip and a missed islanding.

The simulation result shows that the maximum pressure in the condenser is less than 5e4 Pa (maximum pressure for the availability of the condenser) as required by the operation rules. The model enables to show that the evolution of the pressure inside the condenser strongly depends on the value of the condensation mass flow rate, the heat exchange between the vapor and the liquid at the bottom of the condenser and the thermal loss to the ambient.

## Nomenclature

### Symbols

$\dot{m}$	Mass flow
$N$	Number of segments for cooling pipes
$\rho$	Fluid density
$h$	Fluid specific enthalpy
$u$	Fluid specific internal energy
$P$	Fluid pressure
$T$	Fluid temperature
$c_p$	Fluid specific heat capacity
$V$	Volume
$t$	Time
$W$	Power
$x_v$	Vapor mass fraction in vapor phase
$x_l$	Vapor mass fraction in liquid phase
$x_{mv}$	Vapor mass fraction in input drain
$z_i$	Pipe inlet altitude
$\Lambda$	Friction coefficient
$\zeta$	Friction corrective coefficient
$\beta$	Corrective term for heat exchange coefficient
$\Delta x$	Tube segment length
$\Delta S$	Heat surface exchange of tube segment
$D$	Tube diameter
$A$	Tube cross section or heat exchange surface
$e$	Wall thickness
$\lambda$	Conduction coefficient
$K$	Heat exchange coefficient
$M$	Mass
$h_c$	Convective coefficient
$h_{conv}$	Convective coefficient of heat transfer by condensation between the vapor and

	<i>the tube bundle</i>
$ntubes$	Number of tubes in the bundle

### Indices

$X_i$ or $X(i)$	Quantity in volume $i$
$X_{i:i+1}$	Flow of quantity between volume $i$ and volume $i+1$
$X_e$ or $X^e$	Quantity at inlet
$X_o$ or $X^o$	Quantity at outlet
$X_l$	Quantity relative to liquid
$X_v$	Quantity relative to vapor
$X_w$	Quantity relative to cavity wall
$X_{w1}$	Quantity relative to pipes wall
$X_{ext}$	Quantity relative to external side of wall
$X_a$	Quantity relative to ambient
$X^{sat}$	Quantity relative to saturated phase
$X_{cond}$	Quantity relative to condensation
$X_{drain}$	Quantity relative to drain
$X_{drain\_l}$	Quantity relative to drain, for liquid
$X_{drain\_v}$	Quantity relative to drain, for vapor

## Abstract

Wavelet analysis is being widely used in different fields for signal processing to increase efficiency and flexibility. A wavelet library has been a standard component in many simulation programs. However, wavelet analysis has not yet been included in Modelica as a standard component. To fill this blank, a comprehensive wavelet library has been developed for Modelica. This library includes fifteen commonly used wavelet families. It can carry out continuous transform, forward and inverse discrete transforms, and multi-level decomposition and reconstruction in one-dimensional space. In addition, special application tools for multi-resolution analysis and wavelet denoising are provided. Moreover, some examples are given to provide the users a quick start point to build up their own algorithms. This library was programmed and tested according to the Modelica language specification 3.2 under the Dymola platform version 2013. The test results prove the functionalities of the library.

*Keywords: Modelica; Dymola; wavelet; Modelica library*

## 1 Introduction

Although the wavelet transform has only been established for several decades [1][2], it has already been applied in many fields because of its superior properties in signal processing. Besides practical applications, the wavelet transform is also a versatile tool for different simulation problems [3][4][5][6]. So far the wavelet transform has become a standard toolbox in many free and commercial simulation programs, such as Simulink™, Mathematica™, Maple™, Vis-Sim™ and many others.

Modelica, as a comprehensive multi-physical simulation tool, has not yet included a library for carrying out wavelet transform. However, there exists demand for using wavelet transform within Modelica. In

2005, Bunte and his colleagues analyzed the simulation data of vehicle steering dynamics generated in Modelica with the wavelet transform [7]. Because of the lack of wavelet transform in Modelica, the analysis had to be done with other software. In the paper of Ji [8] in 2010 about a Modelica signal analysis tool towards the design of more electric aircrafts the authors expressed the wish to do the analysis using wavelet transform directly within Modelica.

The first application for the failure analysis in the power system using the prototype of the Modelica wavelet library was already introduced in 2012 [9]. After the successful development, the final Modelica wavelet library is introduced in this article. It includes the following features.

- Fifteen wavelet families;
- Continuous transform;
- Discrete forward and inverse transforms;
- Multi-level decomposition and reconstruction;
- Multi-resolution analysis;
- Denoising and data compression;
- User friendly graphic user interface (GUI);
- Importing simulation data from the hard disk;
- Fully open source under Modelica License 2.

In the first release version, the library has the following limitations.

- Only one-dimensional transformations are implemented.
- Only post-processing is possible. The algorithms cannot execute in real time applications.
- The data to be analyzed must be have equidistant time grids.
- The library is developed and tested under Dymola 2013 demo version.

## 2 Wavelet transform

The basic knowledge about wavelet theory is required in order to use the wavelet library. In this section, a very brief description about the wavelet the-

ory will be given [1][2]. The theoretical part of [9] is roughly repeated here but with improvements for better understanding of common readers.

## 2.1 Definition

The wavelet transform can be considered as a further development of the Fourier transform, or more precisely, of the short time Fourier transform (STFT) [10]. Using the STFT, people try to localize the signal changing by selecting suitable time windows. This transformation, however, has its inherent drawbacks. The most significant one is its limit in time-frequency resolution due to the uncertainty principle. The wavelet transform overcomes this problem. This transformation is defined as [1]:

$$[W_{\psi}f](a, b) = \frac{1}{\sqrt{|a|}} \int_{-\infty}^{\infty} \overline{\psi\left(\frac{t-b}{a}\right)} f(t) dt. \quad (1)$$

This equation defines the wavelet transform of the function  $f(t)$  using wavelet function  $\psi$  at scale  $a$  and position  $b$ . The bar above function  $\psi$  stands for conjugation. For given  $a$  and  $b$ , the transformation result is a single real number, named wavelet coefficient. The wavelet function must satisfy some conditions to ensure that it is an orthonormal function:

- (1) Zero mean:  $\int_{\mathbb{R}} \psi(t) dt = 0$ ;
- (2) Unit square norm:  $\int_{\mathbb{R}} |\psi(t)|^2 dt = 1$ ;
- (3) Compact support:  $\psi(t) = 0$ , for  $|t| > C$ , where  $C$  is a positive real number.
- (4) Dyadic orthogonality:  $\langle \psi_{jk}, \psi_{lm} \rangle = \delta_{jl} \delta_{km}$ ,  
for  $\psi_{jk} = 2^{\frac{j}{2}} \psi(2^j x - k)$ . Here  $\langle \cdot, \cdot \rangle$  means inner product of two functions.

The wavelet function only represents the signal components that have zero mean, or high frequency components. For the zero and low frequency components, a scaling function, which has unit mean value, is required. The wavelet and the scaling functions with the dyadic scaling and translation parameters build a complete orthogonal basis in the Hilbert space.

The precise mathematical description of orthonormality is easily found in almost every book about the wavelet transform, e.g. [1] and [2], and will not be repeated here.

From this definition it is known that the wavelet transform is the integral of the multiplication of the signal to be studied,  $f$ , with a wavelet function,  $\psi$ . It has the same form as the STFT. However, not like the STFT, where only sine and cosine functions are used for the transformation, the wavelet transform uses different wavelet functions, which can be se-

lected according to the specific problems from a principally unlimited set.

Parameter  $a$  defines the width and height of the wavelet function  $\psi$  keeping its unit square norm. If  $a$  makes  $\psi$  narrower, the wavelet represents fast changes and the transformation focuses on the high frequency components of the signal. Parameter,  $b$ , shifts the wavelet function along the time axis, so that the transform helps us to observe signals at different locations. Using different values  $a$  and  $b$ , it is possible to observe the signal at different positions in the time domain and in different frequency ranges with only one transformation.

Two forms of wavelet transform are available: Continuous wavelet transform (CWT) and discrete wavelet transform (DWT). In CWT both scale and position parameters are continuous real values. The transformation result, i.e. the wavelet coefficient, is therefore also continuous. CWT expresses the signal changes in a continuous manner. It is more suitable for the visual examination. However, the transform result contains redundant information and the transform requires large calculation efforts. The general CWT has no corresponding inverse transformation.

## 2.2 Discrete wavelet transform (DWT)

In the DWT only discrete values of the scale and location parameters are used. The values are determined according to point (4) of the wavelet properties. The transformation result, i.e. the wavelet coefficient, is therefore discrete.

As an example, the following figure shows the form of the third order Daubechies scaling and wavelet functions [1].

Figure 1: The third order Daubechies scaling and wavelet functions (a) with their Fourier transforms (b)

From the Fourier transforms it can be seen that the scaling function mainly covers the lower frequency range while the wavelet function stretches in a higher frequency range. This coincides with the aforementioned description. From this point of view, DWT is actually the division of the time signal into different frequency bands. Thus, it is straightforward to understand that the calculation of DWT is realized

using filter banks. In inverse DWT the calculation is similar. This process can be illustrated with Figure 2.

Figure 2: DWT and inverse DWT calculation using filter banks

DWT transforms the original sequence in two new series:

- (1) the approximation coefficients,  $cA(k)$ , representing the low frequency components, obtained using the low pass filter for decomposition,  $h_{d0}$ , and
- (2) the detail coefficients,  $cD(k)$ , representing the high frequency components, obtained using the high pass filter for decomposition,  $h_{d1}$ .

The symbol  $\downarrow 2$  means down-sampling. The operation is to delete one from every two adjacent coefficients, in order to remove the redundant information. The inverse DWT carries out the reversed operation. The operator,  $\uparrow 2$ , expands a coefficient series by inserting a zero between every two adjacent elements. After that the two series are operated with two filters, respectively, and added together to get the original signal.

### 2.3 Multi-resolution analysis

Considering the DWT process shown in Figure 2, sequence,  $cA(k)$ , which represents the low frequency components, can be further divided into a lower frequency part and a higher frequency part. This process can be repeated and a series of coefficient sequences representing different frequency ranges will be obtained, as shown in the following figure:

Figure 3: Wavelet multi-level decomposition

This process is named as wavelet multi-level decomposition. The output of this operation,  $cD_1, cD_2, \dots, cD_n$  and  $cA_n$ , are different levels of DWT coefficients, representing the signal components from higher to lower frequencies. This analysis provides a convenient tool to observe different frequency components of the signal depending on time.

Similar to the calculation process of inverse DWT, if the algorithm goes in an inverse direction of Figure 3, we will get the original signal using the wavelet coefficients of different levels. This process is called signal reconstruction.

Applying multi-level decomposition, we can project a signal into a sequence of nested subspaces. We are then able to observe the original signal in different subspaces that contain different details of the signal. This realizes the multi-resolution analysis (MRA) of the signal using wavelet transform.

## 3 Realization

The wavelet library is developed according to the Modelica Language Specification 3.2 with the simulation environment software, Dymola 2013 (32-bit) demo version. Although the Dymola demo version has limitations on the complexity of simulation models, it does not impose any limitations in programming.

### 3.1 Library structure

The wavelet library structure is sketched in Figure 4.

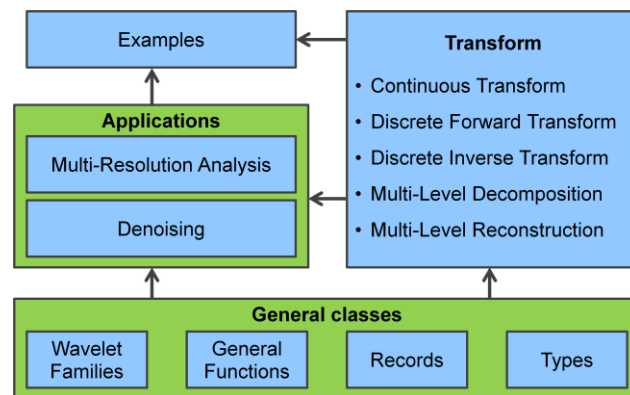

Figure 4: Wavelet library structure

The whole library is composed of eight packages and 64 single classes, plus an external C-file to support generating Meyer wavelets. All of these elements are summarized in four parts as shown in the figure.

The central part of this library is the package “Transform”, which includes the functions carrying out different wavelet transformations.

The part “General classes” provides a fundament for realizing the wavelet transforms and other operations, as shown in the bottom part of the above figure. Four packages are included in this part. They are

- “Wavelet Families” for generating wavelet filter banks and functions,
- “General Functions” for the basic data operation and processing,
- “Records” for the definition of data structures and supporting GUI, and
- “Types” to define enumeration parameters.

Two wavelet applications – MRA and denoising – are provided. It should be noted that the wavelet denoising package can also be applied for the data compression since these two operations use the same concept and algorithm [2].

In addition, the package “Examples” consists of functions and models for six examples to provide the users a quick introduction to the wavelet library.

### 3.2 Wavelet library release

The functional part of this library consists of only two files:

- “Wavelet.mo” as the main library package to include all Modelica codes, and
- “fft\_c.c” as an external C-function to calculate Fourier transform for generating Meyer wavelets.

Two example data files, testSignal1.mat and testSignal2.mat, are delivered, although they could be very easily generated by running the two example models in the library.

In addition, a “Help” folder including all descriptions of this library is also a part of the delivery.

### 3.3 Required components

Besides the Modelica standard libraries, the full performance of this library relies on two further libraries, **Modelica\_LinearSystem2** and **Plot3D**. The former one is a free library available from Modelica Association. The latter one is delivered with Dymola, and is only used for showing CWT results. In the free demo version of Dymola, Plot3D works but is limited to two-dimensional images.

### 3.4 Wavelet families

Fifteen wavelet families are available in this library.

- Haar
- Daubechies , up to the 20-th order
- Symlets , up to the 20-th order
- Coiflets , up to the 5-th order
- Biorthogonal spline, 15 variations
- Reverse biorthogonal spline, 15 variations
- Discrete Meyer
- Meyer

- Gaussian , up to the 8-th order
- Mexican hat
- Morlet
- Complex Gaussian , up to the 8-th order
- Complex Morlet
- Complex Shannon
- Complex frequency B-Spline , unlimited order

The package “Families” consists of fifteen functions for the wavelets listed above. Two more functions that are directly related to wavelet families are also included: “scalingWaveFunc” for generating the wavelet and scaling functions of a specific wavelet, and “wavFunc” providing a common entry to access all fifteen wavelets.

### 3.5 Wavelet transform

Five variations of one-dimensional wavelet transform have been implemented in the library. The related functions are included in the package “Transform”.

CWT is provided with two variations for more flexibility. One CWT variation accepts a wavelet name while the other one accepts a wavelet function as the input parameter. According to the wavelet theory, no inverse transform exists for general CWT.

For the discrete version, both forward and inverse wavelet transforms are possible. They are realized with two Modelica functions, respectively.

In the discrete domain, the multi-level data decomposition and the reconstruction are carried out by actually applying the discrete wavelet transform and inverse transform in a cascaded manner. The algorithms are implemented by two Modelica functions, “wavDec” and “wavRec”, respectively.

In addition, two more functions are included in this package, too, since they are closely related to the transforms. Function “wavRec1” reconstructs the data using only the wavelet coefficients of one specific level. This is actually a subset of multi-level reconstruction. The other function “wavCoef1” is used to extract the wavelet coefficients of a certain decomposition level. These two operations are specially useful for wavelet applications, such as MRA and denoising.

### 3.6 Applications

The wavelet library provides two applications, the MRA and the denoising, which are supposed to be the mostly used functionalities for processing the simulation data.

The principle of the wavelet MRA has been described in section 2.3. With this tool the user is able to divide the signal into different scales, or frequency regions, and observe the signal with different resolution. Using different Modelica functions, users can get the MRA results either in the numeric form or in the graphic form with curves. In addition, this tool provides the flexibility to tune the coefficients of every single level, so that the user can intentionally strengthen or suppress the information in some certain levels. An example of MRA is to be given later in this article.

Like MRA, the wavelet denoising is carried out based on wavelet multi-level decomposition and reconstruction. The wavelet denoising is suitable only for data with high signal-to-noise ratio. Based on this condition, the wavelet coefficients representing the noise have smaller values compared with those representing useful information. By removing these small coefficients, the noise can be eliminated from the data. The threshold to separate the noise and the information coefficients is the key to this algorithm. It can be selected by the user or automatically estimated by the tool. It has to be noted that, if automatic estimation is used, the noise in the data must have Gaussian distribution with zero mean and unit standard deviation.

As an extra possibility, data compression can be realized by the denoising application tool since these two operations are actually based on the same algorithm. For more information about this topic, relevant literatures, such as [1] and [2], can be referred to.

### 3.7 Graphical user interface

A graphical user interface (GUI) is important for a user-friendly environment in this library. The GUI is mainly realized by using Modelica “Types” combining the simulation environment software for inputs and diagrams for outputs.

By combining the GUIs for input and output, a very simple but convenient interactive operation is possible. It is also possible to realize more complex and user-friendly interactive performance using specific scripts written by users.

### 3.8 User’s guide

A complete User’s Guide in PDF format with a detailed description of every single class in this library is delivered in the release version. In addition, a “Help” folder is included in the delivery package. This folder contains HTML files with hyper-links.

Within the library, no separate package serving as a User’s Guide is provided since all related descriptions about the Modelica classes, including Packages, Models, Functions, Types and Records, have already been embedded in the library. These descriptions can be easily accessed in the simulation environment software. Hyper-links are included in the description texts for quick movement among the library to access the information from different classes.

## 4 Testing the library

The algorithms of this wavelet library were completely tested with the black-box method. Testing vectors have been defined for each algorithm. The function outputs were checked visually and numerically. The numeric check was carried out with the assistance of MATLAB because most algorithms written in the Modelica wavelet library are included in the MATLAB wavelet toolbox. For these algorithms, the same input parameters were given to the functions of the Modelica wavelet library and the corresponding commands in MATLAB. The calculation results of both tools were compared. An algorithm of the library is considered correct if the discrepancy is below a certain limit.

All testing results were recorded and summarized. As an example, Table 1 shows the summary of the testing results of the function “Wavelet.Families.wavCoiflets”, which is used to generate the wavelet filters associated with Coiflets wavelets.

Table 1: Testing recording for Wavelet.Families.wavCoiflets

order	F	lod	hid	lor	hir	Result
1	-	-	-	-	-	Error = 0
2	-	-	-	-	-	Error = 0
3	-	-	-	-	-	Max. error < 1e-16
4	-	-	-	-	-	Max. error < 1e-16
5	-	-	-	-	-	Error = 0

The first six columns of the table records the input and output values of the function. Since the data amount of the output values is too large, the data are stored in a separate file. The last column “Result”, records the errors of the outputs obtained by the Modelica function under test compared with the data calculated by the same algorithm written in MATLAB.

All other functions in the library were tested with the same process and altogether 133 numeric testing results were recorded. The errors are illustrated in Figure 5. Since the values are shown in logarithm axis,

the first 58 points with zero value are not plotted. The testing showed that the more than half of the tests have the errors below  $2e-16$ , which is around the digital error of a double precision floating number. Other errors with the values up to  $5e-14$  might be caused by the precision of the direct constant numbers and difference in details of the coding in the algorithms.

Figure 5: Error distribution of the testing results

In addition, visual checks were carried out for all functions that have graphical inputs and outputs. All results coincided with the specifications. For the functions outputting curves and images, the graphic data are actually numerical results and also tested numerically.

## 5 Examples

In this section, we take two examples to partially show the usage and functionalities of the new Modelica Wavelet Library in the simulation environment, Dymola.

### 5.1 The signal under study

The signal under study is defined in equation (2).

$$\begin{aligned}
 y &= y1 + y2 \\
 y1 &= \begin{cases} \sin(2\pi 10t), & t < 0.5 \\ 0.2 \sin(2\pi 10t), & t \geq 0.5 \end{cases} \\
 y2 &= \begin{cases} 0.2 \sin(2\pi 50t), & t < 0.5 \\ \sin(2\pi 50t), & t \geq 0.5 \end{cases}
 \end{aligned} \quad (2)$$

It is a time-variant signal containing two frequencies, 10 and 50 Hz. At time  $t = 0.5$  s, the magnitudes of the two frequency components alternate. Signal  $y$  is generated with the Modelica model “testSignal2” in the package “Examples” of the wavelet library. It is shown in Figure 6.

Figure 6: The signal under study for the examples

Since the wavelet transform can only be correctly performed with an equidistant time grid, the simulation data should be stored with an equidistant time grid. Otherwise, the data have to be converted to equidistant time grid with the library function “interpL” before applying wavelet transform. In the examples, this is ensured by setting the sampling frequency “fs” to a none-zero positive value.

### 5.2 Wavelet multi-resolution analysis

Firstly we carry out an MRA using the wavelet library to observe the signal around the transient time,  $t = 0.5$  s with different resolutions. This is done by executing the function “fileDataMRA” in the package “Examples”. Most of the input parameters can be left at default values except the following ones:

- Time range for analysis is set as  $t_0 = 0.25$  and  $t_1 = 0.75$  since we are only interested in the transient region;
- Sampling frequency  $fs = 480$ , so that the highest frequency in the testing data is 240 Hz ( $fs/2$ );
- $Nd = 7$  in the wavelet definition “wd” to select the 7-th order Daubechies wavelet;
- $decLevel = 3$  in the MRA parameters “mraParameters” for carrying out a three level wavelet decomposition; and
- $rA = 0$  in “mraParameters” to remove the lowest frequency components in the reconstructed signal.

After execution, we get eight curves displayed in two diagrams in Dymola. In the first diagram, the original signal and the data in the approximation level and three detail levels are displayed. They are shown here in Figure 7.

Figure 7: The original signal and decomposed data

The x-axis of the diagram shown in Dymola is given in data point. There are 240 data points; and the symbol of the original data is shown as “u” instead of “y”.

The wavelet decomposition in this MRA separates the original signal into four time series containing different frequency components. This is illustrated with Figure 8.

Figure 8: Separation of the frequency components with three-level wavelet multi-resolution analysis

Since the sampling frequency is  $f_s = 480$  Hz, we know that the 10 Hz component of the original signal is projected into level A3 and the 50 Hz component falls in D3. From Figure 7 we also see some oscillations in level D2. This is because the wavelet decomposition does not realize perfect frequency separation. Furthermore, some peaks in level D1 represent the frequency transient and edge effect, which imply fast changing events.

The second half of the MRA in this example is data reconstruction after the tuning of the wavelet coefficients. This is shown with four curves in the second

diagram, which is not repeated in this article. Since we have set  $rA = 0$ , meaning to remove the information in the approximation level, which mainly contains the 10 Hz component, the reconstructed data mainly contains the 50 Hz component, as shown Figure 9. We can see that this signal is almost identical to the middle part (0.25 – 0.75 s) of signal y2 in Figure 6.

Figure 9: The reconstructed data after removing the approximation coefficients in wavelet MRA

### 5.3 Continuous Wavelet Transform

The second example demonstrates CWT for the same signal as shown in Figure 6. By executing the function “fileData\_cwtn” without changing any default parameters we can get the CWT result illustrated with a 2-dimensional image or a 3-dimensional surface, depending on the version of Dymola used. The image with pseudo-colour is shown in Figure 10.

Figure 10: Continuous wavelet transform of the signal under study

The coefficients are shown with warmer colours (yellow-orange-red) for larger magnitudes and colder colours (green-light blue-dark blue) for smaller magnitudes. The horizontal axis represents the time from 0 to 1 second. The vertical axis represents the wavelet scales from 1 to 64. The relationship between scales and frequencies is determined by both the sampling frequency of the data and the wavelet used. By observing this CWT image we can draw several conclusions:

- The frequency transient happens at  $t = 0.5$  s.
- Both low frequency components (here 10 Hz) and high frequency components (here 50 Hz) are present throughout the time span of the signal.

- Before 0.5 s low frequency components are much stronger than the high frequency components. This reverses after 0.5 s.

## 6 Conclusion

This article describes a new wavelet library developed for Modelica. This library contains fifteen wavelet families commonly used in research and engineering applications, continuous wavelet transform, discrete wavelet transform both in forward and inverse directions, two application tools and several examples. In addition, the library provides graphic user interfaces for some functions to support a user-friendly workflow. Moreover, it includes documentation embedded in the library, plus an external user's manual.

During and after the development work, black-box testing was carried out for all algorithms. The testing results have proved the correctness of the library.

The first release of this Modelica wavelet library is limited to one-dimensional wavelet transforms for post-processing of the simulation data. Several wavelet calculations, such as wavelet packet and two-dimensional transform, are not yet included. This could be gradually added in the future. Nevertheless, the introduction of this wavelet library will definitely enrich the functionality of Modelica and contribute much to the Modelica society.

## Abstract

This paper describes a new approach to sizing an electric drivetrain, including its power supply. The advantages of a real battery testing system are combined with the advantages of a Modelica model of a product. A testing system analyzes battery performance under specific constraints such as differing temperatures, vibrations and humidity. Since these constraints are hard to replicate in a model, an experimental rig is an optimal solution for battery tests [1]. Virtual engineering of a real system is advantageous in terms of the speed of modifications, the measurement of all relevant data and the low cost of development. The coupled virtual model and experimental testing rig for batteries constitute the basis for this new concept and improve the development of the electric powertrain.

*Keywords: battery, hardware-in-the-loop, real-time*

## 1 Introduction

Mobile applications are increasingly using electric power supplies, which have to be sized optimally. Electric vehicles are stimulating the development and optimization of future drivetrains. Their physical and temporal range is very important.

This study focuses on one of the main components, the power supply. Batteries are normally tested in test rig environments. The advantages of an experimental rig are its versatility, e.g. for climate tests, vibration tests and discharge tests. One of its most important features is its safety for operators and the environment. Tests of batteries installed in real vehicles or equipment involve various safety issues and unforeseen conditions or defects can cause injuries or other safety-critical situations.

Figure 1: Hardware-in-the-loop with a real battery

Since current battery models are often incomplete or only describe properties in certain areas, the advantages and potentials of real test environments also ought to be factored into the modeling of mobile systems and, specifically into the modeling of electric drivetrains.

## 2 The Experimental Vehicle RAVON

Since detailed data from vehicle manufactures was unavailable for the development of the methodology presented here, the AWD off-road vehicle RAVON (Robust Autonomous Vehicle for Off-road Navigation) developed by the Technical University of Kaiserslautern, Germany was used as the test subject.

Figure 2: The autonomous vehicle RAVON

This unmanned electric vehicle is normally used as a test object to study autonomous, behavior-based strategies for motion adaptation, localization and navigation in rough outdoor terrain. Equipped with four synchronous wheel hub motors and four batteries, the vehicle can be used under a variety of temperature, humidity and terrain conditions. The electric vehicle is powered by eight 12V batteries with a total voltage of 48V. This power supply must be adequate for the entire task.

Since the data needed to create a mechatronic model of RAVON (e.g. CAD data, drivetrain and control parameters and battery specifications) were available in advance, modeling with Modelica could start immediately.

### 3 The Modeling Procedure

The RAVON's CAD data are available in STEP format. These data are the basis for the mechanical parts of the chassis with interfaces to other physical domains in Modelica. The Fraunhofer Institute for Factory Operation and Automation IFF in Magdeburg has an automated CAD-to-simulation procedure that effectively converts CAD data into Modelica description [2].

Figure 3: Modelica model generated semi-automatically from CAD data

The program's database contains XML data on the mechanical model's physical and kinematic properties (masses, moments of inertia, joint constraints, etc.) as well as triangulated VRML geometry exported directly from the CAD system. Since it also supports closed kinematic loops, this new procedure also makes it possible to model any complex mechanical system efficiently.

### 3.1 RAVON Subsystems

The virtual RAVON platform must communicate with a real battery test rig in real time. Apart from incorporating the semi-automatically generated chassis model, the most demanding task was modeling the entire electric drivetrain so that it is real-time capable. The uppermost vehicle model was decomposed into two Modelica subsystems, *Chassis* and *Drive* (see Figure 4).

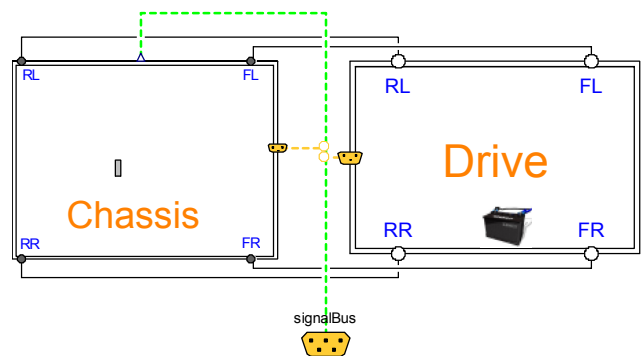

Figure 4: Modeled subsystems of RAVON

The virtual parts of the *Drive* model can be matched with their real counterparts. A *Huebner HAC 71.11.6* permanent magnet synchronous induction machine and a *CycloDrive 6000* planetary gear are mounted in each wheel-hub model. The electrical machines were parameterized in Modelica using real manufacturer data. A DC interface to a common external power supply was also included.

The drive subsystem of a single wheel with the DC/AC converter and the motor controller is pictured in Figure 5.

Figure 5: Controlled wheel-hub motor model

The motor controller model is based on a conventional cascade structure with an outer speed control loop and an inner current control loop. PI controllers with limited outputs are used in both cases. Since the real-time capability had top priority, some simplifications were made in the model of the motors' power electronics, among others. Since they would not influence the model's accuracy significantly, fast PWM signals were not included. The torque control algorithm is based on field-oriented vector control [3]. The controller parameters were selected to attain maximum speed with minimal overshoot.

## 4 Battery Testing System

This study aimed to utilize a real battery testing system in order to integrate a real battery's complex behavior in early stages of product development. Rather than using a real product prototype to record battery charging profiles, a virtual prototype is incorporated in the workflow. A real testing rig can be used to swap energy bidirectionally between the virtual model and the real battery, depending on the prevailing conditions.

Figure 6: FuelCon battery testing system

Since the Modelica model provides the load for a real battery, its performance can be analyzed dynamically. The testing system from the company FuelCon allows users to set different environmental parameters such as ambient pressure, temperature, atmospheric humidity and movement. Various types of batteries, e.g. lithium-ion, lithium-polymer, NiCd, NiMH or lead-acid, can be tested with this testing system. The Evaluator-B series battery testing system has an interface that is connected with external current profiles [4]. The methodology developed here with the virtual vehicle model uses this function to repeatedly supply actual current and receive the battery voltage.

## 5 Integration of the Real Testing System in a Hybrid Simulation

The objective of this study was to integrate a real battery testing environment in a hardware-in-the-loop simulation setting. Battery voltage and computed electric current signals must be exchanged bidirectionally during a test run. The testing system is equipped with load and charger electronics. This makes it possible to charge or discharge the batteries depending on prevailing electric currents. Dynamic processes such as current peaks can also be analyzed with this approach.

### 5.1 Software Interfaces

The FuelCon testing system's operator interface utilizes Visual Basic (VB) scripts running in an embedded Windows environment. The Fraunhofer IFF developed the COMsigate interface to extend the operator interface's range of functions. The COMsigate software module employs the User Datagram Protocol (UDP) for communication between the testing system and the outside world.

The main VB script runs in a loop during battery-coupled hardware-in-the-loop tests. It reads the actual battery voltage ( $U$ ) and can set a new electric load ( $I$ ) every 10ms in keeping with the latest UDP packet received through the COMsigate.

Matlab/Simulink was incorporated in the tool chain because of its excellent interoperability and advanced toolboxes [5]. Its UDP communication blocks were used to transmit the battery signals  $U$  and  $I$  bidirectionally through the COMsigate interface. In addition autonomous driving course profiles, the vehicle model can also be interactively controlled with a joystick module that enables users to define own test cycles in Matlab.

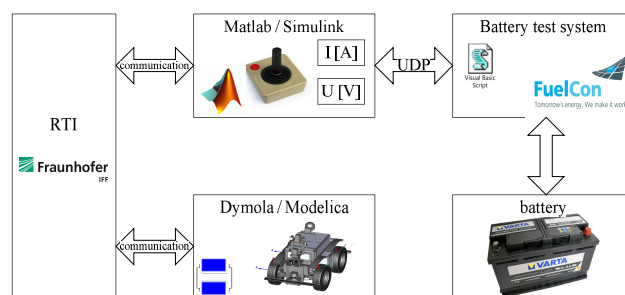

Figure 7: Tool chain of the hybrid simulation of RAVON with a real battery in a test rig

The Fraunhofer IFF developed the Real Time Interface (RTI) to support real-time communication between heterogeneous software applications [6]. RTI's shared memory is used to exchange battery charge states and reference speed signals between Matlab/Simulink and the Dymola simulator [7] running the RAVON model.

The reference vehicle speed and the axles' steering movement are supplied to Dymola. Each electric drive is controlled separately. The vehicle's acceleration is determined by the electric current in the respective motors. The virtual supply voltage is the value of the real battery measured in the test rig. Thus, the real battery's performance influences the simulated vehicle's electric power.

## 6 Results

The first tests revealed that the dynamic processes between the battery testing system and the vehicle model reflect the theoretical considerations. The first example (Figure 8) presents a battery performance test using a static power consumption scenario. The model vehicle had to travel at a constant reference speed. Decreasing voltage increases the demand for electric current as the battery discharge. Since the mechanical power demanded is constant this phenomenon can be explained by the electric power balance equation:  $P_{elec} = U \cdot I$ .

Figure 8: Discharging at constant travel speed

The actual speed remains constant until the maximum current is reached, which is defined by the battery. From this point onward, the vehicle's speed cannot be kept constant and decreases. Afterward,

the electric current reaches a constant value and the battery voltage continues to fall.

The results presented in Figure 9 depict forward and backward acceleration and deceleration maneuvers with sudden stops. The battery's demand for current increases during the acceleration phase and the battery's voltage drops temporarily. The current peak when the electric motor switches from loading to braking is evident. Such current peaks during charging and discharging can affect a battery's life and also influence a battery's state of charge.

Figure 9: Analysis of dynamic behavior

A continuous and rapid change of direction was investigated in the next test scenario. Electric current and voltage propagation were analyzed. Figure shows the rate of speed as well as the related current and voltage.

Figure 10: Continuous and rapid changes of direction

The current peaks in the case presented here are many times higher than those in the test scenario in Figure 9.

## 7 Conclusions

This paper describes a novel hardware-in-the-loop approach to connecting mobile mechatronic system models with a real battery testing system. It can be used to test the entire system's energy balance under realistic conditions. This makes it possible to perform stress and durability tests without having to build complex prototypes first. Battery size and the product's electromechanical properties can be optimized. As a result, product development is expedited and validated by early testing. This approach is suitable for more than just electric vehicles. It can also be applied to all types of battery-powered devices with higher power requirements.

## Abstract

In this poster the *Modelica Systems Physics library* is presented. The Systems Physics library is a free open-source library with models for different areas of physics [1]. The primary use of the library is for educational purpose in Physics courses at medium level.

The library contains models from five different domains (hydraulics, translational and rotational mechanics, electrodynamics and thermodynamics). In the future, we plan to add chemistry as a sixth domain. Each domain contains connectors containing a substance-like quantity and the corresponding potential; basic models (capacitance and resistance); sensors and actuators as well as some domain specific elements, such as nonlinear accumulator, nonlinear resistors, valves, springs or inductances. In addition to the constitutive equations each model also comprises the energy balance. For example, dissipative elements calculate the loss energy and even the entropy production with the help of an additional thermodynamic connector.

## 1 Introduction

Systems Physics is a novel approach to physics with which beginners are able to grasp the fundamental concepts underlying processes in nature and technology [2]. It is based on everyday concepts known from fluids which are familiar to everybody. The analogy between physical quantities and fluids offers a very intuitive approach to physics [3]. The powerful pictorial modeling offered by Modelica helps students to understand basic physical processes.

Moreover, here is an immense number of problems that can be addressed by this approach which are usually not included in the standard physics textbooks at undergraduate level. With the help of this Modelica library, students are able to model rather

complicated physical systems (e.g. friction) with little mathematical knowledge.

In the first two semesters at the ZHAW School of Engineering students learn the modeling concept of system dynamics with Stella or Berkeley Madonna. Thereby they learn the basic structures and formulas (balance equation, constitutive laws and the energy carrier concept) of physics. The *Systems Physics* library could then be used in subsequent semesters in order to deepen this knowledge.

Systems Physics combines the modeling concept of System Dynamics with a unified description for all branches of classical physics known from Bond Graph theory [4]. Our concept of energy carrier is similar to that of the Bond Graph theory. But there is a crucial difference. In Bond Graph theory, force and torque are potential quantities (effort quantities) and the kinematic variables velocity and angular velocity are seen as flow quantities. In Systems Physics however, this approach is not possible because force and torque are part of the balance equation and velocity and angular velocity are the “driving force” for the appropriate currents. Therefore force and torque are flow variables and the two velocities are effort or potential quantities.

In our model based approach students start by formulating the balance of a fundamental quantity (bathtub-thinking for volume, mass, electrical charge, momentum, angular momentum, entropy or amount of substance). Then they have to specify the currents and the rates of change (feedback-thinking). On a second layer they can add the balance of energy (bookkeeper-thinking).

Our vision of a new physics course for engineers or natural and medical scientists covers system dynamics modeling in the first year and object-oriented modeling in the following years of studies [5].

## 2 Structure

The systems physics library includes the domains hydraulics, electrodynamics, translational mechanics, rotational mechanics, thermodynamics and chemistry. Each domain includes a substance like quantity and a corresponding potential. All connectors are constructed according to this basic structure (Table 1)

In all branches of physics there are many different storage systems such as tanks, plastic bottles, capacitors, moving or rotating bodies, heat accumulators. For each storage system we can write down two balance equations: one for the basic quantity  $M$  (volume, electric charge, momentum, angular momentum, entropy); and one for the Energy  $W$ . The balance equations for  $M$  and  $W$  are given by

$$\sum_i I_{M_i} = \frac{dM}{dt} \quad (1)$$

$$\sum_i I_{W_i} = \frac{dW}{dt} \quad (2)$$

where  $I_M$  are substance currents and  $I_W$  are energy currents. For the entropy balance equation a production rate  $\Pi_S$  is introduced in addition to entropy currents.

The domain specific potential  $\varphi_M$  (pressure, voltage, velocity, angular velocity and absolute temperature) connects the current for the basic quantity with the energy flux

$$I_W = \varphi_M I_M \quad (3)$$

A Model with two ports and a conserved quantity (ideal volume, electric charge, momentum or angular momentum) contains at least one equation for conservation and one for the power

$$I_{M1} + I_{M2} = 0 \quad (4)$$

$$P = \Delta \varphi_M I_M \quad (5)$$

These equations are formulated in separate *partial models*. In thermodynamics we need two different partial models, one for heat conductance which conserves energy

$$T_1 I_{S1} + T_2 I_{S2} = 0 \quad (6)$$

and one for ideal heat engines which conserve entropy

$$I_{S1} + I_{S2} = 0 \quad (7)$$

An additional equation calculate the production of entropy in the partial model for heat conductance

$$I_{S1} + I_{S2} = \Pi_S \quad (8)$$

or the power in a partial model for ideal heat engines

$$P = \Delta T I_{S1} \quad (9)$$

Ideal heat pumps are modeled similar to hydraulic pumps: in the same way as a hydraulic pump pumps water or oil heat pumps pump entropy. This is one of the main messages of Systems Physics.

Table 1: flow and potential variables in the different domains of Systems Physics

domain	quantity	potential
hydraulics	volume	pressure
electrodynamics	charge	voltage
translational mechanics	momentum	velocity
rotational mechanics	angular momentum	angular velocity
thermodynamics	entropy	temperature

### 2.1 Hydraulics

The volume of an incompressible fluid is the basic quantity in hydraulics and pressure is the associated potential. Because pressure multiplied by volume flow equals the flux of energy, the conservation of energy is guaranteed.

The hydraulics library includes different storage elements like open vessels, spring-loaded tanks and other accumulators, pipes with laminar and turbulent flow characteristics as well as various valves. The inertia of the fluid flowing through the pipe is responsible for the inductive effect. In all three system categories (capacitance, resistance and inductance) the stored or dissipated energy is calculated. In an additional resistor element, the entropy is recalculated and is connected by a thermal connector. The temperature of this connector determines the viscosity of the fluid.

Two ideal pumps are modeled, one with a signal input for pressure difference and one with a signal input for the volume flow rate. In addition, the library contains sensors for pressure and volume flow.

### 2.2 Electrodynamics

The electrodynamics library based on the Modelica standard libraries with capacitor, resistor, diode and inductor. In addition, an isolated metal sphere is modeled for charge storage in experiments with high voltage.

The energy balance is calculated in all elements. This calculation is made for didactic purpose and for energy check in complex systems. A resistor with a thermal connector wherein the entropy is calculated enables the modeling of electro-thermal elements such as resistance heating or light bulb.

### 2.3 Mechanics

The mechanics library includes two parts: one for motion along a straight line and one for rotation around a fixed axis. Therefore, the associated quantities momentum and angular momentum can be treated as scalars. The similar statement is true for the associated potentials (velocity and the angular velocity). The tight separation of the balance equation for momentum or angular momentum from kinematics has some implication: mass and moment of inertia have only one connector and distance or angle can only be calculated in elements that describe the flow of momentum or angular momentum.

In addition to the linear systems some more elements, such as friction, air resistance or elastomer spring are modeled. An ordinary rope or string is a further element often used in physics instruction. It is modeled as a spring-damper-system with predetermined breaking point. As in hydraulics and electrodynamics some elements for momentum or angular momentum flow are provided with a heat connector. The produced entropy is calculated and the temperature has an influence on the constitutive laws of these elements.

Figure 1: A model of an Atwood machine with two weights and bearing friction. The symbolic earth with five connectors for the flow of volume, momentum, angular momentum, electric charge and entropy stands for the surrounding.

The mass element has a momentum source which strength corresponds to the tangential component of the weight force. A further element contains the equation for the relativistic mass. In this element,

energy and momentum are connected with the help of the famous Einstein equation. The model of a simple rocket engine completes the model zoo, although this element belongs to the open systems, which are not included in this library. Figure 2 shows the velocity-time behavior of a rocket another system that can be easily modeled with our approach.

Figure 2: Velocity-time-diagram of a rocket ascending in an isentropic atmosphere with constant gravitational field

Translational and rotational mechanics are connected to each other by means of pulleys. The corresponding model has four connectors, three for translation and one for rotation. With two bodies, two strings, a pulley and a bearing friction, we can model Atwood's machine (Figure 1).

### 2.4 Thermodynamics

If we take entropy as the basic quantity of thermodynamics it's easier to write down the correct equations than if we take the energy as a conserved quantity [6]. However, for the equations themselves, it does not matter whether we start from the energy or from entropy as we have shown in the introduction. There are two different models which specify the transport of heat, the heat conduction and the ideal heat engine.

We describe homogeneous systems, which are heated at a constant pressure, with the state variable enthalpy  $H$ . Enthalpy is a special form of energy and a thermodynamic potential. Although entropy flow and temperature are calculated in the connector, this is no problem with respect to the balance equation for energy

$$TI_s = \frac{dH}{dt} \tag{10}$$

More generally, a homogeneous thermodynamic system can at least change entropy and volume. Therefore the system has temperature and pressure as two associated potentials. To discuss and model

such a system we have developed the Carnotor, a simple machine with a thermal and a hydraulic connector (Figure 3). Carnotor is a portmanteau composed of Carnot and Motor (German word for engine).

The Carnotor consists of a double-acting cylinder filled with the substance to be examined on one side of the piston and an ideal fluid on the other side. To each port we can add a pump, a closing-off or a big storage tank. With this equipment students can analyse all four basic processes of thermodynamics (Table 2).

The corresponding model calculates pressure and temperature from the change of volume and entropy. For the ideal Gas, the constitutive laws are as follows

$$S = S_0 + nR \ln\left(\frac{V}{V_0}\right) + \frac{f}{2} nR \ln\left(\frac{T}{T_0}\right); \quad (11)$$

$$pV = nRT \quad (12)$$

$f$  stands for the degrees of freedom of gas molecules,  $n$  for the amount of substance and  $R$  for the gas constant. Equation (12) is known as ideal gas law.

Table 2: The four basic processes in thermodynamics

process	heat port	hydraulic port	unchanged
isochoric	heat pump	closing-off	volume
isobar	heat pump	storage tank	pressure
isentropic	closing-off	hydraulic pump	entropy
isotherm	storage tank	hydraulic pump	temperature

Figure 3: The Carnotor has two ports, one for heat and one for an ideal fluid. Both ports can be combined with a closing-off, a storage tank or a pump

Figure 4: This system contains four models for ideal gas, two ideal heat pumps, two ideal hydraulic pumps, a heat flow and a volume flow element.

The Carnotor can be taken as the core element for a lot of thermodynamics engines. Figure 4 shows a model with which one can simulate all four basic processes simultaneously

### 3 Conclusions

Systems Physics provides a consistent, coherent and relevant structure of physics. A huge number of dynamical systems can be modeled with the same heuristic approach. The equation of balance for substance-like quantities like volume, mass, electric charge, momentum, angular momentum and entropy yields the backbone for such models. By adding the constitutive laws for accumulators and conductors we get the basic equations. In a third step we can add energy as a second substance-like quantity. The energy balance analysis is often useful but not necessary for simple systems. But energy conservation becomes an inevitable requirement in more complex systems like thermodynamic accumulators.

Systems Physics has been developed on the basis of the Karlsruher Physikkurs [7] and taught in different physics courses at Zurich University of Applied Sciences.

With the help of the *Systems Physics library* we hope that we can convince more and more teachers of the usefulness of this method. A countless number of dynamic models are waiting to be modeled with a System Dynamics or a Modelica tool.

On Youtube you can find some tutorials on specific topics of the *Systems Physics library* [8]

## Abstract

Omni wheel is defined as one having rollers along its rim. Respectively omni vehicle is one equipped by omni wheels. Several steps of development of dynamical model of the omni vehicle multibody system are implemented. Essential parameters of the model: (a) number of rollers per the wheel, and (b) angle of the roller axis inclination to the wheel plane, are introduced. Initially, dynamics of the free roller moving in a field of gravity and having a unilateral contact constraint with horizontal surface is modeled. The contact tracking using simplified and efficient algorithm turns out being possible. On the next stage the omni wheel model is developed and debugged. After that the whole vehicle model is assembled as a container class having arrays of objects as instantiated classes / models of omni wheels and joints. Dynamical properties of the resulting model are illustrated via numerical experiments.

*Keywords: omni wheel; contact tracking; unilateral constraint; contact detection; model of friction*

## 1 Introduction

Investigation of omni vehicle dynamical properties is sufficiently popular topic in frame of the multibody dynamics [1, 2, 3, 4]. The omni vehicle is one having omni wheels, wheels equipped by rollers along the rim. Simplified, idealized models having contacting rollers as an infinitely small discrete elements are known. Thus one has a resulting non-holonomic constraint being “uniformly distributed” over the wheel rim. As a result, paradoxically, the physical objects, omni wheels, describe approximately, in this situation, an idealized object, “simplified” infinitesimal model.

Our goal in this paper is to develop a technique for

building up a dynamical prototype for the “real” model of the omni vehicle explicitly involving dynamics of physical rollers. Here we rely upon the “simple” 3D multibody dynamics library classes utilized previously in several examples of the multibody systems dynamics [5]. Simultaneously this library enables us to create complex dynamical models including unilateral constraints of different nature.

Unlike to [2, 3] we emphasize here on the details of the unilateral constraint implementation paying special attention to contact switching when rollers changing.

## 2 Problem formulation

Upon describing the omni vehicle model construct note that the number of rollers per each wheel and the angle of inclination of the roller axis of symmetry to the wheel plane are both fundamental parameters of the vehicle dynamical model. For simplicity and presentation clarity we currently consider omni wheels being equipped by four rollers. Also, for simplicity rollers themselves have their axes of symmetry lying in the wheel plane, see Figure 1. These fundamental parameters are easily changed in a way simple enough. We assume also that the rollers are located on the omni wheel such that for wheel vertically aligned a projection of the curve of contact consists of segments in the sequence, each segment corresponding to the contact of individual roller. These segments are connected in a way such that the normal relative velocity at contact is equal to zero at the switching point of rollers. This means that the normal impact is always absent. Discontinuities of the tangent relative sliding velocity are absent for zero angle of inclination. But the tangent force of friction may have discontinuity of the first kind in the worst case of angle of inclination if the

roller symmetry axis to the wheel plane is non-zero. Thus, the wheel linear and angular velocities will be continuous at an instant when roller switching contact. Similar statement takes place for rollers, as well. Then tangent impacts are also absent.

Figure 1: The omni wheel vertically aligned.

Note, in addition, that the curve of contacting points forms the  $xy$ -projection onto the wheel plane, having a shape of the circle of radius  $R$ , see Figure 1. Thus for translational and rotational motion we have continuity as well. Resuming we are able to conclude that the regularity of motion is conserved as roller switching at contact. At least on the level of integrity of the omni wheel. Recall, that all the description above takes place for vertical alignment of the omni wheel.

On the next level of assembling process, several omni wheels are interconnected with the moving platform of the vehicle, see Figure 2, using joint constraint as a class from the previous stage. In our case, number of wheels may be three or more. They can form different configurations on the platform body. We analyse an example with three wheels forming an equilateral triangle in the plane of the platform, see Figure 2, parallel to the coordinate horizontal plane  $zx$ . Axis  $y$  here is assumed vertical.

### 3 The roller dynamics model

Firstly, we presume that the roller is axisymmetric spindle-shaped rigid body having outer surface defined in body frame of reference  $Oxyz$ , see Figure 3, by

Figure 2: The three wheeled vehicle. Top view.

equation

$$x^2 + \left( \sqrt{y^2 + z^2} + R_1 \right)^2 = R, \quad (1)$$

where  $R$  is the omni wheel radius,  $R_1 = R \cos \alpha$  is the distance from the roller center to the wheel center,  $\alpha = \pi/n$  is the half of the roller opening angle of visibility from the wheel center,  $n$  is number of rollers per wheel.

Figure 3: The roller over horizontal surface. Lateral view.

Dynamics of the roller translatory–rotary motion is implemented using equations of Newton – Euler as was shown in [6]. And rotational motion was modeled by the quaternion algebra [7].

Algorithm for contact tracking plays an important role for the correct and efficient work of the computer model of the contacting process of the roller and the horizontal surface. For modeling and simulation of the rigid body dynamics with unilateral constraint we apply the technology described in [8]. So we could have used in the object of contact a system of well known algebraic or implicit differential–algebraic equations. However, these equations degenerate at the roller tips defined by equations  $x = \pm R \sin \alpha$  in the roller coordinates, see Figure 1. Usually, such a degeneration causes an abnormal completion of the simulation process.

In our case of the spindle-shaped roller over the horizontal surface, arranging the contact tracking procedure turns out being sufficiently simple. So one can point out explicit procedure for computing the nearest point  $P_B$  of the roller to the horizontal surface, see Figure 4. This surface has its own nearest point  $P_A$  at contact. Evidently the point  $P_A$  is a vertical projection of the point  $P_B$  of the roller.

Figure 4: Contact tracking scheme.

Denote by  $\mathbf{i} = (1, 0, 0)^T$  the unit vector along the axis  $O_B x_B$  of the roller connected coordinate system from Figure 4. This vector is resolved with respect to (w. r. t.) the system  $O_B x_B y_B z_B$ . Let  $T_B$  be the rotational matrix of the roller w. r. t. the inertial frame of reference. The latter frame, in our case, coincides with the fixed horizontal surface coordinate system  $O_A x_A y_A z_A$ . Also, let  $\mathbf{r}_B$  be the roller current mass center radius vector w. r. t. the inertial system, and  $\mathbf{n}_A = (0, 1, 0)^T$  be the ascending vertical unit vector. Simultaneously  $\mathbf{n}_A$  is the normal vector to the horizontal plane.

Conventionally, we denote the plane as body A, and

roller as body B. Let  $\mathbf{d}$  be the horizontal unit vector defined by equation

$$\mathbf{d} = \frac{T_B \mathbf{i}_B \times \mathbf{n}_A}{|T_B \mathbf{i}_B \times \mathbf{n}_A|}.$$

Therefore, the directed segment  $\overrightarrow{O_B \mathcal{O}}$  must have a length  $R_1$  and be defined by formula

$$\overrightarrow{O_B \mathcal{O}} = R_1 \mathbf{d} \times T_B \mathbf{i}_B.$$

Here,  $O$  is the curvature center for the circle of the roller vertical section, see Figure 4. This segment is located simultaneously in the vertical plane and in the wheel plane. Thus from Figure 4 we see that the lowest point  $P_B$  of the roller outer surface is defined by equation

$$\mathbf{r}_{P_B} = \mathbf{r}_B + R_1 \mathbf{d} \times T_B \mathbf{i}_B - R \mathbf{n}_A \quad (2)$$

since the  $P_B$  lies on the same vertical with the point  $O$  and on the circle mentioned above. To compute position of the point  $P_A$  one has to put

$$\mathbf{r}_{P_A} = (x_{P_B}, 0, z_{P_B})^T. \quad (3)$$

All the procedure above is valid only if the vector  $T_B \mathbf{i}_B$  is inclined to the horizontal plane within an angle  $\pm \alpha$ . Otherwise one has to put  $P_B = B_-$  where  $B_-$  is the “left”, see Figure 4, tip of the roller for angle of the vector  $T_B \mathbf{i}_B$  inclination greater than the value  $\alpha$ . If this angle is less than  $-\alpha$  then one has to guess  $P_B = B_+$  where  $B_+$  is the “right” tip of the roller.

Finally, one can write down a contacting condition between roller and horizontal surface in the form

$$|T_B \mathbf{i}_B \cdot \mathbf{n}_A| \leq \sin \alpha. \quad (4)$$

This condition, however, is satisfied simultaneously for the lowest, being in contact, roller, and the highest one. To reject the latter case one can add to condition (4) yet another one

$$y_B < R \quad (5)$$

where  $y_B$  is the altitude of the roller mass center w. r. t. inertial frame of reference.

So a conjunction of conditions (4) and (5) is equivalent to the case of contacting. Otherwise condition of normal reaction being zero should take place. Indeed, according to Signorini’s law a following alternative is implemented for each individual roller: (a) contact takes place – relative normal velocity at contact should be zero; (b) contact is absent – normal reaction (and tangent too) of unilateral constraint should be zero.

Condition (a) has several alternative possibilities of implementation. Firstly, from the geometric viewpoint a presence of contact is equivalent to the scalar condition

$$y_{P_B} = 0. \quad (6)$$

Its absence is equivalent also to the scalar condition

$$F_n = 0$$

where  $F_n$  is the normal component of a reaction force acting on the roller at the point  $P_B$ .

Computational experience show that equation of contact in the form (6) usually causes an abnormal termination of the simulation process for the dynamical model of the roller. One has similar result if we use equation

$$v_n = 0$$

as an implementation of condition (a). Here  $v_n$  is the normal component of the relative velocity at contact point. And only equation of the form

$$\dot{v}_n = 0$$

leads to the required result: object of contact works properly during the simulation process. One has to recall here that all the implementation of the contacting process has the “rigid” point-contact model.

For each roller of the omni vehicle model when contacting the friction model being used is “turned on”. In our model being developed the “simple” law of the Amontons – Coulomb dry friction is applied. Actually we use known piecewise approximation [8] to exact dry friction instead. This approximation has high accuracy over long time intervals [9]. In general, implementation of unilateral constraint model is based on the results outlined in [8].

If the angle of inclination for the roller axis of symmetry to the wheel plane has non-zero value then some of the above relations ought to be slightly corrected. In this case, rollers become distorted along the wheel rim. Given the position  $\mathbf{r}_O \in \mathbf{R}^3$  of the wheel center, point  $O$ , see Figure 4, firstly, we have to build up an auxiliary base consisting of unit vectors:

$$\mathbf{i}' = T_B \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix}, \quad \mathbf{j}' = \frac{\mathbf{r}_O - \mathbf{r}_{O_B}}{|\mathbf{r}_O - \mathbf{r}_{O_B}|}, \quad \mathbf{k}' = \mathbf{i}' \times \mathbf{j}'.$$

After that a matrix of coordinates change has the form  $T' = (\mathbf{i}'\mathbf{j}'\mathbf{k}')$  where  $\mathbf{i}', \mathbf{j}', \mathbf{k}'$  are assumed as vector columns. This matrix defines transformation from inertial frame of reference connected with the fixed

body  $A$  to the frame defined by the vector base  $B' = \{\mathbf{i}', \mathbf{j}', \mathbf{k}'\}$  introduced above in the following way

$$\begin{pmatrix} x_A \\ y_A \\ z_A \end{pmatrix} = T' \begin{pmatrix} x' \\ y' \\ z' \end{pmatrix}.$$

To reduce an analysis to the case of  $\beta = 0$  already considered above we have to rotate the base  $B'$  about  $\mathbf{j}'$  by the angle  $-\beta$  such that after the rotation a new base  $B = \{\mathbf{i}, \mathbf{j}, \mathbf{k}\}$  should be aligned with the wheel plane containing the unit vectors  $\mathbf{i}, \mathbf{j}$ . The rotation mentioned has the matrix

$$S = \begin{pmatrix} \cos \beta & 0 & -\sin \beta \\ 0 & 1 & 0 \\ \sin \beta & 0 & \cos \beta \end{pmatrix}$$

in the base  $B'$ . Then in the base of the indicated body  $A$  the rotation of the unit vector  $\mathbf{i}'$  can be represented as follows  $\mathbf{i} = T'S(1, 0, 0)^T$ . Suppose also  $\mathbf{j} = \mathbf{j}', \mathbf{k} = \mathbf{i} \times \mathbf{j}$ . Evidently  $\mathbf{k} = \mathbf{d}$  where  $\mathbf{d}$  is the unit vector given above.

Thus based on the formula (2) and taking into account Figure 4 we can conclude that for the case of  $\beta \neq 0$  the following result takes place

$$\mathbf{r}_{P_B} = \mathbf{r}_B + R_1 \mathbf{j} - R \mathbf{n}_A - \frac{R_1 \tan \beta \sin \gamma}{\sqrt{1 - \sin^2 \gamma}} \mathbf{j} \times \mathbf{i}, \quad (7)$$

where the angle  $\gamma$  satisfies the equation

$$\sin \gamma = \mathbf{i} \cdot \mathbf{n}_A.$$

## 4 Assembling vehicle model

An assembling process of the omni vehicle prototype is implemented in two steps: (a) assembling the omni wheel consisting of the wheel itself and a set of rollers attached to the wheel; (b) assembling the vehicle by instantiating objects of the omni wheel class from stage (a) into the container class of the vehicle prototype.

To connect rollers, rather objects of the roller class, and the wheel we use model of the joint constraint previously developed and described in [5]. It is simply revolute class with free relative rotation about its axis. Codes of all the classes / models for the prototype are implemented as Modelica classes library. See visual model of the omni wheel in Figure 5. Here, in our example we selected for simplicity and certainty  $n = 4$ .

The model of main interest is one of the whole vehicle which is “assembled” on the second stage of the assembling process. Connecting devices were also implemented as objects of the same joint class from stage

Figure 5: The omni wheel visual model.

(a). These joints connect the vehicle body and each of wheels. All joints above allow relative rotation without any resistance and lock sliding along the joint axis. See visual model of the vehicle in Figure 6. Here, for presentability, objects are shown as scalar elements. Actually, one has to instantiate corresponding arrays of objects of classes “Roller” and “OmniWheel” for arbitrary  $n$  and arbitrary number of wheels in the vehicle.

Recall that before the DAE index reduction process implemented in Dymola the whole vehicle model consists of: (a) one rigid body of the vehicle platform; plus (b) three rigid bodies of the vehicle wheels; plus (c) twelve rigid bodies of rollers located on the wheels. According, for instance, to [5] for each object of rigid bodies we implement six Newton’s ODEs for the mass center motion plus seven Euler’s ODEs for rotational motion about the mass center. For the latter case we have four Euler’s kinematical equations for the rigid

body quaternion plus three Euler’s dynamical equations for the rigid body angular velocity. Totally, the whole vehicle model includes system of ODEs of order  $16 \cdot 13 = 208$ . Besides, constraint objects are able to generate additional differential equations.

Wheels being assembled into the vehicle will keep the vertical alignment unavoidably. For this reason the simplified contact tracking algorithm described above works properly.

Computer experiments were performed for different numbers of rollers per wheel and using several frictional models at contact between roller and the horizontal surface. Corresponding results were compared. For instance an evolution of the contact process for one wheel of the three wheeled vehicle is shown in Figure 7. Paying attention to the Figure legend we are seeing variables with suffixes “.h” and respectively curves of four colours. This variables represent so called mutual approaches for contacting bodies. Their values are simply distances between rollers of

Figure 6: The omni vehicle visual model.

the wheel and the horizontal surface of rolling. These curves correspond to rollers being in different phases of wheel rotation: before contact, at contact, after the contact. See an instance of the roller change being zoomed in Figure 7. For implementing such a switching it is sufficiently simple to use if-clause thus alternating states of the contact existence / non-existence. Corresponding fragment of Modelica code may have the following representation

```

...
if noEvent(abs((T_B*i)*nA) < cos_of_max and
             h < R) then
  Drelvn = 0;
  Forcet = -fric*relvt*(if
                       noEvent(relvtsqrt <= delta)
                       then 1/delta
                       else 1/relvtsqrt)*Forcen + mu*nA;
else
  Forcen = 0;
  Forcet = zeros(3);
end if;

```

```

Drelvn = der(relvn);
...

```

The first if-operator here is responsible for the unilateral constraint detection. Its condition is equivalent to conjunction of conditions (4) and (5). Drelvn is the variable being equal to the derivative of the relative normal velocity at contact. So we have an alternative: (a) Drelvn = 0 means the contact existence or (b) Forcen = 0 means contact absence or, equivalently, zero-valued force of reaction. Vector variable Forcet simulates tangent force of friction, being computed here using piece-wise linear approximation of dry friction.

Simultaneously, one can also observe the unilateral constraint accuracy being kept by the model at contacting, see Figure 8. In this Figure we can observe how a numeric error of the unilateral constraint feasibility slowly diverges, mutual approach . . . h gradually

Figure 7: Process of rollers contact replacement

Figure 8: Accuracy of the unilateral constraint.

grows, for each successive roller in contact. Meanwhile, an absolute value of error stays near negligible value of  $10^{-7}$  meters. Change of the curve colour corresponds to change of the contacting roller.

## 5 Conclusions

As a summary of main results obtained in the course of the omni vehicle model development we can highlight the following issues:

- There exist a possibility for smooth impactless switching between rollers at contact upon rolling of omni wheel;
- Efficient and simplified contact tracking algorithm was implemented;

- Dynamics of vehicle was investigated for different number of rollers per wheel;
- Influence of friction model on dynamics of the omni vehicle was analyzed.

This work was performed with partial support of RFBR, projects 11-01-00354-a, 12-01-00536-a, 12-08-00637-a.

## Abstract

Due to different requirements for simulation during the design process of an electric drive system, investigations were carried out to supply models of different stages with consistent sets of parameters. Therefore physical models of the Modelica Standard Library were equipped with state-of-the-art control strategies to operate in realistic conditions. In the presented case the losses computed by the physical model were stored in characteristic tables to speed up simulation in cases where dynamics are of minor interest. These models can then be used for energetic, thermal and life-time analysis with a consistent set of parameters generated from their physical counterparts.

*Keywords: PMSM, induction machine, characteristic maps, field oriented control, MTPA*

## 1 Introduction

The continuous progress in the electrification of the powertrain in the automotive industry requires numeric based computer simulations to handle the growing complexity. During development various types of simulations are needed, some of which are summarized in Table 1. Simulations of category 1 focus on brief events and need very detailed models for reliable predictions. In category 2 a tradeoff between accurate and fast models must be found, whereas category 3 and 4 especially require models which are optimized on computation time due to the long simulation runs.

The machine models of the Modelica Standard Library (MSL), which are described in detail in [3] and [1], are based on physical equations using space phasor theory. They consider leakages of the magnetic field with stray inductances and include basic models for the copper, stray load, core and friction losses.

Category	Objectives	Simulated time
1	switching operations nonlin. in the drivetrain	0.01 s – 1 s
2	dynamic events short-term performance controller behavior	0.1 s – 100s
3	energy consumption thermal behavior performance analysis	10s – $1 \times 10^4$ s
4	aging simulation life-time of components	$1 \times 10^6$ s – $1 \times 10^9$ s

Table 1: Categories for simulation

Hence, they are well suited for simulations of category 2. However, for their application in the electric powertrain control is required, which is offered in the commercial Smart Electric Drives Library (SED), but not in the MSL. For long simulation runs the SED Library also provides quasi stationary machine models [6], but these models only consider ohmic losses. Therefore, this paper describes the implementation of advanced control for the MSL machine models of the permanent magnet synchronous machine (PMSM) and the induction machine, to use them for the creation of characteristic maps for lookup table based map models. These map models include all losses which are modeled in the MSL machines in tables and allow significant improvements of the required computation times compared to the physical models. This advantage basically results from the negligence of dynamics caused by control and machine physics.

## 2 Control of the PMSM

The principle for field oriented control of the PMSM is to achieve a control concept known from the elec-

Name	Unit	Description
$i_d$	A	Direct current of PMSM
$i_q$	A	Quadrature current of PMSM
$i_{sx}$	A	Current for field generation in IM
$i_{sy}$	A	Current for torque generation in IM
$\omega_{nom}$	rad/s	Nominal angular velocity
$U_s$	V	Norm of stator voltage
$U_{sMax}$	V	Norm of max. allowed stator voltage
$\tau_{electrical}$	Nm	Electrical torque inside machine

Table 2: Variables used in the PMSMs control algorithm

trically excited DC machine, where the magnetic flux and the torque are controlled separately. The important variables in this section are shown in Table 2.

### 2.1 The Control Scheme

As this paper focuses on the computation of losses we will not discuss the control theory in detail. Still it is important to notice that the control scheme has major influence on the generated losses. Therefore a number of effects extending the basic concept of field-oriented control have been implemented in the machine control. These are

- Voltage limitation
- Current limitation
- Field weakening<sup>1</sup>
- Maximum torque per ampere

Although these effects influence losses, it is not in the scope of this paper to review how losses are changed based on different implementation of the control algorithm. An overview of the applied scheme is presented in Figure 1.

### 2.2 Simulation Results

Figure 2 depicts the obtained simulation results where a speed step of  $2 \cdot \omega_{nom}$  was applied to a permanent magnet synchronous machine. One can see in Figure 2 b) how  $U_s$  increases proportional with the speed until  $U_{sMax}$  is reached. Then the field weakening controller starts to decrease  $i_d$  and the speed continues to rise at an expense of a decreasing the inner torque  $\tau_{electrical}$ . In Figure 2 c)  $i_q$  is plotted over  $i_d$ , where the current vector moves along the maximum

<sup>1</sup>The algorithm used in this paper is based on a comparison of  $U_s$  and  $U_{sMax}$  and is based on theory presented in [4]

torque per ampere (MTPA) trajectory and then follows the current limit circle.

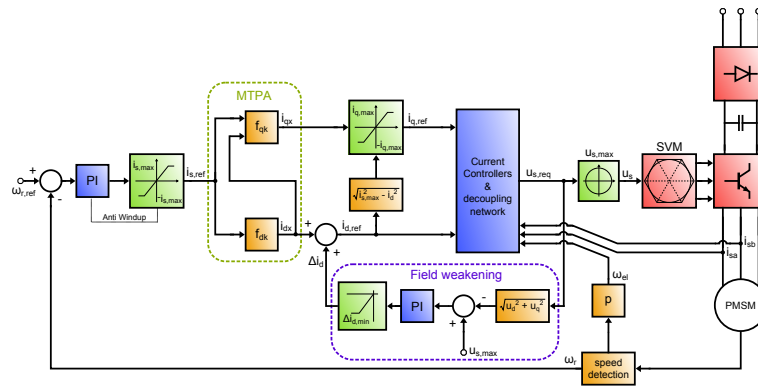

## 3 Induction machine

The control of the induction machine follows similar principles as it was presented for the PMSM. The stator voltage equation is used to create a decoupling network and to parameterize the current controllers. One difference is, that in general the rotor flux oriented reference frame is used to obtain separate control of the flux and the torque, which requires an estimator for the non-measurable rotor flux. The other difference is, that the flux must be generated, which is performed with the current component  $i_{sx}$ , whereas the  $i_{sy}$  is used for the torque generation. Differing from the PMSM the coordinate system is based on the  $x$ -axis that is aligned with the direction of the flux, whereas the  $y$ -axis is orthogonal to that and therefore responsible for generating the torque. They are named differently from the PMSMs coordinate system as the flux direction is moving at different speed from the rotors angular velocity. For more detailed informations it is referred to [5, Ch. 2 and 4.1.1] and [4].

In Figure 3 the control scheme of the induction machine is shown, which features voltage limitation, a field weakening controller and a controller for maximum torque in the upper field weakening region, which limits the output of the speed controller. For both machines, the PMSSM and the induction machine a torque controller was implemented additionally to the presented speed controller.

From the simulation results, illustrated in Figure 4, one can see how the rotor flux is generated with  $i_d$  in the first 0.5s. Then the speed increases until the voltage limit is reached, which requires to reduce the magnetizing current shown at the bottom right, which is used to create the rotor flux. As shown in the simulation results in Figures 2 and 4, a reliable control algorithm for both machine types was implemented. Thanks to the field weakening controllers and the output limitations it is ensured that the voltage and current limitations are not exceeded. Hence, the controlled machine models can be used in batch simulations in order to compute the characteristic map for a given set of machine parameters as well as stator current and stator voltage limitations.

### 4 Characteristic Maps

If a driving cycle is simulated for a hybrid or an electric car the energy consumption of different parts and the resulting attainable range are usually most important, whereas quantities like the magnetic flux or the voltage drops at the stray inductances are of minor interest. Therefore it is not required to have detailed physical models and the use of averaged models is sufficient. For electric machines such models can be composed of characteristic maps, in which the losses at various operating points are stored.

Characteristic maps of machines can also be used if the losses of a real machine are measured in different operating points. Then a convenient way to have an accurate model of this machine is to use the measurement results in the simulation within lookup tables. However, in an early design stage the real machine might not be available. Therefore in this paper

a method is presented which allows to calculate characteristic maps from simulations which are performed with physical models of a machine. In the paper the machine models from the Modelica Standard Library are used, but they can be replaced with more or less accurate models. This possibility is a major advantage compared to other methods e.g. averaged models that do simplifications to the models to make it compute faster. This way the modeling detail can be increased to a very high level only influencing the map generation time. As this has to be carried out once only for every new machine it is of minor importance compared to the many times the map-based model is simulated.

In the following sections it is shown how the maps can be generated and lookup table based models are presented which utilize those.

Figure 4: Simulation results of the induction machine: a) Reference and actual angular velocity; b) voltage limit, unlimited and limited voltage; c) current component  $i_d$ ; d) estimated magnetizing current

Figure 5: Model for loss calculation of a torque controlled induction machine

must specify the resolution of the map, which is used to determine which operating points will be simulated.

The calculated losses  $P$  of the simulated operating points are stored in matrices, with the first column containing the torque and the first row the angular velocity, resulting in

$$\begin{bmatrix}
 0 & \omega_{start} & \omega_2 & \dots & \omega_{stop} \\
 0 & P_{1,1} & P_{1,2} & \dots & P_{1,y} \\
 \tau_2 & P_{2,1} & P_{2,2} & \dots & P_{2,y} \\
 \tau_3 & P_{3,1} & P_{3,2} & \dots & P_{3,y} \\
 \vdots & \vdots & \vdots & \ddots & \vdots \\
 \tau_{stop} & P_{x,1} & P_{x,2} & \dots & P_{x,y}
 \end{bmatrix} \cdot \quad (1)$$

The ascending values in the first row and column are required for the usage in the lookup tables *Modelica.Blocks.Tables.CombiTable2D*. The range for the angular velocity is given by the lowest and the highest entry

of the user. The torque is simulated from zero up to the highest torque value which was entered. The area in between is discretized according to the user chosen resolution.

In Figure 7 an exemplary maximum torque curve and the performed discretization are illustrated. Due to arbitrary user inputs for the torque curve and the discretization, it is not possible to always simulate exactly up to the maximum torque curve. Hence, to cover the desired region it is required to perform one simulation above the curve. This is also illustrated in Figure 7, where simulated points are marked with  $\times$ , whereas for non-simulated points circles are used.

Since the whole matrix presented in Equation 1 has to be filled with values, the points marked with circles in Figure 7 have to be guessed somehow. To do so, the function *Modelica.Math.Vectors.interpolate* is used to

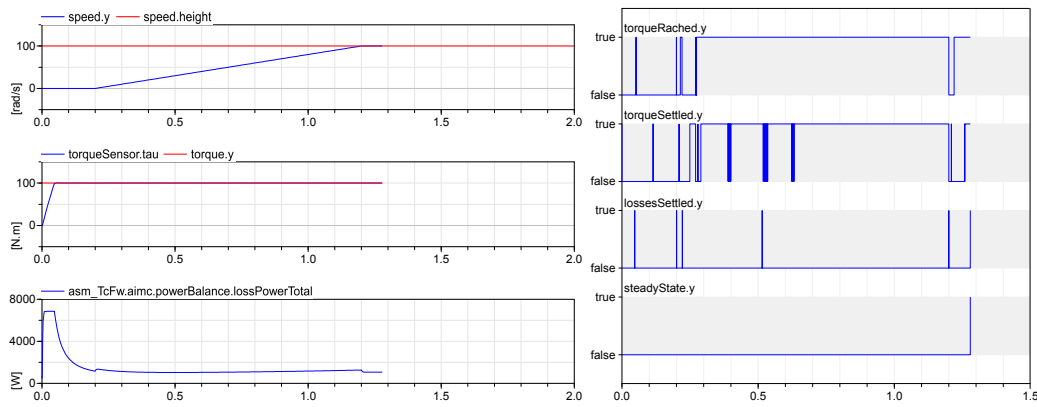

Figure 6: Simulation results of *TorqueControlledPhys2Map\_ASM*

Figure 7: Exemplary maximum torque line and the performed discretization for a map of  $5 \times 15$

perform linear extrapolation from simulated values, which it does although the name would not indicate that. The extrapolated values for not simulated operating points in Equation 1 are calculated from the two rows above. This and the linear extrapolation might not be suited very well to calculate the correct values, but since it is used for the area above the maximum torque curve, the machine will hardly enter this region and it is still a much better approximation compared to leaving the losses on zero.

## 4.2 Model to utilize Characteristic Maps

To use the calculated maps in simulations, the model *TorqueControlledCharacteristicMap* is used, which is illustrated in Figure 8. It features two electrical DC connectors to the left, a mechanical connector to the right and a real input for the desired torque at the top. Hence, it is meant to replace a controlled electric machine with inverter. Via a parameter the .mat file containing the losses is specified.

The torque reference given with the real input *desiredTorque* is limited by *limitTorque* according to the maximum torque line, which the user has defined during map generation. Thereafter the first or-

der element *firstOrder* introduces a delay between desired and obtained torque<sup>2</sup>. The first order element is connected to the torque source *mechanicalTorque*, which accelerates *rotorInertia*. Parameters are provided in the model, which allow the user to deactivate *limitTorque* and *firstOrder*. Then the gain blocks to *noTorqueLimit* and *noFirstOrder* are used instead.

In the violet colored box “Losses” one lookup table of the type *CombiTable2D* from the MSL is used for each loss type. By knowing the actual speed and torque, the operating point is identified and the losses of this point can be determined with the tables. Afterwards the electrical power is calculated from the sum of the losses and the measured mechanical power. This allows the calculation of the electrical current that must flow by measuring the voltage at the DC connectors.

## 4.3 Comparison Results

The hardware, software and solver settings which were used for the measurement of the computation time and the required time for map generation are summarized in Table 3.

### 4.3.1 Computation Time for Map Generation

The required computation time for the generation of characteristic maps was tested for each machine type for the two different map resolutions  $15 \times 30$  and  $30 \times 60$ . In Table 4 the results are shown. The column “unsim.” notes the number of skipped simula-

<sup>2</sup>The element is intended for the torque set machines to model the electric time constant. For torque controlled machines it is disabled per default, but it can be used to approximate the transfer function of desired to obtained torque.

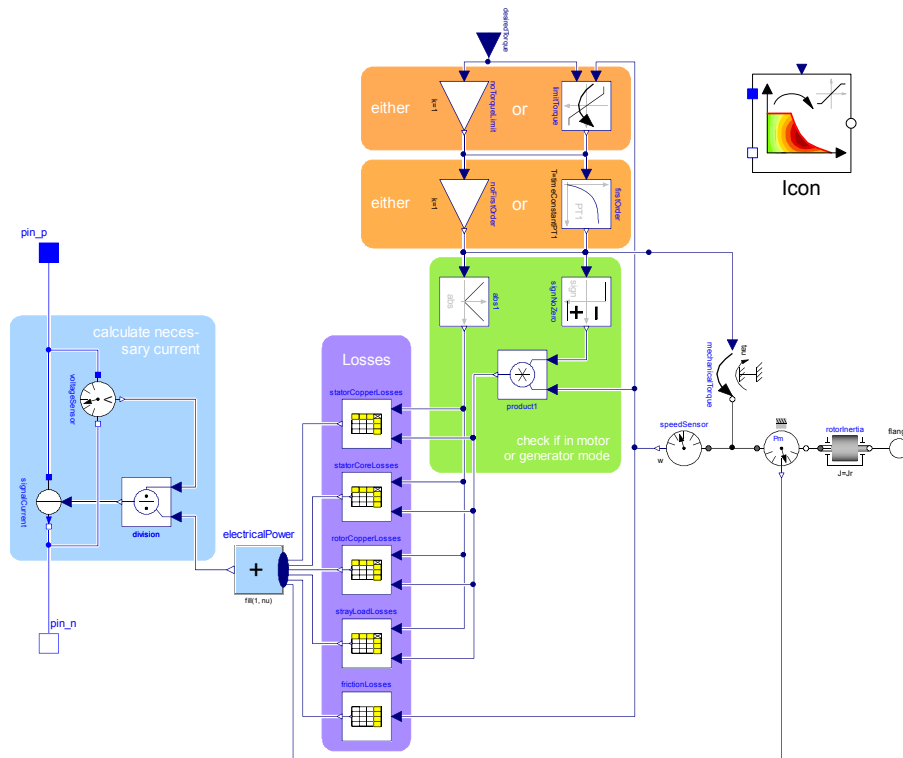

Figure 8: Model and icon for the torque controlled characteristic map

Hardware	Processor	Intel Core i7-2670QM
	RAM	8 GiB DDR3
Software	OS	Windows 7, 64 bit
	Dymola	2013 FD01, 32 bit
Settings	Solver	Dassl
	Tolerance	0.0001 (default)

Table 3: Used hardware, software and solver settings for time measurements

Type	tau	w	unsim.	req. time	time/sim.
ASM	15	30	204	190 s	0.78 s
ASM	60	30	854	740 s	0.78 s
PMSM	15	30	120	95 s	0.29 s
PMSM	60	30	488	370 s	0.28 s

Table 4: Required computation time (req. time), skipped simulations (unsim.) and required time for one simulation (time per sim.) for the generation of characteristic maps of different resolutions ( $\tau \times w$ )

tions, where the operating points lay above the maximum torque curve.

In the column “time/sim.” it is revealed that the required time for one simulation is constant for the different machine types. Hence, maps with 1000 calculated points are generated within 13 minutes for induction machines and less than 6 minutes for PMSMs. However, the map generation time is highly sensitive to the specified limits in which the losses and the torque have to settle. As it can be noticed in Figure 6 for the plot “torque settled” to low margins can result in chattering depending on the operating point. Hence, the high number of events slows down the map generation process significantly. So far no effort was spent to further investigate on that effect, but it would be well worth the effort if map generation time is of impor-

tance.

From Table 4 one can tell that the solving of the ASM’s models is about eight times as computationally intensive than the PMSM’s. This is caused by either the higher complexity of the ASM’s model due to effects like slip that is not present in the PMSM or due to the more complex controller structure. The exact cause has to be further investigated in future efforts.

### 4.3.2 Accuracy of the Losses

To compare the losses of the map model with those of the physical model, the setup depicted in Figure 9 is used. With `desiredSpeed` and `desiredTorque` the operating point is set for the map based and the

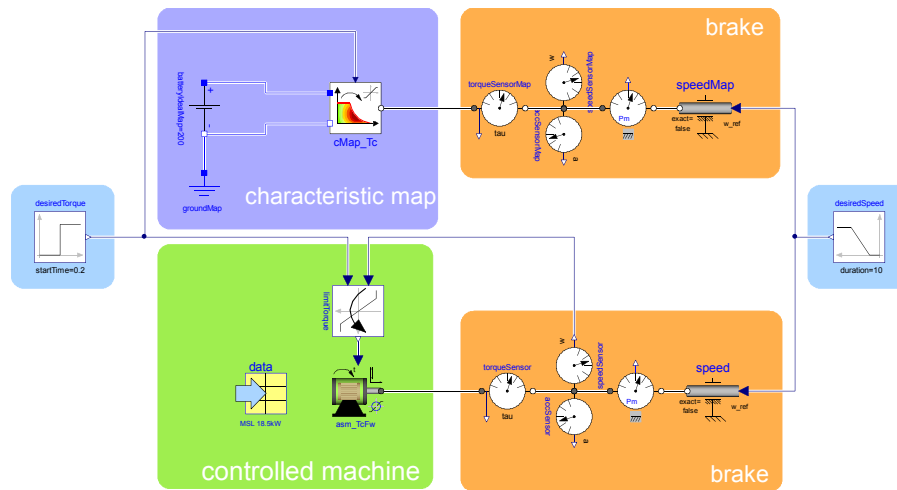

Figure 9: Used model for comparison of torque controlled map and physical machine

physical models and the input of the physical model is limited to the maximum torque curve. Similar models were used to compare the losses of the other machine types.

In Figure 10 the losses of an efficiency map are compared with the physical model. The desired torque is set on 100 N m, whereas the speed is increased from 0 rad s<sup>-1</sup> to 400 rad s<sup>-1</sup> within 10 s.

The comparison results of the torque controlled PMSM are shown in Figure 11. As one can see, the losses match very well. The plot “Deviation of total losses” at the bottom right shows the difference of the total losses calculated with the physical model and with the map model. Except of the negative peak at the beginning, the total deviation remains below 18 W. With the total losses starting at 1000 W and reaching about 1800 W when the highest deviation is observed the maximum error is 1%. The peak is caused by the stator core losses, since the current controllers set the maximum possible voltages at the beginning to obtain the desired torque. As the core losses are plotted over speed, this peak is hidden behind the axis to the left at 0 rad s<sup>-1</sup>.

### 4.3.3 Simulation Time

To compare the computation time of physical and map-based models, the model shown in Figure 12 is used. A sinusoidal or a trapezoid torque is requested from the machine and a speed dependent torque is used as load. With the integrator the total loss energy is obtained, which allows to check for the global error of the most interesting quantity at the end of the simulation. This error is computed between physical and ta-

ble based model, not the analytic solution as the word "error" may indicate.

The results for the sinusoidal input are depicted in Table 5. For every machine type the map model and the physical machine were tested for a simulation time of 1000 s and for 10000 s. Along with the required simulation times the speed improvement factor is given. In addition, the loss energy at the end of the simulation and the error of the map model are specified.

One can see that improvements of the simulation time of more than a factor of 200 can be obtained, while the error is kept below 1%. The highest improvements are achieved for the induction machine, while the torque set PMSM is only accelerated by a factor of 7.

## 5 Conclusion

The presented method allows convenient use of controlled physical electric machine models including advanced functionalities, to generate data for map-based models in order to accelerate simulations with still accurate results.

With the map models speed improvements with factors starting from 7, reaching up to 230. However the computation times of the physical models are highly sensitive to the performed simulation, the input signal and to the tuning of the controllers. Hence, it is required to test the models within specific applications to figure out which factors are obtained in practice.

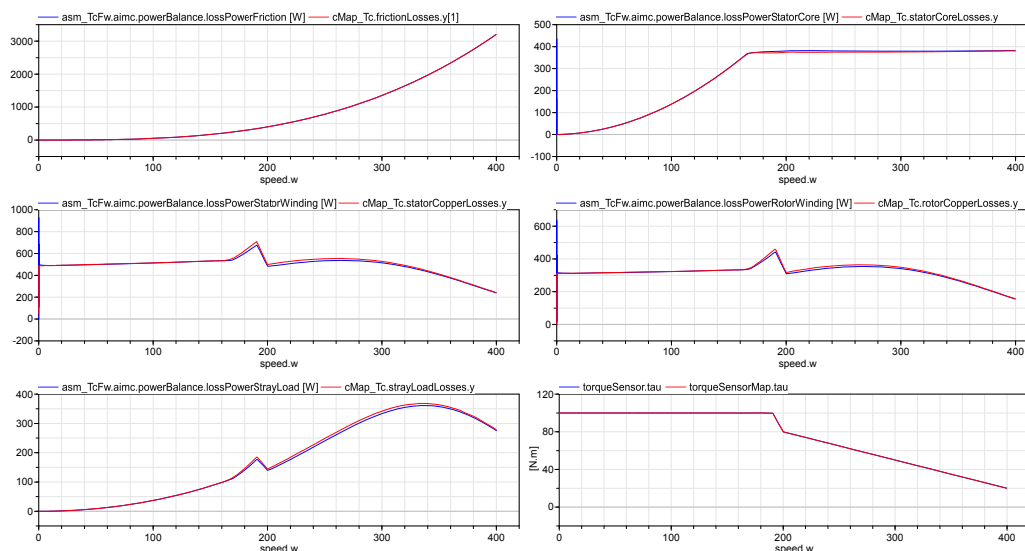

Figure 10: Losses of a physical induction machine model (blue) and characteristic map (red) with a resolution of  $15 \times 15$  for the motor mode

Type	CPU times			loss energy at simulation end		
	phys.	map	factor	phys.	map	error
ASM, 1000 s	82 s	0.35 s	234	1753.60 kJ	1763.04 kJ	0.5 %
ASM, 10000 s	807 s	3.5 s	230.5	17537.90 kJ	17633.20 kJ	0.5 %

## Abstract

This paper presents the BuildSysPro Modelica library developed by the department of Energy in Buildings and Territories (EnerBaT) of EDF R&D. After a description of the library's structure and content, BESTEST validation results and a use case are presented.

This library is designed to be used in several contexts including building physics research, global performance evaluation, technology development and impact assessment. It is also a basis for urban and building stock simulation. BuildSysPro is intended for a relatively large audience ranging from R&D scientists to building services engineers.

BuildSysPro contains classes to describe the whole building and its energy systems including envelope components, HVAC systems and other energy conversion devices (DHW, thermal and photovoltaic panels...) and boundary conditions models. The models are designed for static and dynamic use, and for the representation of 0D/1D pure thermal and fluid dynamics. BuildSysPro in its current version contains around 380 models and 130 functions.

*Keywords: Modelica library; Building; Dynamic simulation; Numerical validations, Energy system*

## 1 Introduction

Since the building sector is one of the main energy consumers nowadays, energy policies drive existent and new buildings towards better performances. These evolutions raise quantity of questions regarding their ability to ensure the occupants' health and comfort while decreasing energy consumption and increasing energy efficiency. These questions rely strongly on multi-domain representations including thermal, electrical, hydraulic or chemical processes. Modelica being an object-oriented, equation based

language, is therefore well suited to represent this kind of coupled problems and complex systems.

The EnerBaT department of EDF R&D developed its own Modelica library, BuildSysPro, in order to perform multi-scale and multi-domain modelling. The choice of a new library was dictated by research needs, very specific for an energy producer and retailer, since they cover many domains.

BuildSysPro provides a comprehensive set of elementary 0D/1D components to describe envelope components, energy equipments and devices, and control systems. It is principally based on two branches of physics: pure thermal and thermo-fluid dynamics modelling. These classes are compliant with the *Thermal.HeatTransfer* and *Media* packages of the Modelica standard library to ensure a good level of interoperability with other Modelica libraries. These models are designed for static and dynamic modelling and can be used to create a whole building and its energy systems.

The BuildSysPro library has already been successfully used in several studies including:

- Technology performances and impact assessment [1][2],
- Sensitivity analysis regarding experimental validation [3],
- Urban simulation [4].

As ThermoSysPro, the EDF Modelica library for modelling power plants, BuildSysPro is developed under Dymola environment but is intended to be tool neutral. The BuildSysPro library is currently only available within partnership projects, but an open version is under construction.

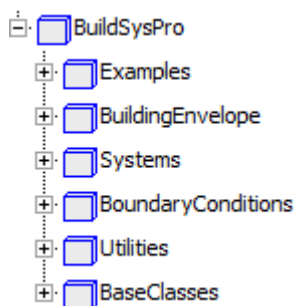

This paper is an overall presentation of BuildSysPro, focusing on the structure and some key elements of the library such as building envelope components, boundary conditions and HVAC systems. The key components of BuildSysPro being based on models from the Modelica standard Library, they are not described in detail. A focus is then made on validation through numerical comparisons with the IEA

BESTEST procedure. Finally the use of BuildSysPro is described on a basic use case aiming at analysing the matching between heat demand and supply in a residential building. For more complex applications and validations, the readers are welcome to read the papers [2], [3] and [4].

## 2 BuildSysPro Overview

### 2.1 Structure

The way of modelling building energy systems with BuildSysPro is similar to the approach commonly used by the building science community. On one side, the building envelope is mainly considered as an energy consumer and on the other side the energy systems and equipments are considered as producers. Figure 1 shows the top-level structure of BuildSysPro. This structure is quite similar to the Modelica standard library. It contains the usual *Examples*, *Interfaces*, *Components*, and *Utilities* packages at different hierarchical levels.

**Figure 1: Structure of BuildSysPro**

At the top level, the *Examples* package contains some reference buildings, including the Mozart house, which is a medium size detached house from a typological study of the French housing stock.

The *BuildingEnvelope* class is intended to describe the building envelope and provides components in a pure thermal or thermo-fluid approach. It also contains generic models of zones which can represent an entire building or a single room.

The *Systems* class is composed of five sub-packages. The *Controls* package provides control and regulation components for HVAC systems or energy equipments. The *Production*, *Distribution* and *Emission* packages provide components to design energy systems including HVAC systems or other equipments such as PV systems. This package also contains a *Utilities* package which provides for instance pre-processors to estimate system parameters from manufacturer data.

The *BoundaryConditions* package contains several models which offer the possibility of reading and pre-processing boundary conditions from files, such as weather data or normative indoor scenarios.

The *Utilities* package includes special Modelica *types*, *records*, *package icons*, *functions*, *blocks* and *models*. The *records* are used to set the parameters of various models in a hierarchical way (wall layers, walls, zones...). A *Math* sub-package contains, inter alia, some non linear solvers. A *Comfort* package includes some basic classes to describe human comfort in a room.

The *BaseClasses* package establishes the link with the Modelica standard library. It contains the same connectors as the *Modelica.HeatTransfer* and *Modelica.Media* packages. It also includes some other elementary models which are not of interest for end-users.

### 2.2 Interfaces

The interfaces of BuildSysPro are based on those from the Modelica standard library to ensure the compatibility of modelling. For instance, the connectors of the *HeatTransfer* class are based on two variables, a temperature as a potential and a heat flow rate as a flow. The *Fluid* class is compliant with the *Modelica.Media* class, that is to say a media model is described with the *Modelica.Media.Interfaces* and a connector similar to the *Media.Examples.Tests.Components.FluidPort*, which does not use stream connectors.

These interfaces were chosen to ensure modular and scalable approaches to model an entire building with its systems and equipments as well as single components or small districts, in pure thermal or in a thermo-fluid approach. Indeed pure thermal modelling can be accurate enough to predict the annual energy consumption due to heating, but not to design an air ventilation system nor to model pollutant transport.

### 2.3 Thermal zone description

Figure 2 illustrates the structure of the *BuildingEnvelope* package.

Figure 2: BuildingEnvelope package

One of the key elements of this package is the thermal wall model. It represents a 1D discrete multi-layer wall with several connectors for boundary conditions. A diagram view of this model can be seen on Figure 3. By convention, the right hand side corresponds to the inside whereas the left hand side can be both, inside or outside boundary conditions.

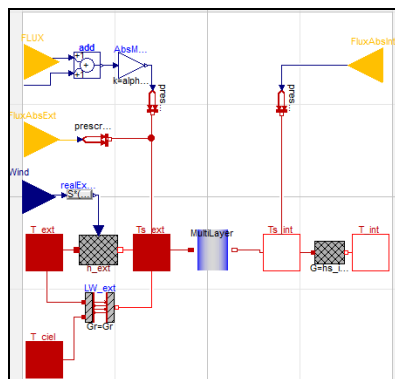

Figure 3: Diagram of the wall model

The blue component in the middle describes the conductive part of the wall. It is based on thermal conductors and capacitors connected in order to represent layers of homogenous material.

The causal connectors represented by yellow triangles are used to convey short wave radiations such as solar irradiance or transmitted solar radiation coming from the windows or the environment. They include either the cosine of the incidence angle, diffuse and direct flux or global flux.

The heat ports connect the model to the surrounding temperatures. Thanks to optional models and connections, convective heat transfers are considered with an  $h$  coefficient either fixed or controlled by wind speed. In the same way, the long wave radiative heat transfer is represented either with a fixed coefficient or with the Stefan–Boltzmann law using dry bulb and sky temperatures. The parameters of the wall model can be easily set thanks to various records. For instance, the parameters of the conductive part use a replaceable *WallType* record which contains the information described in Figure 4.

```

record WallType
  "Generic record for the conductive part of a wall"
  parameter Integer n=3 "Number of layers";

Figure 4: WallType record

A typical one-zone thermal model would be essentially composed of walls, one air node and air renewal. Figure 5 presents this simple thermal zone using combined convective and radiative heat transfers (without taking into account the wind speed or the sky temperature). Thus, depending on the assumptions considered, other types of thermal zones can be designed. For instance, instead of distributing the transmitted solar radiation onto the floor, other weighting methods can be used depending on the solar absorption coefficients and surface areas or view factors, as in the BESTEST calculations.

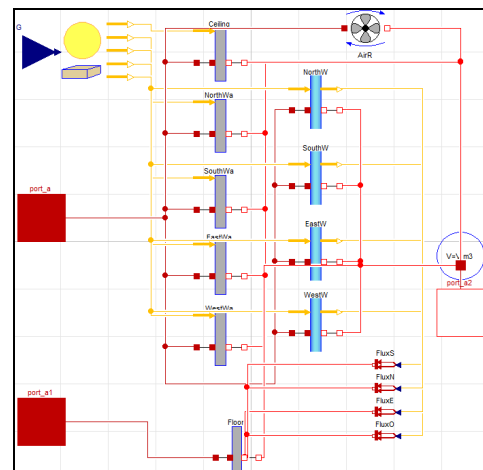

Figure 5: Diagram of a simple thermal zone

## 2.4 Systems and equipments

Figure 6: Systems package

As previously said, the *Systems* class is composed of five sub-packages mainly providing control strategies, production, distribution and emission compo-

nents. Some of these components are declined in different modelling levels adapted to different case studies: annual, daily, hourly or even sub-hourly time steps for prototyping and precise control.

For example, a simple convector can be used for studies on the electrical grid considering the 220V-50Hz power supply and the electronic regulation and components of the convector. Conversely, it can be modelled as an ideal heater or with chrono-proportional controls closer to the real dynamic behaviour for hourly outputs and human comfort studies.

Another example is thermodynamic systems, such as heat pumps, modelled in BuildSysPro either with an idealised coefficient of performance, or with empirical formulations depending on the boundary conditions (as in the use case described in paragraph 4), or with detailed modelling of the vapour compression and refrigeration cycle.

## 2.5 Boundary conditions

The boundary conditions describe the conditions on both sides of the building envelope. Figure 7 illustrates the structure of the *BoundaryConditions* package.

Figure 7: *BoundaryConditions* package

On the outdoor side, the weather data are applied with special treatment for solar data, and on the indoor side a temperature set point or other occupancy schedules are applied.

The weather data reader model requires a file that mainly contains the outdoor dry air temperature, the sky temperature, the relative humidity of the air, the wind data (speed and direction) and two solar radiations amongst diffuse horizontal, global horizontal, direct horizontal and direct normal. Inside the weather data reader model, the different missing fluxes are computed along with the position of the sun.

These weather solar data are then treated by models in the *Solar* package to obtain the incident direct and diffuse solar flux on the different surfaces, allowing a gain in computation time, especially for multi-zone modelling. Furthermore and as previously shown, specific yellow interfaces are included in BuildSysPro in order to graphically differentiate the solar boundary conditions in the model diagrams.

Figure 8 shows an assembly of the weather data reader and a boundary conditions model for shaded windows. The model in the middle computes incident solar radiation on a window under a solar mask from weather data.

Figure 8: Example of the use of boundary conditions models – Shaded window

## 3 Validation cases

### 3.1 Introduction to validation methods

Software products can be validated with three complementary methods: analytic solution, empirical validation and comparative tests [5]. The first method is well suited for elementary models such as conductive transfer in walls for which an analytical solution is known. Empirical methods and experimental data are essential for the validation of complex models, but are difficult to analyse since there is a lot of uncertainties. Comparative tests are more repeatable and standardized tests are still carried out by the scientific community for the validation of different types of software. Thus, we have the ASHRAE standards in the USA and ISO norms in Europe.

Until 2010, the department of Energy in Buildings and Territories of EDF R&D mostly used CLIM2000 software [6] for research purposes. Before integrating new models, BuildSysPro was a quickly rebuilt version of CLIM2000 in Modelica language, possible since both approaches are very close:

- Variable time step solver,
- Equation-based modelling, describing the physical laws,
- Acausal connectors (heat ports),
- Graphical interface where elementary models are disposed and connected together.

CLIM2000 was validated with experimental measurements and comparative tests such as the International Energy Agency Building Energy Simulation Test and Diagnostic Method (IEA BESTEST). The results obtained with these validations were accurate and BuildSysPro was first validated by comparing the results of elementary models (conduction through walls, transmission through windows ...) with those of CLIM2000.

As a first approach, we will focus on the comparative BESTEST validation of BuildSysPro. This procedure is adapted to validate simple building components and has been previously applied to other libraries (e.g. [10]). As such, it is a good starting point in the validation of a new library.

### 3.2 Comparative tests: the BESTEST qualification procedure

The BESTEST method consists in a benchmark procedure for dynamic building energy simulation software established by a set of reference programs [7] [8]. This procedure was applied to validate the building envelope model of BuildSysPro, as has been done with CLIM2000 or other software and more recently some Modelica libraries [9] [10]. The entire procedure is described in [8], so we will only give the key points here.

The BESTEST procedure starts with a basic building envelope controlled in temperature with only one thermal zone. The envelope is derived into two inertia classes: light and heavy weight. This building is located in Denver, with an extreme climate: cold clear winters and hot dry summers. The building envelope is very sensitive to the external boundary conditions.

Small variations are made to this envelope, its control strategies and its internal gains, so that it might help in identifying deficient parts of the models thanks to diagnostic flow diagrams. A program successfully passes the validation if the required outputs are positively compared with the reference programs' outputs. Table 1 summarizes the base cases (600 to 650 and 900 to 950) and the free-floating cases (600FF to 950FF) since other cases defined in BESTEST are only used for diagnostics.

CASES	Opaque surface		Windows			Intern. gain [W]	Scenario H, C, V	Infiltration ACH	
	Type	$\alpha$ int/ext	$\epsilon$ int/ext	[m <sup>2</sup> ]	Or. Shade				
600	BML	0.6	0.9	12	S	-	200	20, 27, -	
610					1mH				
620					6 / 6	E / W			-
630					1mHV				
640					12	S			-
650							Setback

950FF									-,-,-

Table 1: Properties changed through the BESTEST cases

### 3.3 Modelling hypotheses

First of all, Figure 9 shows the graphical view of the BESTEST zone with a shaded south-oriented window. This diagram is more complex than the basic room shown in Figure 5 since more physical phenomena were considered. The reading of such an assembly is not yet user-friendly since the models were constructed with many conditional interfaces depending on the physical complexity chosen for the modelling. In the future, the data connectors (wind, temperatures, solar information, ...) will be grouped together with a Modelica Bus and this information will be used or not by the models.

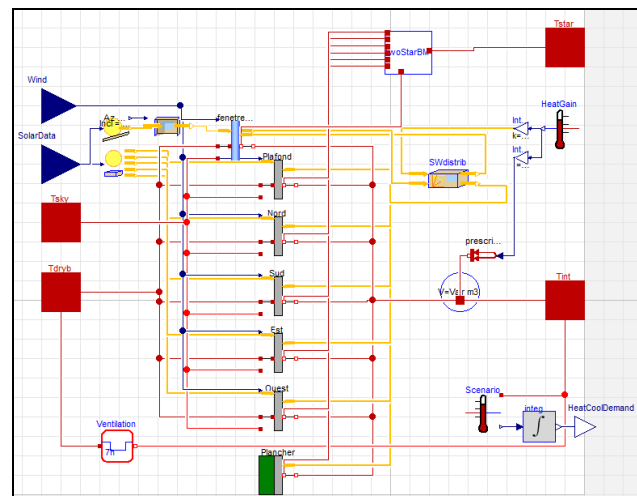

Figure 9: Graphical view of the South-shaded base model for the BESTEST in Dymola

We will not give an exhaustive list of the modelling hypotheses since there are many BESTEST specifications. We will only give the key points as to how the weather data were obtained and what were the hypotheses taken for modelling the envelope and the radiative heat transfers. Some models were improved from CLIM2000 to go through the BESTEST cases, since in the CLIM2000 version used for the BESTEST validation, a combined coefficient for convection and radiation was used and there were no shading devices.

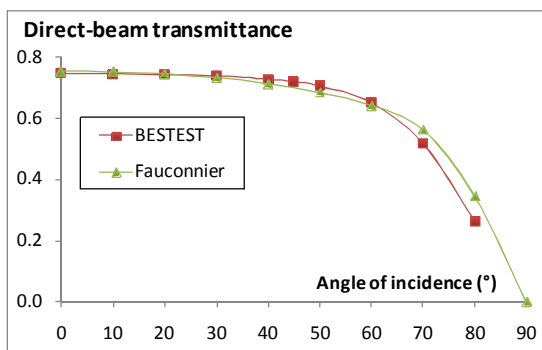

#### Weather data

The weather data file TMY for Denver was read before the simulations to extract the necessary inputs: direct normal and diffuse horizontal radiations, dry bulb and sky temperatures and wind speed. The data were read in local time with a delay of 30 minutes according to BESTEST reports. The sky temperature was obtained by a pre-processing using the Black-body model of the "Buildings" Modelica library [11]

which estimates it from total opaque sky cover, dry bulb temperature and dew point temperature.

### Envelope modelling

For conductive heat transfers, the walls are modelled with discrete element schemes as described in paragraph 2.3. The windows are modelled with a simple thermal conductor obtained from the U-value minus the convective and radiative parts of the heat transfer. The optical properties of the windows were estimated from the g-value and heat gain coefficient at normal incidence [12] given in the BESTEST specifications. The diffuse and direct properties are then very close to the ones recommended as seen in Figure 10 for direct beam transmittance.

**Figure 10: Angular dependence of the direct-beam transmittance of the double-pane window**

Convective heat transfer is modelled with a constant coefficient for the interior surfaces and with a correlation function of wind speed and surface texture for the outside.

### Radiation modelling

The solar irradiation is estimated with a clear-sky model with a separation between direct and diffuse radiations. The quantities transmitted into the room are redistributed as described in the BESTEST specifications using the view factors, surface areas and infrared emissivities.

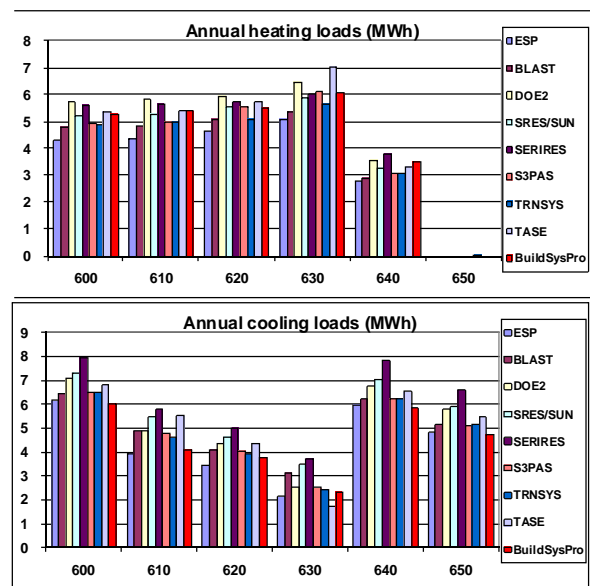

Longwave radiative heat transfers between wall surfaces and the outside environment are modelled using the corresponding temperatures (dry bulb and sky temperatures) and the sky and ground view factors for tilted surfaces. On the inside, a Two-Star model is used so that each surface exchanges with a virtual blackbody characterised by its radiative temperature [13].

## 3.4 Results of the qualification test

All the cases indicated in Table 1 were simulated with BuildSysPro. The figures below show only a

few representative results since the BESTEST method gives many outputs. The required outputs were integrated over the past hour as asked, especially since we used a variable time-step solver (DASSL). There are two kinds of outputs – annual and daily – as indicated in the list below:

- Annual heating and cooling loads (See Figure 11 for low-mass cases 600 to 650) and annual hourly-integrated peak loads.
- Annual hourly-integrated maximum and minimum temperatures for free-floating cases and annual hourly 1°C temperature bin frequencies.
- Annual unshaded incident solar radiation, annual transmitted solar radiation (shaded and unshaded).
- Hourly heating and cooling loads (See Figure 12 for high-mass case 900).
- Hourly free-float temperature (See Figure 13 for high-mass case 950FF).
- Hourly unshaded incident solar radiation (See Figure 14 for South and West radiation on a clear day).

**Figure 11: Heating and cooling loads for lightweight cases**

**Figure 12: Hourly heating and cooling loads for high-mass case 900**

**Figure 13: Hourly free-float temperature for high-mass case 950FF**

**Figure 14: Hourly incident solar radiation – South and West on a clear day (July 27)**

In conclusion to all these test-cases, BuildSysPro obtains comparable results with the reference programs of the BESTEST qualification procedure. This validates the modelling approach of the library and the implementation in Modelica.

## 4 Use case

The use case presented in this section illustrates building energy analysis which can be easily done thanks to BuildSysPro. It is based on previous work [14].

### 4.1 Introduction

In low energy buildings and passive houses, the free available energy from the building's surroundings

should cover a significant share of the energy demand unlike common buildings for which it is mainly covered by HVAC systems. As a consequence, the heating and cooling demands are reduced and, most of the time, fluctuate around 0 W. Such a system should not be assessed based solely on energy consumption indicators; a dynamic analysis should also be conducted. This kind of study may allow the investigation of performance degradation due to part-load operation or energy storage potential.

### 4.2 Building envelope

For this use case, the “Mozart” house is selected. It is a detached home, one of the most representative of the French housing stock. The “Mozart” house is considered as medium size with 100 m<sup>2</sup> of living area and an air volume of 252.15 m<sup>3</sup>. The building is described in a low energy configuration. The U-values of the different envelope components are relatively low compared to the French housing stock.

The house is represented as only one thermal zone however internal walls are modelled and therefore contribute to the thermal inertia. The short wave radiations transmitted inside the building envelope through the windows are entirely absorbed by the floor. The long wave radiative heat transfers are taken into account through a combined heat transfer coefficient.

### 4.3 Boundary conditions

The building envelope is studied in a temperate climate, more precisely with the weather data from Trappes located near Paris in France. The weather reader model provides the outdoor dry air temperature, the direct and diffuse solar radiations and the sky temperature. The humid air and the wind data (speed and direction) are not used in this simple case. A fixed set point of 19°C for the indoor air temperature is used. For the sake of simplicity, no internal heat gains were taken into account.

Considering these boundary conditions, the annual heat demand for the building envelope is around 20 kWh.m<sup>-2</sup>.year<sup>-1</sup>.

### 4.4 HVAC systems

The HVAC systems are composed of a mechanical ventilation system and an intermittently controlled heat pump. This is an air to water heat pump which supplies hot water to a radiant heating floor. Under nominal conditions, the heat pump provides 2400 W of heat at a COP of 4.2. A dynamic empirical model

is used to represent the heat pump. It takes into account the operating conditions, the part load degradation and minimal operating time. The ventilation system is represented by a static model with an air change rate of  $0.35 \text{ vol.h}^{-1}$ .

## 4.5 Results

As previously mentioned this use case shows the advantage of using Modelica/Dymola and BuildSysPro for a simple building energy analysis.

First, the energy demands can be obtained throughout the year. Figure 15 shows the relative frequencies of the hourly heating and cooling demands, red and blue bars respectively. This figure provides statistical data about the structure of the energy demand for this specific building and these boundary conditions. This information is widely used for sizing applications or investigating the potential of a thermal storage.

**Figure 15: Relative frequencies of the hourly heating and cooling demands [Wh]**

However, one important matter with building energy systems is the ability for the HVAC systems to match the energy demand. As previously mentioned, for low energy buildings, the heating and cooling demands may fluctuate around  $0 \text{ W}$ , far away from nominal conditions, and therefore decrease the system's performances. Figure 16 (a) and (b) illustrate the relative frequencies for the hourly heat supply and the COP and give information on the heat pump's effective operating conditions.

**Figure 16: Relative frequencies of (a) heat supply [Wh] (b) COP [-]**

The discrepancies between Figure 15 for the hourly heating demand and Figure 16 (a) indicate that the intermittently controlled heat pump is not adapted for this building; a variable-speed controlled heat pump would be more suited. It induces a decrease in performances which can be observed on Figure 16 (b) compared to the nominal COP of 4.2.

All the figures presented in this section were obtained thanks to a post-processing of the simulation result files. BuildSysPro provides some basic functions for result export and analysis; however it is not intended to provide a comprehensive set of post-processing methods.

## 5 Conclusions

The BuildSysPro library has demonstrated its capabilities to model complex buildings and energy systems. It is a solid solution to two initial problems of our work:

- designing a library of models able to deal with advanced scientific problems related to low-energy buildings
- and providing a global solution for the modelling and simulation needs of the EnerBaT department

The knowledge and experience derived from our previous research tools have been integrated in BuildSysPro. It is developed with a goal of simplicity, yet is comprehensive enough to be used for building physics and technology development as well as global performance assessment or prospective simulation, making it the reference modelling and simulation tool for the entire EnerBaT department as of today.

BuildSysPro is also built with a multi-domain and multi-scale approach, as it is able to handle purely thermal problems as well as coupled multiphysics,

ranging from the basic envelope component to the entire building or building stock. In addition, some use cases have confirmed the strength of the modular approach for quick studies.

Moreover, the envelope modelling of this library has been validated thanks to the IEA BESTEST qualification method. Though this approach is basic and quite far from the complexity of a real building, it is a necessary step in the evaluation of building models. Indeed, a Modelica library for modelling buildings that does not pass the BESTEST validation cases would be considered as untrustworthy.

Upcoming work will include specific validation campaigns that will be conducted with experimental data from European laboratories.

Research in progress and future developments will also use other capabilities of Modelica such as FMI for co-simulation or hardware-in-the-loop applications in addition to the current work around low-energy building envelope and systems.

# Efficient Numerical Integration of Dynamical Systems based on Structural-Algebraic Regularization avoiding State Selection

Lena Scholz    Andreas Steinbrecher  
Technical University Berlin, Department of Mathematics  
Str. des 17. Juni 136, 10623 Berlin

## Abstract

Differential-algebraic equations naturally arise in the modeling of dynamical processes, in particular using MODELICA as modeling language. In general, the model equations can be of higher index, i.e., they can contain *hidden constraints* which lead to instabilities and order reductions in the numerical integration. Therefore, a regularization or remodeling of the model equations is required. One way to obtain the required information on the hidden constraints is a structural analysis based on the sparsity pattern of the system. For the determination of a regular index-reduced system formulation then, usually, a crucial step is the so-called *state selection*. In this paper, we will present a new approach for the remodeling of dynamical systems that uses the information obtained from the structural analysis to construct a regularized overdetermined system formulation. This overdetermined system can then be solved using specially adapted numerical integrators, in such a way that the state selection can be performed within the numerical integrator during runtime of the simulation.

*Keywords: DAEs; regularization; structural analysis; overdetermined system; state selection*

## 1 Introduction

The MODELICA language is a common tool for modeling of dynamical processes. In general, the model equations that describe the dynamical process consist of differential equations in combination with algebraic constraints, i.e., we have to deal with so-called *differential-algebraic equations* (DAEs).

The solutions of such systems have to satisfy the algebraic constraints, but, in general, not all constraints are stated in an explicit way. In particular, if the resulting system of DAEs is of higher index there exist so-called *hidden constraints* and the numerical treatment leads to instabilities, inconsistencies and

possibly non-convergence of the numerical methods, see [2, 4, 6, 8]. Thus, a *regularization* or *remodeling* of the model equations is required to guarantee stable and robust numerical computations, see also [3, 6, 8, 15].

The current state of the art in many modeling and simulation tools to deal with high index DAEs is to use some kind of structural analysis based on the sparsity pattern of the system. Here, generic structural information is used to identify the constraints, to determine the index of the system, and to compute an index-reduced system model. Hereby, a crucial step is the so-called *state selection* that is required in order to introduce new algebraic variables (the so-called *dummy derivatives*) for the selected differential components of the DAE system in order to obtain a regular index-reduced formulation.

In this paper, we present a new regularization approach for the remodeling of dynamical systems that uses the information provided by the structural analysis, in particular by the Signature Method [12], to construct an overdetermined system regularization that can be solved using a specially adapted numerical integrator. This approach has the great advantage that the problem of state selection can be moved within the numerical integrator and can therefore be performed during the runtime of the simulation.

In the following, we consider *quasi-linear DAEs* of the form

$$E(x,t)\dot{x} = k(x,t), \quad (1)$$

on the domain  $\mathbb{I} = [t_0, t_f]$  with initial values  $x(t_0) = x_0 \in \mathbb{R}^n$ , where  $E \in \mathcal{C}(\mathbb{R}^n \times \mathbb{I}, \mathbb{R}^{n,n})$  is called the *leading matrix* of the quasi-linear DAE and  $k \in \mathcal{C}(\mathbb{R}^n \times \mathbb{I}, \mathbb{R}^n)$  its *right-hand side*. Furthermore,  $x : \mathbb{I} \rightarrow \mathbb{R}^n$  represent the *unknown variables*. The DAE system (1) is assumed to be uniquely solvable and nonredundant. Furthermore, we assume that the rank of the leading matrix  $E$  is constant for

all  $(x, t) \in \mathbb{R}^n \times \mathbb{I}$  and that the rank of the partial derivatives of the (hidden) constraints with respect to  $x$  is constant for all consistent  $(x, t) \in \mathbb{R}^n \times \mathbb{I}$ . Note that in general these assumptions are not necessary and can be relaxed, see [16].

## 2 Structural Analysis of DAEs

In many simulation environments like DYMOLA, OPENMODELICA or MAPLESIM a structural analysis is used to reduce the index of the DAE system relying on its sparsity structure, e.g., there are various versions and extensions of *Pantelides Algorithm* [10] in combination with the *Dummy Derivative Approach* [9], or the *Signature Method* [12]. These structural approaches have the great advantage that fast and efficient linear optimization algorithms based on graph theoretical concepts can be used and further structural information like a block lower triangular form of the system can be extracted which is essential for efficient and fast computations.

In this section, we will shortly review the basic steps of the Signature Method ( $\Sigma$ -method) introduced in [12]. For ease of representation we write the model equations (1) as

$$F(t, x, \dot{x}) = 0 \tag{2}$$

with  $F(t, x, \dot{x}) := E(x, t)\dot{x} - k(x, t)$ , where  $F \in \mathcal{C}(\mathbb{I} \times \mathbb{R}^n \times \mathbb{R}^n, \mathbb{R}^n)$ , and we denote by  $F_i$  the components of the vector  $F$  and by  $x_j$  the components of the vector  $x$ . Then, the  $\Sigma$ -method consists of the following steps:

1. Built the *signature matrix*  $\Sigma = [\sigma_{ij}]_{i,j=1,\dots,n}$

$$\sigma_{ij} := \begin{cases} \text{highest order of derivative of } x_j \text{ in } F_i, \\ -\infty \text{ if } x_j \text{ does not occur in } F_i. \end{cases}$$

2. Find a *highest value transversal* (HVT) of  $\Sigma$ , i.e., a *transversal*  $T$  of  $\Sigma$

$$T = \{(1, j_1), (2, j_2), \dots, (n, j_n)\},$$

where  $(j_1, \dots, j_n)$  is a permutation of  $(1, \dots, n)$ , with maximal value  $Val(T) = \sum_{(i,j) \in T} \sigma_{ij}$ .

3. Compute the *offsets vectors*  $c$  and  $d$  with  $c_i \geq 0$  such that

$$\begin{aligned} d_j - c_i &\geq \sigma_{ij} \text{ for all } i, j = 1, \dots, n, \\ d_j - c_i &= \sigma_{ij} \text{ for all } (i, j) \in T. \end{aligned} \tag{3}$$

4. Form the  $\Sigma$ -*Jacobian*  $\mathfrak{J} = [\mathfrak{J}_{ij}]_{i,j=1,\dots,n}$ , with

$$\mathfrak{J}_{ij} := \begin{cases} \frac{\partial F_i}{\partial x_j^{(\sigma_{ij})}} & \text{if } d_j - c_i = \sigma_{ij}, \\ 0 & \text{otherwise.} \end{cases}$$

5. Built the *reduced derivative array*  $\mathcal{F}(t, \mathcal{X}) = 0$  consisting of

$$\begin{aligned} F_i(t, x, \dot{x}) &= 0, \\ \frac{d}{dt} F_i(t, x, \dot{x}) &= 0, \\ &\vdots \\ \frac{d^{(c_i)}}{dt^{(c_i)}} F_i(t, x, \dot{x}) &= 0 \end{aligned}$$

for all  $i = 1, \dots, n$  with

$$\mathcal{X} = [x_1, \dot{x}_1, \dots, x_1^{(d_1)}, \dots, x_n, \dot{x}_n, \dots, x_n^{(d_n)}]^T.$$

6. Success check: if the algebraic system  $\mathcal{F}(t^*, \mathcal{X}^*) = 0$  has a solution  $(t^*, \mathcal{X}^*) \in \mathbb{I} \times \mathbb{R}^{n+\sum_{i=1}^n d_i}$  and  $\mathfrak{J}$  is nonsingular at  $(t^*, \mathcal{X}^*)$ , then the  $\Sigma$ -method succeeds.

If the  $\Sigma$ -method succeeds, it allows to determine the *structural index* of the DAE as

$$v_S := \max_i c_i + \begin{cases} 0 & \text{if all } d_j > 0, \\ 1 & \text{if some } d_j = 0. \end{cases}$$

We call  $\mathfrak{J}$  the  $\Sigma$ -Jacobian since it is in general not the analytical Jacobian, but defined by the offset vectors. The HVT as well as the offset vectors can be computed efficiently by solving a *linear programming problem* (LPP) and the corresponding dual problem, see [12]. Note that usually there is not only one uniquely determined HVT, and also the offset vectors  $c$  and  $d$  are not uniquely defined by the conditions (3). However, there exists a unique element-wise smallest solution of the dual problem, the so-called *canonical offsets*, that is independent of the chosen HVT.

If the  $\Sigma$ -method succeeds for a given system (2) at a consistent point, the canonical offset vector  $c$  gives the required information which equations have to be differentiated and how many times in order to be able to extract all hidden constraints. Thus, the reduced derivative array  $\mathcal{F}$  can be obtained by adding the derivatives of  $F_i$  up to order  $c_i$  to the original system for all  $i = 1, \dots, n$ .

**Example 2.1** We illustrate the steps of the  $\Sigma$ -method for the example of the simple pendulum of mass  $m = 1$ ,

length  $\ell > 0$  under gravity  $\mathbf{g}$ , see also [12]. The system equations are given by

$$\begin{aligned} F_1(t, x, \dot{x}) &= \dot{p}_1 - q_1 &= 0, \\ F_2(t, x, \dot{x}) &= \dot{p}_2 - q_2 &= 0, \\ F_3(t, x, \dot{x}) &= \dot{q}_1 + 2p_1\lambda &= 0, \\ F_4(t, x, \dot{x}) &= \dot{q}_2 + 2p_2\lambda + \mathbf{g} &= 0, \\ F_5(t, x, \dot{x}) &= p_1^2 + p_2^2 - \ell^2 &= 0, \end{aligned} \quad (4)$$

with  $x = [p_1 \ p_2 \ q_1 \ q_2 \ \lambda]^T$ . The signature matrix for this system is given by

$$\Sigma = \begin{bmatrix} \boxed{1} & - & \boxed{0} & - & - \\ - & \boxed{1} & - & \boxed{0} & - \\ 0 & - & \boxed{1} & - & \boxed{0} \\ - & 0 & - & \boxed{1} & \boxed{0} \\ \boxed{0} & \boxed{0} & - & - & - \end{bmatrix},$$

where the two possible HVTs are marked by gray and blue boxes. (Here, the entry  $-$  stands for  $-\infty$ .) The canonical offset vectors are given by  $c = [1, 1, 0, 0, 2]$  and  $d = [2, 2, 1, 1, 0]$  (independently of the chosen HVT). The corresponding  $\Sigma$ -Jacobian is given by

$$\mathfrak{J} = \begin{bmatrix} 1 & 0 & -1 & 0 & 0 \\ 0 & 1 & 0 & -1 & 0 \\ 0 & 0 & 1 & 0 & 2p_1 \\ 0 & 0 & 0 & 1 & 2p_2 \\ 2p_1 & 2p_2 & 0 & 0 & 0 \end{bmatrix}$$

and the reduced derivative array takes the form

$$\mathcal{F}(t, \mathcal{X}) = \begin{bmatrix} \dot{p}_1 - q_1 \\ \dot{p}_1 - \dot{q}_1 \\ \dot{p}_2 - q_2 \\ \dot{p}_2 - \dot{q}_2 \\ \dot{q}_1 + 2p_1\lambda \\ \dot{q}_2 + 2p_2\lambda + \mathbf{g} \\ p_1^2 + p_2^2 - \ell^2 \\ 2p_1\dot{p}_1 + 2p_2\dot{p}_2 \\ 2p_1\ddot{p}_1 + 2\dot{p}_1^2 + 2p_2\ddot{p}_2 + 2\dot{p}_2^2 \end{bmatrix} = 0. \quad (5)$$

Thus, the  $\Sigma$ -Jacobian  $\mathfrak{J}$  is nonsingular at every consistent point and the  $\Sigma$ -method succeeds with  $v_S = \max_i c_i + 1 = 3$ .

The information provided by the HVT and the offset vectors can also be used to introduce new algebraic variables for selected differential variables yielding an extended square regularized system, for details see also [13]. However, it may happen that the success check of the  $\Sigma$ -method fails as can be seen in the following example.

**Example 2.2** Consider the simple DAE system

$$\begin{aligned} \dot{x}_1 &= x_3 + b_1 \\ \dot{x}_2 &= x_4 + b_2 \\ 0 &= x_2 + x_3 + x_4 + b_3 \\ 0 &= -x_1 + x_3 + x_4 + b_4 \end{aligned} \quad (6)$$

which is regular and of differentiation index ( $d$ -index) 3. If we apply the  $\Sigma$ -method to system (6), we get the signature matrix

$$\Sigma = \begin{bmatrix} \boxed{1} & - & 0 & - \\ - & \boxed{1} & - & 0 \\ - & 0 & \boxed{0} & 0 \\ 0 & - & 0 & \boxed{0} \end{bmatrix} \quad (7)$$

with marked HVT on the diagonal and canonical offset vectors  $c = [0, 0, 0, 0]$  and  $d = [1, 1, 0, 0]$ . The corresponding  $\Sigma$ -Jacobian is given by

$$\mathfrak{J} = \begin{bmatrix} 1 & 0 & -1 & 0 \\ 0 & 1 & 0 & -1 \\ 0 & 0 & -1 & -1 \\ 0 & 0 & -1 & -1 \end{bmatrix} \quad (8)$$

and  $\mathfrak{J}$  is singular, i.e., the  $\Sigma$ -method fails.

Example 2.2 shows that for regular and therefore uniquely solvable systems the structural analysis can fail. In the following, systems for which the success check fails since the  $\Sigma$ -Jacobian is singular will be called *structurally singular*<sup>1</sup>. It has been shown in [13] that this is the case for certain coupled systems that are obtained by coupling semi-explicit  $d$ -index 1 subsystems, when the coupling results in redundancies or in an increase in the index. Nevertheless, the structural approach works well in many cases and for many important structures as e.g. systems in Hessenberg form, see [12].

**Remark 2.3** It has been shown in [12] that Pantelides Algorithm [10] and the Signature Method described above are essentially equivalent in the sense that if they can both be applied and they both succeed (or converge) they result in the same structural index and the offset vector  $c = [c_i]$  corresponds to the number of differentiations for each equation  $F_i$  as determined by Pantelides Algorithm. The advantage of using the Signature Method is the fast and efficient computation of the offset vectors via LPPs and the direct success

<sup>1</sup>Note that the term *structurally singular* is also used with a different meaning in other areas of research.

check (i.e., checking the regularity of the  $\Sigma$ -Jacobian) that allows us to use the results for further treatment. Note that Pantelides Algorithm will not converge in cases where the success check of the Signature Method fails.

### 3 Regularization using Overdetermined Formulations

Regularization approaches for high index DAEs like the Dummy Derivatives Approach [9] or index reduction by Minimal Extension [7] consist of adding the hidden constraints to the system equation and the selection of certain differential components that can then be replaced by new algebraic variables in order to lower the index of the system and to obtain a new regular index-reduced system formulation. Hereby, a problem is that the choice of states that are selected can change during the numerical integration (e.g., if the pendulum moves from the vertical to the horizontal position). Thus, if the state selection is performed outside the numerical integrator this often is computational inefficient. In the following, we will present a regularization of quasi-linear DAEs (1) that are of higher index, i.e., that contain hidden constraints. This regularization is based on an overdetermined system formulation in order to overcome the difficulties in the numerical simulation.

If the structural analysis presented in Section 2 succeeds, the offset vector  $c$  gives us the required information about the hidden constraints in the system. If the success check of the  $\Sigma$ -method fails, we can use the procedure proposed in [14, 15] to determine the hidden constraints of a quasi-linear DAE (1).

**Remark 3.1** For structurally singular systems in semi-explicit form arising in coupled systems of DAEs a combined structural-algebraic approach has been proposed in [13] that can be applied in cases where the success check fails, but nevertheless allows us to use certain information provided by the structural analysis. In this way, the determination of the hidden constraints can be improved.

Let us denote the hidden constraints by

$$0 = h(x, t), \tag{9}$$

where  $h : \mathbb{R}^n \times \mathbb{I} \rightarrow \mathbb{R}^c$  with  $\text{rank} \left( \frac{\partial h}{\partial x}(x, t) \right) = \text{const.}$  for all consistent  $(x, t) \in \mathbb{R}^n \times \mathbb{I}$ . Adding the hidden constraints to the quasi-linear DAE (1) leads to the

overdetermined DAE

$$E(x, t)\dot{x} = k(x, t), \tag{10a}$$

$$0 = h(x, t) \tag{10b}$$

consisting of the original quasi-linear DAE (1) and all hidden constraints (9). This overdetermined formulation (10) is equivalent to the original DAE (1) in the sense that both have the same solution set. Note that the unknowns  $x$  are unchanged, i.e., a transformation of the state variables is not necessary and the number of unknowns is not increased (in contrast to the dummy derivative approach). The overdetermined formulation (10) has the advantage that all constraints are stated in explicit form, i.e., no hidden constraints exist anymore. A further advantage of the overdetermined formulation (10) is the fact that it is not necessary to apply analytical manipulations for the determination of a square and uniquely solvable system of DAEs (provided that consistent initial values are given).

**Example 3.2** For the simple pendulum the hidden constraints can be derived from the reduced derivative array (5) and consists of

$$\begin{bmatrix} p_1^2 + p_2^2 - \ell^2 \\ 2p_1q_1 + 2p_2q_2 \\ -4p_1^2\lambda + 2q_1^2 - 4p_2^2\lambda - 2p_2g + 2q_2^2 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix}. \tag{11}$$

### 4 Numerical Approach

Unfortunately it is impossible to model and integrate the overdetermined formulation (10) within the common MODELICA frameworks. Therefore, the above described approach has been incorporated into a prototype MODELICA framework named MPSSim (Multi-Physics System Simulation). Here, a direct numerical integrator has been adapted for the overdetermined regularization (10).

In the following, the used adapted numerical integration scheme is exemplary illustrated for the implicit Euler method. In this case, the discretization of the overdetermined system (10) leads to the overdetermined nonlinear system

$$0 = \begin{bmatrix} E(x_k, t_k)(x_k - x_{k-1}) - \tau_k k(x_k, t_k) \\ -\tau_k h(x_k, t_k) \end{bmatrix} \tag{12}$$

to determine the next iterate  $x_k$ . Here  $\tau_k$  denotes the stepsize in the integration step  $k = 1, \dots, N$  in the Euler scheme,  $t_k$  the discrete time point, and  $x_k$  the approximation of the solution  $x(t_k)$  at the point  $t_k$ .

The nonlinear system (12) is no longer exactly solvable because of discretization and rounding errors during the numerical integration. Therefore, it is only possible to find an approximation  $\tilde{x}_k$  which minimizes the residual  $r \neq 0 \in \mathbb{R}^{n+n_c}$  with

$$r = \begin{bmatrix} r_D \\ r_C \end{bmatrix} = \begin{bmatrix} E(\tilde{x}_k, t_k)(\tilde{x}_k - x_{k-1}) - \tau_k k(\tilde{x}_k, t_k) \\ -\tau_k h(\tilde{x}_k, t_k) \end{bmatrix}$$

in a certain sense. In general, such an approximation results in a residual  $r_C \neq 0$ , which in turn leads to unfulfilled constraints, i.e.,  $0 \neq h(x_k, t_k)$ , not even within machine precision. This would lead to the typical difficulties in the numerical integration of higher index DAEs, i.e., instabilities, convergence problems, inconsistencies, or the solution drifts away from the original solution manifold.

In order to avoid these problems it is necessary to make sure that the constraints are always satisfied during numerical integration. This can be achieved if the nonlinear system (12) is treated separately such that the next iterate  $x_k$  satisfies the lower part, i.e., the constraints, exactly or within a prescribed precision, while  $x_k$  yields a minimal residual in the upper part, i.e., in the differential part. The described numerical approach is implemented in the software package QUALIDAES (QUAsi LInear DAE Solver). This software package is suited for the direct numerical integration of regularized overdetermined model equations and is based on the 3-stage implicit Runge-Kutta method of type Radau IIa of order 5, see [5, 6]. QUALIDAES is integrated as numerical solver into the MPSSim framework. In the current version the user has to provide the model equations already given in overdetermined regularized form (10) formulated as MODELICA model. Then, using the translator M02FOR [1] a FORTRAN source code is generated that can be used to solve the model equations with the solver QUALIDAES. The FORTRAN source code is automatically compiled and linked to the solver QUALIDAES. In Figure 1 the approach for the numerical treatment of models defined in MODELICA using MPSSim is illustrated. Note that within this framework, it is not necessary to determine a dynamic (state) selector, since this is achieved automatically within the separated treatment of (12) by its numerical solution, as described above. For a convenient usage also a graphical user interface (GUI) has been implemented in Matlab (see Figure 2) allowing the graphical representation of the obtained numerical results and can be used for further post-processing.

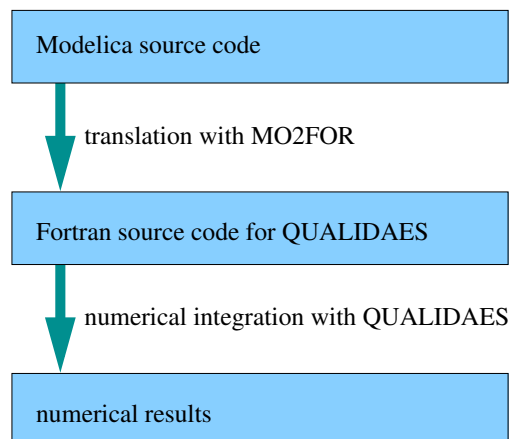

Figure 1: Scheme of MPSSim

## 5 Numerical Example

To show the promising performance of integrating a DAE system using MPSSim with an overdetermined system formulation we have compared the simulation of the simple pendulum equations given in Example 2.1 using MPSSim, MapleSim, Dymola and OpenModelica. In order to have a measurement for the error we include another equation in the system describing the total energy

$$E = \frac{1}{2}m(q_1^2 + q_2^2) + mgp_2$$

that should be preserved for all  $t \in \mathbb{I}$  and every solution of the system (4). We use a gravitational constant of  $g = 13.7503716373294544 \frac{m}{s^2}$  to ensure a time period of  $T = 2s$  for the motion of the pendulum and a mass of  $m = 1kg$  as well as a length of  $\ell = 1m$ . At first we simulate the system for  $t \in [0s, 100s]$  with given (fixed) consistent initial conditions

$$\begin{aligned} p_1(0) &= 1, & p_2(0) &= 0, & q_1(0) &= 0, \\ q_2(0) &= 0, & \lambda(0) &= 0, & E(0) &= 0, \end{aligned}$$

and a prescribed error tolerance of  $10^{-7}$  (for both the absolute and relative error). In the simulation with MPSSim we solve the overdetermined formulation (4) together with (11) containing all hidden constraints, while the other simulation tools use the original d-index 3 formulation (4) and the index reduction is performed within the tool using different index reduction strategies. The values  $E(t_f)$  of the total energy at the final time point  $t_f = 100s$  together with the required CPU times needed for the integration are listed in Table 1. In Dymola a modified version of the multi-step solver Dassl is used. Here, quite a large number of state selections are required (alternating selecting the

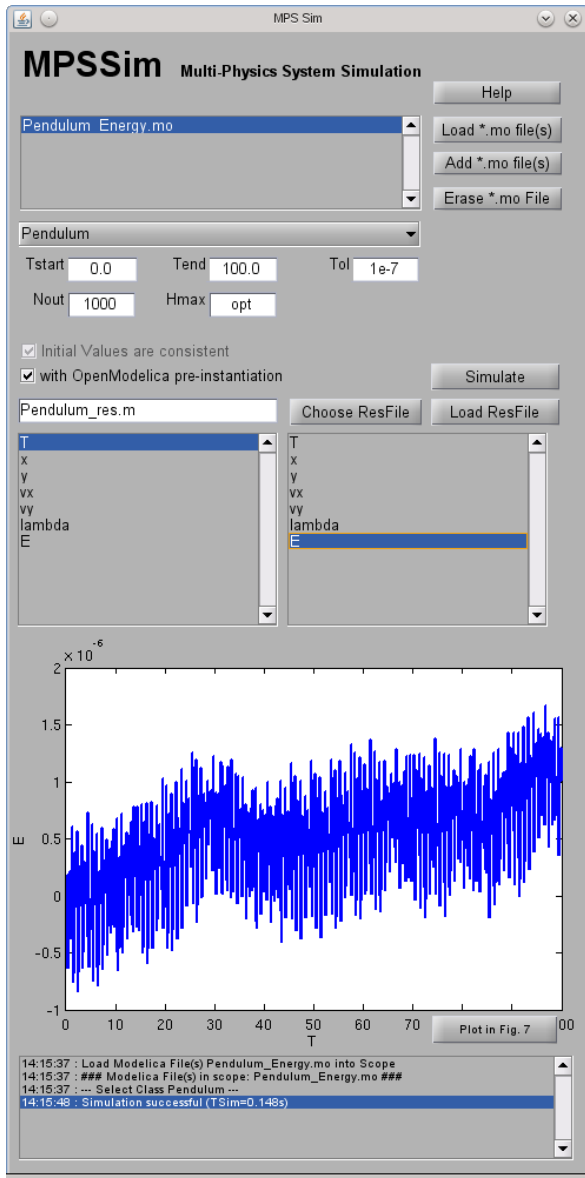

Figure 2: Matlab-GUI of MPSSim

states  $p_1$  and  $q_1$ , or  $p_2$  and  $q_2$ ). In MapleSim we use once the provided solver CK45 suited for semi-stiff problems, which is usually less accurate but faster, and once the Rosenbrock method suited for stiff systems, which yields a higher accuracy at the expense of more required CPU time. Furthermore, the corresponding results obtained for a long time simulation for  $t \in [0s, 1000s]$  are listed in Table 2. Note that OpenModelica fails to integrate the system in this case.

Comparing the obtained results one can see that the projection strategy onto the constraint manifold used within MapleSim yields an accurate numerical solution, while the numerical results obtained with Dymola

Simulation tool	$E(t_f)$	CPU time
MPSSim	$1.13 \cdot 10^{-6}$	0.148s
MapleSim (Rosenbrock)	$0.00 \cdot 10^{-0}$	4.484s
MapleSim (CK45)	$1.50 \cdot 10^{-5}$	1.604s
Dymola	$2.14 \cdot 10^{-3}$	0.890s
OpenModelica	$-1.60 \cdot 10^{-3}$	2.938s

Table 1: Simulation result of the pendulum equation with energy conservation for  $t \in [0s, 100s]$

Simulation tool	$E(t_f)$	CPU time
MPSSim	$1.89 \cdot 10^{-5}$	1.364s
MapleSim (Rosenbrock)	$5.00 \cdot 10^{-6}$	45.358s
MapleSim (CK45)	$1.49 \cdot 10^{-4}$	15.645s
Dymola	$2.14 \cdot 10^{-2}$	8.830s
OpenModelica	—	—

Table 2: Simulation result of the pendulum equation with energy conservation for  $t \in [0s, 1000s]$

are less accurate. The numerical results obtained with MPSSim are accurate within the range of the prescribed error tolerance at low computational costs. However, note that using MPSSim only the costs for the numerical integration of the overdetermined system are measured, while the CPU times of the other tools also contains the costs for index reduction, state selection, projection, and further transformations.

## 6 Conclusions

In this article we have discussed the efficient and robust numerical simulation of dynamical systems that are modeled with MODELICA. We have presented a regularization method for quasi-linear DAEs that is based on an overdetermined system formulation that is obtained by adding all hidden constraints explicitly to the original model equation. The information on the hidden constraints can be obtained from a structural analysis of the system. If a structural analysis cannot be applied these information can be obtained in an analytical way. The overdetermined system formulation can then directly be integrated using a specially adapted numerical integrator. The great advantage of the direct discretization of the overdetermined

formulation is the fact that it is not necessary to determine a selector analytically in advance and that the number of unknowns in the DAE is not increased. A further advantage of an overdetermined regularization with respect to the numerical integration is the possibility to add solution invariants, e.g., mass, impulse or energy conservation laws, to the constraints, which often stabilizes numerical integration. Performing the state selection within the numerical integrator also allows us to switch between different state selections and also opens the door to handle structure varying system models [11]. Currently, no MODELICA simulation framework is able to handle overdetermined system formulations. Therefore, a prototype MODELICA framework MPSSim is presented that includes a translator M2FOR that is used to translate an overdetermined system model provided in MODELICA into FORTRAN source code which can then be integrated using the software package QUALIDAES. MPSSim is still at an early state of development and will be continuously improved.

## Abstract

The quantity of initial equations required in an object-oriented model can only be determined at system level. Since Modelica models are generally designed by components, it is difficult to calculate the amount of initial equations needed at system level, especially when changes are applied to the model, e.g. by adding or removing components. Therefore, it is more convenient to define initial equations at component level. Due to component connections, algebraic dependencies between states may be introduced, which eventually lead to the removal of states when symbolic index reduction algorithms are applied. In this process, the corresponding initial equations are not automatically removed, which results in an over-determined initial system.

This paper describes an algorithm that detects such redundant equations and determines if they are consistent or not. Consistent redundant initial equations can thus be removed automatically, and inconsistent ones can be reported to the modeler. A prototype of the algorithm is implemented in OpenModelica, tested on several representative cases, and compared to previously presented concepts.

*Keywords: initialization; higher-index; simulation; over-constrained*

## 1 Introduction

### 1.1 Statement of the Problem

Initial equations in Modelica are usually defined at the component level, and they are as many as the dynamic variables of the component, i.e., the potential states.

When connections are made, connection equations can induce algebraic constraints on dynamic variables. The dummy derivatives algorithm is used by many Modelica tools to dispose of some potential states and obtain an index-1 problem. As a result, there will be more initial equations than states, leading to an over-constrained initialization problem.

It is agreed that index reduction is necessary in object-oriented modeling to achieve full modularity without compromises, and suitable means to handle it have been developed over time, so it is obviously necessary to extend the handling to initialization as well. In the majority of cases the over-constrained initialization problem turns out to be consistent, and should therefore be handled automatically, without any intervention by the end user; inconsistent initialization problems should be reported in a user-friendly way.

### 1.2 Overview of Existing Solutions

OpenModelica has been using a numerical approach to solve this problem for a long time, as discussed in [1]. The initialization problem is turned into an optimization problem, where the sum of square of all residuals is minimized; if the problem is consistent, then the minimum is zero, otherwise the inconsistency is spread among equations, which is generally not a good idea. However, solving an optimization problem is much harder and time-consuming than solving a system of equations, and it might easily be possible to get trapped in local minima. Also, convergence problems quickly get worse when increasing the size of the system, up to the point where a solution cannot be reliably found unless guess values very close to the solution are given to all the problem unknowns. This gets even worse in the case of hybrid models, where

some parts of the system contain discrete equations. Even for determined initialization systems, the numerical approach is only applicable in very special cases. In practice, this limits the application of the method to very simple models. So far, large-scale and hybrid models are reliably initialized using the symbolic initialization method described in [2], which has been further developed to also handle over-determined systems.

To our knowledge, there is no other Modelica tool available that has a general approach to handle over-determined initialization problems. The package *ModelicaTest*, which is offered by the Modelica Association together with the Modelica standard library (MSL), has been extended to provide a free-accessible set of appropriate test models. This can be used to compare the excellence of the initialization capabilities of different tools.

### 1.3 Structure of the Paper

In Section 2, an simple introductory example is discussed in detail to demonstrate the problem being tackled in this paper. In Section 3, an algorithm is presented to locate redundant equations which arise when symbolic index reduction is applied, and detect whether they are consistent or not. In Section 4, it is shown how the proposed algorithm works. A few simple test cases and the results of a more involved test case are discussed. Section 5 concludes the work with final remarks and suggestions for future work.

## 2 Introductory Example

This section describes how over-constrained initialization problems arise, by means of a simple electric circuit model, where two series-connected capacitors are connected to a constant voltage source. A graphical representation is shown in Figure 1 and an equation-based model description where all alias variables have been removed is shown in Listing 1.

Both of the capacitors introduce a potential state  $u_i$ . Due to component-based modeling, both capacitors may also introduce initial equations, for example  $u_i = 5$ .

An algebraic constraint among potential states is introduced by connecting the capacitors in parallel to a voltage source, so this model has index-2. Hence, symbolic index reduction is used (see [3], [4]) to transform this system into an equivalent index-1 system of lower order. During this process, one of the potential

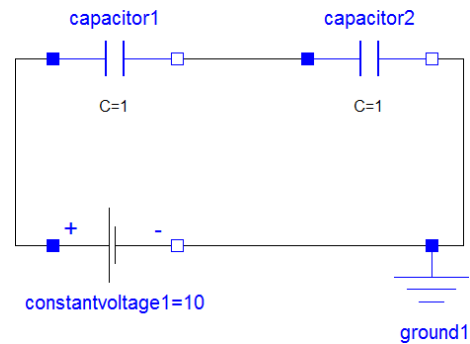

Figure 1: Introductory example - object diagram

states becomes an ordinary algebraic variable and the additional equation  $0 = \text{der}(u_1) + \text{der}(u_2)$  gets introduced to keep the dynamic system determined.

```

12 |    i = C*der(u2);
13 |    u = u1 + u2;
14 | end example;

```

Listing 1: Introductory example - flat Modelica model

After the dynamic system is transformed to index-1, the initial equations will be added. As a result, an over-determined system arises that needs to get matched. There will be at least one unmatched equation for each redundant initial equation. Also note that there is no unique matching (besides the matching within each strong component) due to the over-determined system structure; different matchings are possible, which leave out different unmatched equations and possibly lead to different sets of strong components. Figure 2 shows one possible matching that will be used for the next steps; the gray equation is the unmatched one.

If all unmatched equations are consistent, then they can be removed and the initial solution can be calculated using robust and efficient algorithms designed for square problems. In order to check the consistency, the matching digraph gets first transformed into a directed graph by replacing each non-matching edge with an arc going from the E-node to the V-node, then by collapsing each V-node with its matching E-node.

Figure 2: Introductory example - matching

Next, Tarjan’s algorithm [5] gets applied on the directed graph, ignoring the unmatched equations, to find out strong components. The result of this procedure is presented in Figure 3, with one strong component at the top of the graph.

The symbolic consistency check will be performed on this graph. The basic idea is to only consider the sub-graph which involves the initial equations and the unmatched equations, in this case the lower part of Figure 3, and to recursively and symbolically solve the equations starting from the sinks and going up to the unmatched equations. In this case, once the three sink node equations have been solved, the gray equation becomes  $10 = 5 + 5$ , which is equivalent to  $0 = 0$ , and thus redundant.

Figure 3: Introductory example - directed graph of the unmatched equation

In general, however, it will not be possible to symbolically solve all the chain of equations leading to the unmatched equation. It is therefore essential to select

a particular matching that makes this possible. A concrete algorithm that does so is presented in the next section.

### 3 Algorithm for Redundant Equation Detection

The goal of this algorithm is to find redundant equations and remove them if they are consistent, or issue an error if they are not. A symbolic approach is preferred, because it avoids the need of setting more or less arbitrary numerical thresholds and using iterative solvers. In general, solving the full initialization problem symbolically is not feasible, because it often contains large and nonlinear coupled systems of equations that cannot be solved in closed form. Therefore, a symbolic approach should aim at finding a suitable subset of the initialization problem that is easy to solve symbolically, to check if there are redundant and consistent equations, so as to remove them.

In a system with  $n$  equations and  $m$  variables, with  $k = n - m$  too many equations, there are  $\binom{n}{k}$  possible sub-sets of equations that may be removed to make the problem square. However, the resulting problem need not only be square, but also have a solution, and many of these sets cannot be removed, because they contain essential (and not redundant) constraints. Hence, an algorithm is needed that efficiently finds those sets that can be removed without losing essential information.

In addition to that, each set of removed equations corresponds to a unique matching (ignoring the different matchings within strong components) of the remaining system. Depending on this matching, a consistence check can be performed by recursively evaluating the sorted subsets. The effort for this evaluation strongly depends on the selected equation dependencies, i.e., on the selected matching.

In practice, such a subset can normally be found, because initial equations are usually linear, involving one unknown, e.g.  $x = x_0$ , or  $\text{der}(x) = 0$ . State derivatives usually show up linearly in balance equations, because they stem from the derivative of some basic quantity (mass, energy, momentum, charge) via differentiation. Connection equations, which usually provide the constraints that make the problem high index, are also linear. In most cases, it should then be possible to symbolically prove that the problem is either consistent or inconsistent, by means of symbolic computations, because the equations to be solved symbolically will belong to the above-mentioned categories.

### 3.1 Proposed Algorithm

1. Apply index reduction and state variable change to the dynamic problem, using the dummy derivatives algorithm.
2. Add the initial equations to the set to form the initialization problem.
3. Build the corresponding E-V graph.
4. Run the matching algorithm; some unmatched equations will remain at the end of the process (one for each redundant initial equation).
5. Transform the E-V digraph into a directed graph by first replacing each non-matching edge with an arc going from the E-node to the V-node, then by collapsing each V-node with its matching E-node.
6. Run Tarjan's algorithm on the directed graph, ignoring the unmatched equations, to find the strongly connected components, and collapse each strong component in a single node.
7. Starting from the sink nodes and proceeding recursively towards the source nodes (unmatched equations), symbolically solve each equation (or system of equations) for its unknown(s) and substitute the result in all the nodes that have arcs pointing to the solved equation node and are needed to validate the unmatched equations.

If the symbolic solution of one equation is not possible (e.g., a sub-expression becomes  $0/0$ ), then try to change the matching from step 4 for the corresponding equation and go back to step 5. If there is no other matching, then the algorithm aborts, and it is neither possible to draw any conclusion on the consistency of the problem, nor to reduce the problem to a square one.

8. If all the unmatched source nodes contain equations equivalent to  $0 = 0$ , then the over-determined system is consistent, and it is possible to turn it into a square equivalent system by just removing all the unmatched equations. If there are one or more source nodes containing equations equivalent to  $0 = 1$ , then the system is inconsistent. For diagnostic purposes, it is possible to report for each node the set of connected equations which are inconsistent. This will help the end user to identify the source of the inconsistency and possibly remove it.

The calculation of the matching in step 4 is essential for this approach. Due to the over-determined system structure, in general various matchings are possible. If a matching for all variables exists that contains no algebraic loops, then it is preferred and should be tried first. Therefore, Tarjan's tearing algorithm described in Cellier's book [6] is applied to the over-determined equation system.

A recursive evaluation of the equation system is possible if and only if during sequential evaluation each next equation depends on exactly one more unknown variable. This means that within the equation system at least one equation exists, which depends just on one variable. Tarjan's algorithm detects this fact, matches the variable to the equation, and reduces the corresponding bipartite graph by removing both nodes and all corresponding edges. The same must hold for the reduced set of equations and can be repeated until all variables are matched.

If during the algorithm all remaining equations depend on at least two unknown variables no matching without algebraic loops exists.

The proposed algorithm extends the existing symbolic initialization method of OpenModelica [2], which is capable to initialize complex hybrid models.

### 3.2 Numeric Fall-back Case

Instead of step 7 and 8 another possible approach would be to leave the unmatched equations out of the problem, solve it, then numerically evaluate the residuals and check if they are small enough. This might be non-trivial in some cases when the involved quantities are very large due to the choice of measurement units and to the size of the system under consideration.

This kind of approach has also the disadvantage that it is not possible to find a different matching if the system ends up in a local singularity.

## 4 Discussion Based on Selected Examples

The proposed algorithm has been tested using the package *OverdeterminedInitialization* from *ModelicaTest*, which has been first created for this purpose at the 80<sup>th</sup> Modelica Design Meeting. This test package contains a list of models from different domains (Electrical, Mechanics, and Fluid) for test purpose, which become over-constrained after index-reduction. The different test cases can be used to cover all kinds of the different issues, that may occur during this process.

Figure 4: Directed graph of the unmatched equations of some simple examples from the package *OverdeterminedInitialization*

Because of the low complexity of the most test cases, they end up with a similar subsystem for the consistence check as the introductory example. Therefore, the consistence check can be performed by evaluating the remaining subgraphs recursively towards the unmatched equations (see Figure 4).

### 4.1 Fluid Model of Two Volumes

Figure 5: *TwoVolumesEquationsFullSteadyState-MassAndEnergy*

One of the most complex examples of the package is the fluid model *TwoVolumesEquationsFullSteadyStateMassAndEnergy*, in which equations and initial equations refer to stored mass and energy within each volume as differentiated variables, but pressure and

temperature are forced to be states using the Modelica stateSelect attribute. Figure 5 shows a graphical representation using MSL components. Note that, due to the way the Modelica.Fluid components are designed, it is not possible to reproduce this situation, so a textual equation-based model is used for testing the algorithm. This model and the respective dependence graph are listed in the appendix. Using transformations like alias elimination, a reduced version can be generated that contains just 10 variables and 11 equations. Figure 6 shows the reduced dependence graph with one possible matching.

The example contains 11 equations, and is over-constrained due to one equation. Therefore, there are 11 sets of equations (each of cardinality one) that may be removed. Depending on the selected set of equations several cases can occur:

1. recursively evaluable systems
2. systems containing algebraic loops
3. systems with local singularities
4. system with structural singularities

Figure 6: A matching of the remaining equation system of *TwoVolumesEquationsFullSteadyState-MassAndEnergy*

Four sets end up in case 1, which is the most desirable case. Here all equations can be solved recursively towards the unmatched ones to check the consistency

of the system. This happens often in simple cases as described above. Unfortunately, there is no guarantee that such a case will always show up in more complex examples. But, if such a case exists, it will be always captured.

Three sets end up in case 2, which is the most common case for real-world problems. In general, there is no way to avoid algebraic loops. However, this case will only need to be taken into consideration if there is no recursively evaluable system available. In that case, advanced symbolic solvers are needed to compute the solution of these loops symbolically. If this is not possible a modified version of the algorithm could switch to a numeric fall-back mode.

Two sets end up in case 3, which occurs, for instance, if a subexpression is evaluated to 0/0. In this case the selected set of unmatched equations can not be used to determine whether the system is consistent or not. The proposed algorithm detects this in step 7, and, if possible, this case is avoided by rejecting the corresponding set and trying another one, in the hope of finding a recursively evaluable one.

Two sets end up in case 4, which gives a non-valid matching for the system. It is not possible to use the selected set of unmatched equations for any conclusion. Because, the proposed algorithm only selects matchable sets of equations, this case is never reached. Furthermore, due to this fact the possible sub-sets of equations that may be reduced is much less than  $\binom{n}{k}$ .

### 4.2 Electrical 3-Phase System

This test model was already presented in [1]:

Consider the following electrical 3-phase power system of Figure 7, where two generating units VS1 and VS2 are connected via a transmission line modeled by components LR1 and LR2.

Figure 7: An electrical power system with two generating units VS1 and VS2 connected via a transmission line

The connectors are written in dq0-coordinates implementing the potential variable  $u_{dq0}$  and the flow variable  $i_{dq0}$ . These quantities are constant in case of a non-distributed steady state, which is generally assumed during the initialization process. Introducing the Park-Transformation  $P$  the 3-phase rotating system

(voltages  $u_{abc}$  and currents  $i_{abc}$ ) can be calculated from the dq0-representation and vice versa.

The transmission line (LR1 and LR2) is modeled by a purely inductive and resistive component, based on the Modelica Electrical Library. Since LR1 and LR2 are connected in series, giving a higher index system, index reduction has to be applied for simulation purposes.

Figure 8: LR2 component with dq0-connectors

The voltage source is described similarly using the Modelica Standard Library combined with the dq0-connectors.

#### 4.2.1 Results Using the Proposed Algorithm

This system covers some important pitfalls. After index reduction, the initial system contains three equations too many. The described approach is not able to find a matching without algebraic loops. Therefore, the resulting loop (with a size of 27) has to be solved symbolically. This is currently not supported from the OpenModelica back-end and might be in general impossible.

As fall-back case the system can be solved numerically during runtime as described in 3.2. For the concrete case of the 3-phase system, the resulting algebraic loop becomes singular if a wrong set of equations is removed. A more advanced solution is described in the following subsection.

#### 4.2.2 Future Work

As stated above, a symbolic solution for the 3-phase system is still needed. One possible idea is to change the consistence check as follows:

Depending on the matching, the following three equations might get selected as the set of removed equations:

$$0.0 = 0.5773502691896258 * (\text{der}(\text{LR2.I1.i}) + \text{der}(\text{LR2.I2.i}) + \text{der}(\text{LR2.I3.i}));$$

$$\begin{aligned}
0.0 = & \text{LR2.Park}[2,1] * \text{der}(\text{LR2.I1.i}) + \\
& \text{LR2.Park}[2,2] * \text{der}(\text{LR2.I2.i}) + \\
& \text{LR2.Park}[2,3] * \text{der}(\text{LR2.I3.i}) + \\
& \text{der}(\text{LR2.Park}[2,1]) * \text{LR1.i\_abc}[1] + \\
& \text{der}(\text{LR2.Park}[2,2]) * \text{LR1.i\_abc}[2] + \\
& \text{der}(\text{LR2.Park}[2,3]) * \text{LR1.i\_abc}[3];
\end{aligned}$$

$$\begin{aligned}
0.0 = & \text{LR2.Park}[1,1] * \text{der}(\text{LR2.I1.i}) + \\
& \text{LR2.Park}[1,2] * \text{der}(\text{LR2.I2.i}) + \\
& \text{LR2.Park}[1,3] * \text{der}(\text{LR2.I3.i}) + \\
& \text{der}(\text{LR2.Park}[1,1]) * \text{LR1.i\_abc}[1] + \\
& \text{der}(\text{LR2.Park}[1,2]) * \text{LR1.i\_abc}[2] + \\
& \text{der}(\text{LR2.Park}[1,3]) * \text{LR1.i\_abc}[3];
\end{aligned}$$

They are quite similar to the next three equations, that are part of the matched system and involved in the algebraic loop:

$$0.0 = 0.5773502691896258 * (\text{der}(\text{LR2.I1.i}) + \text{der}(\text{LR2.I2.i}) + \text{der}(\text{LR2.I3.i}));$$

$$\begin{aligned}
0.0 = & \text{LR1.Park}[2,1] * \text{der}(\text{LR2.I1.i}) + \\
& \text{LR1.Park}[2,2] * \text{der}(\text{LR2.I2.i}) + \\
& \text{LR1.Park}[2,3] * \text{der}(\text{LR2.I3.i}) + \\
& \text{der}(\text{LR1.Park}[2,1]) * \text{LR1.i\_abc}[1] + \\
& \text{der}(\text{LR1.Park}[2,2]) * \text{LR1.i\_abc}[2] + \\
& \text{der}(\text{LR1.Park}[2,3]) * \text{LR1.i\_abc}[3];
\end{aligned}$$

$$\begin{aligned}
0.0 = & \text{LR1.Park}[1,1] * \text{der}(\text{LR2.I1.i}) + \\
& \text{LR1.Park}[1,2] * \text{der}(\text{LR2.I2.i}) + \\
& \text{LR1.Park}[1,3] * \text{der}(\text{LR2.I3.i}) + \\
& \text{der}(\text{LR1.Park}[1,1]) * \text{LR1.i\_abc}[1] + \\
& \text{der}(\text{LR1.Park}[1,2]) * \text{LR1.i\_abc}[2] + \\
& \text{der}(\text{LR1.Park}[1,3]) * \text{LR1.i\_abc}[3];
\end{aligned}$$

Instead of solving the entire algebraic loop symbolically, it might be possible to transform each of the removed equations into an equation of the matched system, and thus prove its redundancy.

The first equation of both sets are already equal, so there is no further consistence check needed. By applying common-sub-expression elimination techniques and advanced alias elimination also the other two equations can be transformed into the other two. For that, it is just needed to figure out that `LR1.Park` is alias of `LR2.Park` and `der(LR1.Park)` is alias of `der(LR2.Park)`.

## 5 Conclusions

This paper has discussed a symbolic algorithm that handles the initialization problem of over-determined systems. The presented approach has not to deal with numerical thresholds and there is no risk of trapping into local minima. Also hybrid models can be handled efficiently. This is a major improvement with respect

to the existing numerical approach within OpenModelica.

This paper focused on symbolic techniques to determine potential redundant equations and ways to analyze whether the system is consistent or not. These work well for problems, which end up in an recursively evaluable initial system. Furthermore, the developed algorithm takes care of singularities, if they occur during the consistency check. More complex problems end up with systems including algebraic loops. If they are not solvable symbolically, a numerical fall-back solution as well as advanced symbolic techniques are proposed.

# Proposal for standardization of Heat Transfer Modelling in NewThermal Library

Susana López      Itzal del Hoyo  
IK4-TEKNIKER

Iñaki Goenaga, 5. 20600 Eibar, Gipuzkoa (Spain)  
[susana.lopez@tekniker.es](mailto:susana.lopez@tekniker.es) [itzal.delhoyo@tekniker.es](mailto:itzal.delhoyo@tekniker.es)

## Abstract

This article presents the `NewThermal` library that extends the capacities of `Thermal` library from the Modelica Standard Library (MSL) including a proposal for standardizing the use of `Material` models. The new library is intended to decouple the models that collect the equations of heat transfer phenomena from the thermo-physical properties of the matters (fluids and solids).

The `NewThermal` library, in the same way that the current `Thermal` library from MSL, is composed of thermal system components to model heat transfer and simple thermo-fluid pipe flow. Nevertheless, the models from the package proposed inherit the thermal properties from `Media` and `Material` models of the fluids and solids involved (either temperature dependent or constant). In this way, the user has three aspects to define; the heat transfer phenomena to be modelled, the geometrical characteristics of the bodies, and the matters involved.

Components inside `HeatTransfer` package are implemented such they can be used for any material model in `Materials` package, in the same way that components from `Modelica.Fluid` were carried out for their use with media models from `Modelica.Media`.

The `NewThermal` library, in addition, provides some general base models for the modelling of 2D and 3D heat conduction in basic solid geometries.

Two examples of use for different domains are presented to illustrate the features of the new libraries.

*Keywords: Modelica; heat transfer; thermal properties; thermal conduction, three dimensional heat flow*

## 1 Introduction

In a general view, any heat transfer phenomena can be described with three different aspects:

- Heat transfer mechanism: conduction, convection or radiation or a combination of them.
- Geometrical characteristics of the phenomena: dimensions of the bodies, relative position between bodies and/or fluids.
- Properties of the substances involved, fluids and solids.

On one hand, in the modelling of any detailed thermal behaviour, the thermal properties of the solids and fluids involved (density, thermal conductivity, specific heat,...) acquire a relevant importance and in many cases it is essential to take into account their dependence on the temperature.

On the other hand, the geometry of real bodies usually can be constructed by the addition of basic geometries, that is, from a macroscopic point of view almost all bodies can be discretized in parallelepipedic, cylindrical and annular nodes (lumped elements) or a combination of them.

Considering this ideas and following the philosophy of replaceable media models in fluid models from MSL[1][2], IK4-TEKNIKER has created the libraries `NewThermal` and `Materials`. This first version provides mainly models for the modelling of conductive heat transfer. But there are described also some guidelines to extend the library to other mechanisms such as convective and radiative heat transfer modelling.

The goal of the `NewThermal` library is to provide standard components for heat transfer modelling dependent on geometry but independent of material properties.

## 2 Materials Library

It is defined as the library of solid material property models. The models from Materials Library are based on the `partialMaterial` partial model. This partial model has declared, as replaceable models, all models required in the modelling of any heat conduction phenomenon. In the figure 1 is shown the replaceable models mentioned above. On one hand, there is the inertia model, required if the heat capacity of the material is taken into account, and on the other hand the models needed for the modelling of heat transport inside the material are available. The latter are chosen depending on the geometries involved, illustrated in the figure 2.

Figure 1: Components of `partialMaterial` class

Figure 2: Box, cylindrical and cylindrical sector geometries

Hence, material models extend from this partial model and add in each case the thermal properties of the substances to be modelled.

That is, in the same way that models from `Modelica.Fluid` library with models from `Media` library, any thermal model can include a replaceable instance of `partialMaterial` which allows selecting models from Materials library choosing between a large list of materials to inherit their thermal properties, as it is shown in the figure 3.

Figure 3: Component for the modelling of the thermal behaviour of a body with cylindrical geometry.

In this case, the external radius and the height of the cylinder are parameters and the specific heat capacity, density as well as conductivity of the material extends from the replaceable material model.

Current `partialMaterial` model includes only replaceable models for the modelling of conductive heat transfer but it is possible to extend it in the future adding replaceable models relative to radiative heat transfer.

## 3 NewThermal Library

### 3.1 General Library Structure

The `NewThermal` library has the same structure as `Thermal` library from `MSL`, as it is shown in the figure 4. All new models are built with connections on existing `Interfaces` package, so they are compatible with any model inside `Modelica.Thermal`.

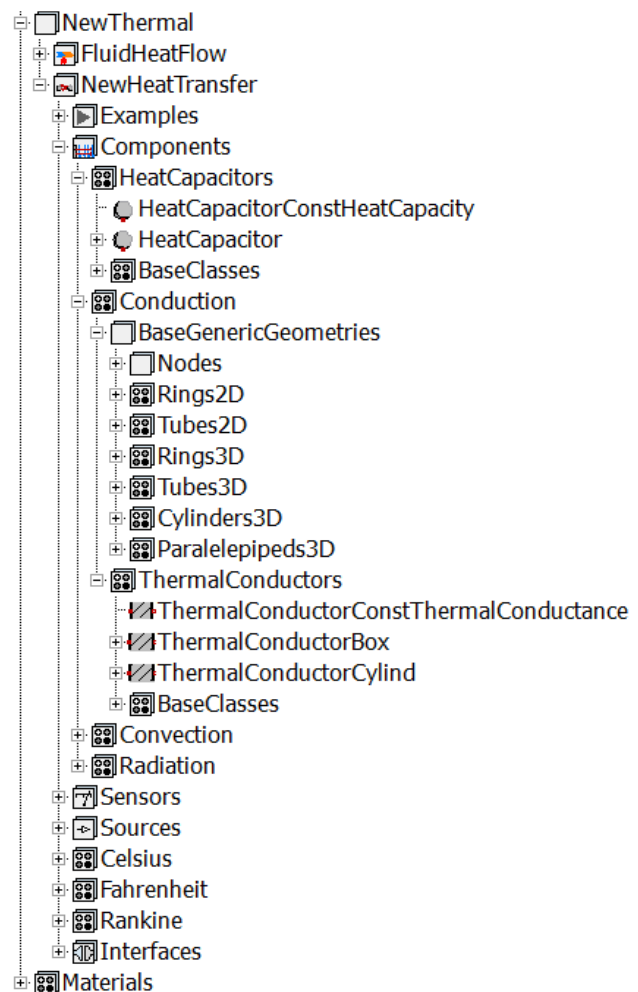

Figure 4: `NewThermal` library structure

Most of new models are based on the use of replaceable material models and for this reason it is essential to open it together with Materials library.

Following sections are focused on HeatCapacitors and Conduction packages that support simulation of heat conduction through any solid.

### 3.2 HeatCapacitor Library

As shown in the library structure, HeatCapacitor subpackage is included in Components package. In this subpackage, a collection of generic models for the heat capacity of a material can be found. In these components, no specific geometry is assumed beyond a total volume with uniform temperature for the entire volume. Furthermore, only one parameter it is required, precisely the volume of the body to be modelled, in such a way that the heat capacity value is inherited from the replaceable material model. The figure 5 shows the information expected from the user when the heat capacitor model is used.

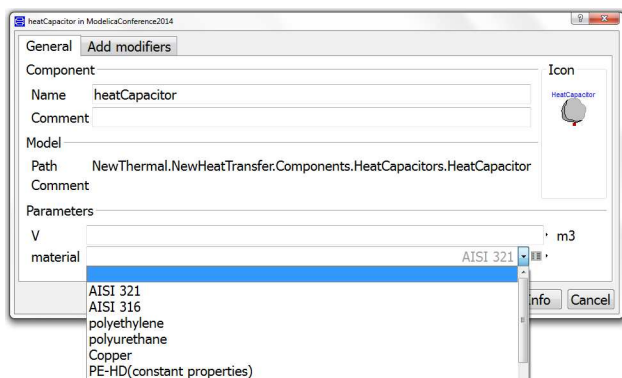

Figure 5: heatCapacitor class

### 3.3 Conduction Library

The Conduction subpackage from NewHeatTransfer package is composed of two groups of models.

In the first one, named ThermalConductors, a collection of thermal conductor models can be found, for 1D conductive heat transport. It contains a sort of models for different geometries with the option to choose the material of the body to be modelled.

The second library, called BasicGenericGeometries, collects a large list of models for the simulation of conduction heat transfer in any 2D or 3D geometry (parallelepipeds, cylinders, rings or tubes) and again all of them have the option to choose the material to be modelled.

#### 3.3.1 Heat Conduction Base Classes

The base classes of the ThermalConductors package are partial models that define the interface and the equation of the heat conduction phenomena. Models of ThermalConductors have only geometry values as parameters, inheriting the value of conductivity from the replaceable material model. The figure 6 shows the information to be defined by the user to model heat conduction in box type geometry.

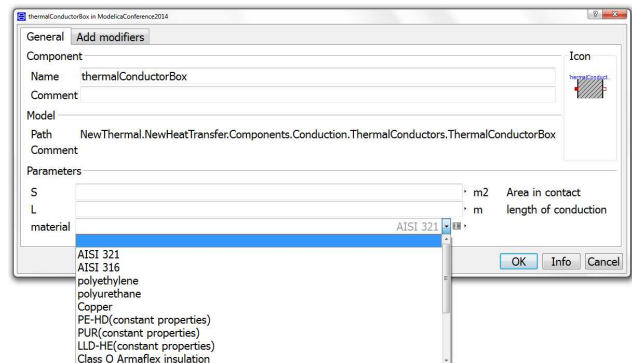

Figure 6: thermalConductorBox model for the transport of heat through box geometry in any material

partialThermalConductor provides the thermal conduction equation  $Q_{flow} = G \cdot dT$ , where  $G$  is defined as thermal conductance of material and its calculation depends on the geometry through which the heat flows. The partial model extends from existing Element1D which provides two thermal ports port\_a and port\_b which are common in all components for modelling heat transfer, such as heat convection or heat radiation.

ThermalConductors package offers a set of models which extend from partialThermalConductor partial model adding the equation characteristic of  $G$  depending on geometry:

- $G = \frac{k \cdot A}{L}$  for a box geometry under the assumption that heat flows along the box length.
- $G = \frac{2 \cdot \pi \cdot k \cdot L}{\log\left(\frac{R_{ext}}{R_{int}}\right)}$  for a cylindrical geometry, under the assumption that heat flows from the inside to the outside radius of the cylinder.

- $$G = \frac{angle * k * L}{\log\left(\frac{R_{ext}}{R_{int}}\right)}$$
 for a sector for any cylindrical geometry, under the assumption that heat flows from the inside to the outside radius of the cylinder.

In all the equations k is the thermal conductivity of the material.

### 3.3.2 Nodes Base Classes for different 2D and 3D geometries

BaseGenericGeometries package in Components.Conduction contains a set of components for the modelling of 2D and 3D heat conduction through bodies with different geometries. These models are built on arrays of components from Nodes package, a collection of models of basic units (lumped elements) for the construction of geometries above mentioned. This approach has been suggested in previous works such as [3].

Thereby, in Nodes package, it can be found annular nodes, parallelepipeds nodes and cylindrical nodes. In the figure 7 the model and icon for parallelepiped node in 3D are shown.

Figure 7: Basic 3D node class

All these components are composed of:

- A heatCapacitor model, from Heat-Capacitor library, for the thermal storage capacity of the node and it is assumed a uniform temperature in it.
- Four/six thermalConductor models, from ThermalConductors library, for modelling the transport of heat. Each couple of thermalConductor models describes the heat transport along the two/three dimensions.

### 3.4 Convection and Radiation Libraries

The models from Convection library, with two heat ports as it is common in all components for modelling heat transfer, are prepared for connecting one of the heat ports to the solid and the other heat port to the fluid, in such a way that the component itself, has as internal variables the temperature at solid and fluid and the heat flow rate from/to solid and fluid. Following the same philosophy used for the creation of HeatCapacitor and Conduction libraries and taking advance of the accessible fluid and solid temperatures involved, all components in Convection library have been provided by a replaceable medium model and correlations for natural and external forced convection [4][5] (forced convection problem inside conduits is already solved in Modelica.Fluid). Thereby, the user only has to provide the geometry information of the body involved in the convective heat transfer and to select the media.

Models in Radiation library respond to the  $Q_{flow} = Gr * \sigma * (port\_a.T^4 - port\_b.T^4)$  radiation formula, where Gr is function of the emittance of material surfaces involved in the thermal radiation and its calculation depends on the geometry and arrangement of surfaces. The emittance of surfaces tends to vary its value with the temperature and this effect is more relevant as the temperature increases [6]. The emittance is considered to be included in material models because it is an intrinsic property of material surface. Therefore, the same as in Conduction library, the Radiation package would offer models for the modelling of thermal radiation depending on the geometry and the arrangement of objects involved but independent on materials.

## 4 Examples

### 4.1 Insulated Pipe

Based on the `dynamicPipe` class from `Modelica.Fluid` and `NewThermal` features, a model of an insulated pipe has been created. Although the model has been named `insulatedPipe`, it describes the hydraulic and thermal behaviour of any pipe with one or more solid layer(s) assuming radial symmetry in all phenomena. Hence, with this model the user can model from a simple copper tube of any home heating system to a more sophisticated plastic tube with some insulation layers.

The cover of the dynamic pipe is compounded at most of five layers of any material from `Materials` library. The first layer is the closest to the fluid, that is, the layer with the smallest radius.

The user has to indicate how many layers the pipe has and the thickness of each layer, as well as the layers materials and the internal radius of the first layer.

If the number of layers is less than five, the user can disable the layers no required, switching to false the corresponding boolean `useLayer`. On the left side of the figure 8, it is shown the two systems of the insulated pipe:

- the hydraulic system defined by the `dynamicPipe` model from `MSL`
- the thermal system for the cover of the pipe, defined by the `multipleCylinder` model

The right side of the same figure shows the five layers of the cover, each one can be disabled if it is not required for the modelling of the insulated pipe.

**Figure 8: `insulatedPipe` (left) and its `multipleCylinder2D` base class (right)**

The `insulatedPipe` model has been built easily with several instances of the 2D tube class from `BaseGenericGeometries` package in `NewThermal.HeatTransfer.Conduction`

(right side of the figure 8). It is prepared to be divided into `nNodes` equally spaced segments along the flow path, therefore, the same number of lumped elements are in all matter layers, as much to fluid line as to cover layers.

The model, in addition, has the option of neglecting the axial conductive heat transfer (parallel to the fluid path) throughout the solid materials of the pipe. This assumption is quite reasonable in some cases, depending on the thermal properties of constituent materials, and it can significantly speed up simulations.

The `insulatedPipe` model has been used for the modelling of pre-insulated pipes in a small District Heating system [7] with good results, error of roughly 5%, in comparison with technical report of heat losses provided by the pipe manufacturer.

**Figure 9: Experimental data and simulation results for `insulatedPipe` model adapted for commercial pipe simulation.**

### 4.2 Heat transfer in 3D cylinder

Based on models from `Tubes3D` library a discretized cylinder was built. The model was used for simulating laser surface hardening process of a crankshaft. In this case, a 3D model was absolutely indispensable because there was a relative movement between the crankshaft and the punctual heat source (punctual laser).

In this case, `Modelica` model was especially interesting in order to define and also simulate the control strategy of the process.

**Figure 10: Simplified sketch of the interaction between the punctual heat source and the crankshaft**

Before using it for this purpose, 3D tube model was validated with a FEM model (MSC NASTRAN®). Both models were discretized in the same way and exposed to the same external conditions to compare the evolution of the temperature in some nodes.

The tube was discretized in:

- Number of rings (radial direction): 20
- Number of sectors: 16
- Number of slices (axial direction): 5

The following external conditions were assumed:

- Convection in internal and external lateral surfaces:
  - $h_{\text{internal wall}}$ : 10 W/m<sup>2</sup>K
  - $h_{\text{external wall}}$ : 100 W/m<sup>2</sup>K
- Constant temperature in the upper and lower external surfaces:
  - Upper surface: 500 °C
  - Lower surface: 100 °C
- Temperature of nodes at  $t=0s$ , 20°C

The good agreement between stationary simulation results of both models can be appreciated in the figure 11.

The discrepancy on transient behaviour is due to different initial conditions in some nodes. All the nodes in the FEM model could not be initialized at 20°C due principally to the way of imposing external conditions. In this case, the nodes from the upper slice and the lower slice were in contact with an imaginary plate at 100°C and 500°C, so that, this nodes inherited directly the temperature of them at  $t=0$ . In Modelica model, nevertheless, all nodes started the simulation at 20°C.

**Figure 11. Temperatures of five nodes of the FEM and Modelica models**

## 5 Conclusions

NewThermal together with Materials libraries have been created by IK4-TEKNIKER in order to extend MSL capabilities for heat transfer modelling. The new libraries decouple material properties from heat transfer phenomena modelling and allow taking into account the influence of temperature on material properties such as thermal conductivity, specific heat capacity, etc.

NewThermal library provides also basic models to simulate 2D and 3D heat conduction problems in bodies with simple geometries.

Two practical examples from different application domains have been shown to demonstrate the use of the libraries.

## Abstract

This paper summarizes the work performed in one of the work-packages of the FP7 *iTesla* project. This work consisted in the development of a power system component library for phasor time domain simulation in Modelica.

The models were used to build power system network models, used in experiments for parameter identification. The experiments were carried out with the RAPID toolbox, which has been developed at SmarTS Lab within the same project. The toolbox was written in MATLAB, making use of FMI Technologies for interacting with Modelica models.

*Keywords:* Power Systems, Phasor Simulation, Modelica, FMI, Parameter Identification, Model Validation.

## 1 Introduction

### 1.1 Conventional Power System Modeling and Simulation

Modeling power system components and networks is important for different studies in the planning and operation of electricity networks [1], and the level of complexity in the models depends on the type of studies carried out [2]. Traditional tools for power system modeling are usually tied to a specific time scale, often limiting the applicability and/or validity of the models to a specific kind of studies [3].

The models can be of Electro-Magnetic Transient (EMT) type [4, 5], which is the most detailed type of power system models; of phasor time-domain (phasor) type, which use a simplified representation commonly used in positive sequence phasor time-domain simulation for stability assessment [2]; or could even use a Quasi Steady State (QSS) representation for simplified long term dynamic simulation [6]. To assemble power

system models using different components of specific type and perform simulations, domain-specific tools are traditionally used; for example [7, 8] are used in the case of phasor-time domain simulation.

Other modeling and simulation approaches which are less utilized in the domain is the dynamic phasors approach [9], and mixed EMT & phasor simulation [10, 11].

The reminder of this article focuses on phasor time-domain power system modeling using the Modelica language and the application of Flexible Mockup Interface (FMI) Technologies for model validation and parameter identification.

### 1.2 Motivation — Modelica, an unambiguous modeling language for Power Systems

Several tools for phasor time domain simulation already exist, but only few of them let the user access the models' code (mainly those that are open source software [12]), lack flexibility in regards to modeling and simulation features provided [2], and have limitations for unambiguous model exchange [13]. This motivated the work presented in this paper which is part of the FP7 *iTesla* project [14], where a power system component library of phasor type models is being developed.

Modelica was chosen as the modeling language for this library as it allows to develop models using a formal mathematical description and because it separates the model from the solver [3]. The models developed in Modelica use an explicit mathematical representation waving out any ambiguity about the model, while enabling further seamless simulation with diverse tools [3].

Modelica is an object-oriented programming language where the parameters of a model are the object's attribute. This facilitates the development of power

system models composed by instances of components previously developed.

To the knowledge of the authors, there have been two previous efforts in the use of Modelica for power system modeling and simulation: the ObjectStab [15] library, and the SPOT [16] library which evolved into the commercial “Electric Power Library” by Modelon AB [17]. While these libraries could have been used for the purposes of this article, there are social aspects of resistance to change [18] that prompted the authors to develop a new library. For example, users of a specific power systems tool are skeptical about other tools different from the one that they use — this is a complex behavior [19] that involves both the change in the human interactions that accompany the use of a specific tool, as well as a concern about the technical aspects of a new technology.

To make a transition where the use of Modelica is accepted by power system practitioners, the authors and other colleagues have used different strategies to overcome the resistance of domain experts. This approach is similar to that in [20]: a first strategy is to promote the use of Modelica in power systems as a medium for unambiguous model exchange [3] which is an Alpha [20] strategy that supports the common goal of model exchange; a second strategy (type Omega [20]) was used to decrease avoidance forces: made a software-to-software validation of each power system component of *trusted* domain-specific power system tools where simulation results between the Modelica library in different tools are appraised against a domain-specific tool [21].

Further details on power system modeling using Modelica as approached in this article are available in [21, 3].

### 1.3 Exploiting Modelica and FMI Technologies

Modelica models can also be exploited through Functional Mockup Interface (FMI) [22]; a standard for model exchange between different tools supporting and implementing the standard. As such, Dymola [23], OpenModelica [24] and JModelica.org [25] implement the standard for both import and export; as well as co-simulation.

FMI Technologies offer wide possibilities for model re-use within different software tools. Thus, the models developed and used in Modelica are not tied to the development environment, contrarily to traditional tools for power system modeling. This flexibility

was taken advantage of to develop a Rapid Parameter Identification toolbox (RAPID).

## 1.4 Paper Organization

The remainder of this paper is organized as follows. The power system component library is described in Section 2. Details of two of the models developed by SmarTS Lab and their validation are shown in Section 3 and a model validation experiment using the RAPID toolbox is presented in Section 4. Conclusions are drawn in Section 5

## 2 Library Structure

The library was developed for power systems phasor time-domain simulation in Modelica. It is comprised by different packages that build its main structure, which is described next.

### 2.1 Structure

A total of 120 models are categorized into the following upper level packages (see Fig. 1):

- Connectors (2):  
The package is comprised by two connectors, one, PwPin, is adopted for treating voltage and current as complex variables. The other, ImPin is a simple connector for real variables.
- Electrical (56):  
The main package of the library with all the power system component models for phasor time domain representation. It is divided into several sub-packages.
- Examples (17):  
A set of examples using the power system component models.
- Interfaces (2):  
Blocks for adding some inputs and outputs to the models.
- NonElectrical (45):  
A set of functions extended from the Modelica standard library and adapted with the connectors of this power system components library.

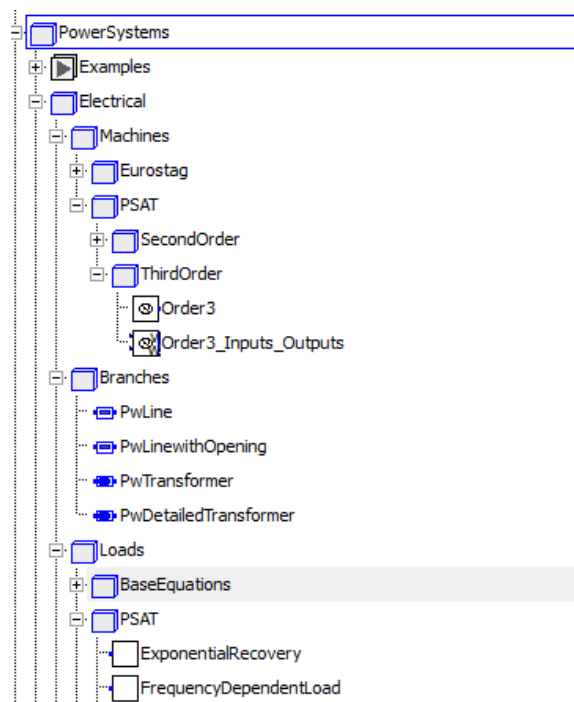

Figure 1. Partial screenshot of the library

## 2.2 Electrical Components

As a joint effort from the different project participants, the power system components models have mostly been transcribed from the *Eurostag* [8] and PSAT [26] software.

Different components such as transmission lines, transformers, buses and some events (line opening and faults) were developed as generic models. All load models, were implemented following the representation used by PSAT and *Eurostag*. Generator models have also been implemented, including detailed models as used in *Eurostag* as well as different models from PSAT. Additionally some non traditional generators have been modeled including photo-voltaic models (3) and two wind turbines models. These models enable the simulation of complete power system networks with any kind of perturbation.

The models developed at SmarTS Lab are the following:

- Load models from PSAT (Exponential recovery, Frequency dependent, Constant PQ, Voltage dependent, ZIP, ZIP Jimma and Mixed loads)
- An Automatic Voltage Regulator (AVR) from PSAT (Type III)
- A Turbine Governor (Type II) from PSAT
- Synchronous generators (second and third order) from PSAT

- Solar photo-voltaic panel (two simplified models from PSAT and detailed model from KTH)
- Doubly Fed Induction Generator (DFIG) wind turbine (PSAT model and GE model)

These models have been developed together with examples, which served for parameter identification experiments such as the one presented in Section 4.

## 3 Implementation and Validation of Power System Component Models

All models developed at SmarTS Lab have been created from a reference model taken in another domain specific simulation environment. They have been subject of a Software-to-Software validation against the reference model by comparing simulation results.

In this Section, two of the models developed at SmarTS Lab are presented in details together with their validation results.

### 3.1 GE Wind Turbine Model

This first study case illustrates the development of a wind turbine generator model taking as reference a MATLAB/SIMULINK implementation of the wind turbine-generator model for grid studies used by General Electric Energy (GE). The wind turbine-generator is Type III, which commonly refers to an induction generator with the rotor winding connected to the grid through a back-to-back converter. The descriptive reference provided by GE Energy can be found in [27].

#### 3.1.1 Modeling

The reference was implemented with function blocks in MATLAB/SIMULINK, organized in three different subsystems (Turbine, Electrical Control and Generator). The system was developed with the voltages (real and imaginary parts) as inputs and currents (real and imaginary parts) as outputs. The system also has an input for the wind speed.

For the Modelica model, the model structure and the block diagram were preserved. The main motivation for this approach was to maintain the existing initialization algorithm used in the reference model. This algorithm is responsible for initialization of, among others, all the integrators in the model.

The resulting model is shown in Fig. 2, where the top-level layer of the model can be observed. The major difference is the integration of the PwPin connector to interface the model to other components, such as

transmission lines. This connector contains two standard variables used for the real and imaginary part of the voltage, as well as two flow variables used for the real and imaginary part of the current.

The Modelica model also implements the initialization algorithm aforementioned. This implementation required to adapt the code to the Modelica syntax by replacing all for-loops by while-loops, as in Modelica for-loops cannot be exited before completion of all iterations.

Figure 2. Modelica implementation of the GE Wind Turbine-Generator Model

The original wind turbine reference model was integrated within a test system comprised by a network model, an infinite bus and a wind generator. The network model was built using an admittance matrix, which in the Modelica implementation was replaced by several transmission lines in series. The remainder of the model in Modelica was implemented with components available in the library. A wind generator was additionally developed in Modelica, to create different wind profiles. The resulting test model is presented in Fig. 3.

Figure 3. GE Wind Turbine Modelica Test Model

### 3.1.2 Validation results

Figure 3 presents the test model, which includes the simulation scenario comprised by a gust of wind at  $t = 5$  s and a fault at one transmission line at  $t = 10$  s.

Both models have the same simulation scenario and are simulated in their respective environment. However, the solver used is different in each environment, a fixed time-step solver ode3 was selected for the reference model, whereas an adaptive time-step solver DASSL was selected for the Modelica model.

A comparison between the simulation of the two models is presented in Fig. 4, where it can be observed that the simulations produce the same response. This validates the implementation carried out in Modelica.

Figure 4. Comparison Modelica vs Simulink for the GE Wind Turbine-Generator Model

However, some differences can be noticed when inspecting the responses more closely. Figure 5 presents an example of this observation. The differences are of a very small order and can be explained by the accuracy of the solvers used in each simulation environment.

Figure 5. Zoom on comparison Modelica vs Simulink for the GE Wind Turbine-Generator Model

## 3.2 Hydro Turbine Governors

The second study case illustrates the development of a hydro turbine and governor model. The reference

is a PSAT implementation of type 5 hydro turbine and governor (HTG Type 5) modeled at KTH and included into PSAT. The HTG Type 5 models includes a PI controller combined with servomotor (turbine governor model) and a nonlinear turbine model, its Modelica implementation is shown in Fig. 6.

The hydro turbine and its governor are widely used for control of mechanical power delivered by the generator, and often show complex dynamic behavior. Due to this fact, it is a perfect component to show the advantages of using the Modelica language instead of conventional power system modeling tools for simulation purposes. In this section two Software-to-Software validation cases are presented. The first shows the benefits of using Modelica with respect to PSAT. The second presents an alternative validation approach where the validation of the HTG Type 5 model is carried out in a hybrid SIMULINK-Modelica model exploiting the FMI standard which allows to include an FMU as a part of the original MATLAB/SIMULINK system.

### 3.2.1 Modeling

The reference model was implemented in MATLAB/SIMULINK using the built-in Control library for the HTG Type 5 and the SimPowerSystems (SPS) library for the single-machine-infinite bus (SMIB) system. A similar system (with a finite load) was modeled in PSAT and taken as a reference for Software-to-Software validation. Next, the Modelica model of the HTG Type 5 and the same system as in PSAT were built in Dymola (Fig. 7).

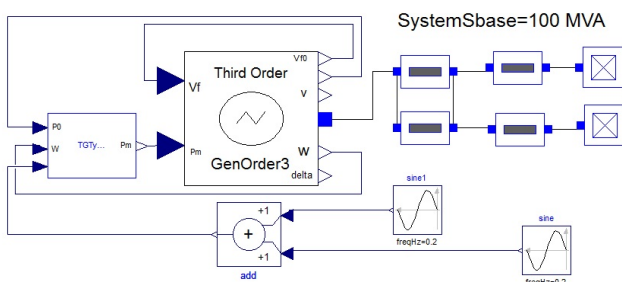

Figure 7. Modelica model of Single machine governed by HTG Type 5 with perturbation

In this the first case, the same initial values are used in Modelica and PSAT, this allows us to carry out the Software-to-Software validation not only in terms of the modeling approach, but also using the same initial conditions.

The types of connectors used in the Modelica model were described above. All the blocks which were

used for the HTG model can be found in the standard Modelica library. For building the hybrid SIMULINK-Modelica model, an FMU file was generated using Dymola to allow simulation in MATLAB/SIMULINK-SPS (Fig. 8). The model was encapsulated into one block, with ability to set up input parameters for the block (Fig. 9) using the FMI Toolbox [28].

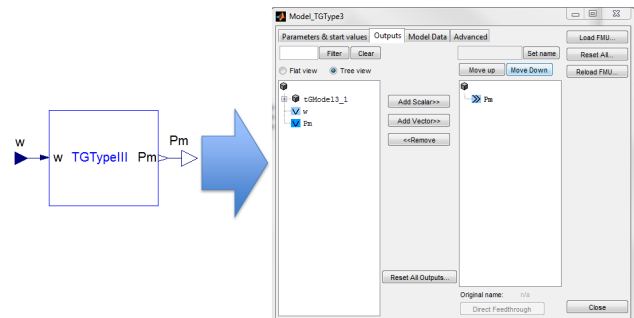

Figure 8. FMU from the Modelica model imported into the FMI Toolbox

Figure 9. Parameters of HTG Type 5 block

Thus, the HTG Modelica model was used to replace the turbine and governor SIMULINK block in the power system model. This allowed simultaneous simulation and comparison of the response between the SPS models and the Modelica models within the same simulation tool (Fig. 10).

### 3.2.2 Validation results

For validation of the hydro turbine and its governor the input (speed) and output (mechanical power) were compared (Fig.11). The results show that the “shape”

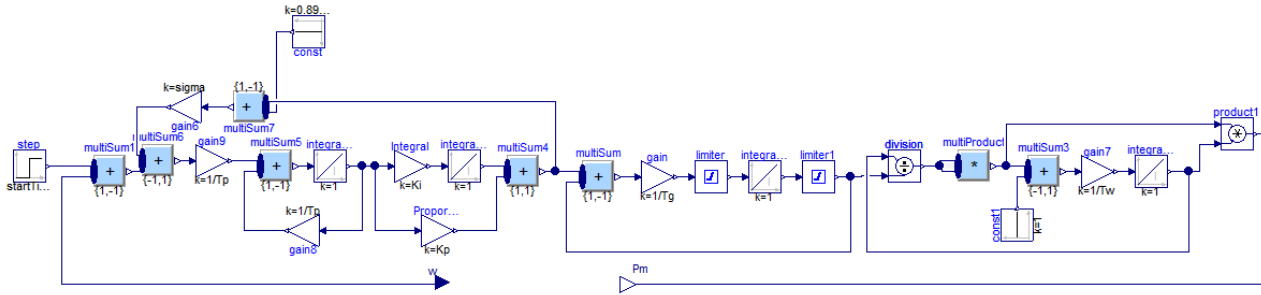

Figure 6. Modelica model of HTG Type 5

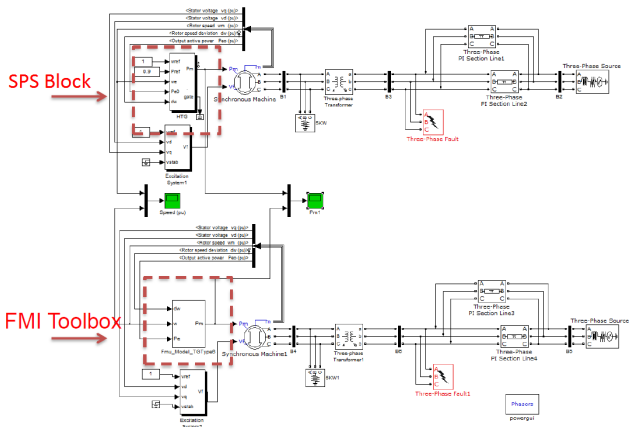

Figure 10. Validation of the HTG model encapsulated using the FMI Toolbox for MATLAB

of the signals match well, but there are some differences. The solver used for simulation with Dymola was DASSL. The differences are due to limitations on the numerical accuracy of the solver in PSAT (a trapezoidal integration with fixed time-step). Please observe that PSAT has a limited number of solvers (trapezoidal integration and forward Euler’s method) and that the time-domain simulation methodology follows domain-specific practices not common to general purpose tools.

In second validation method, which uses SIMULINK models with the Modelica model embedded in an FMU block and the MATLAB/SIMULINK-SPS reference model, the speed and the output mechanical power were compared (Fig. 12). The results show a very good match between the corresponding outputs.

### 4 Model Validation using Modelica and FMI Technologies

This power system component library has been developed within the FP7 *iTesla* project with the goal of using the models for power system model validation. The choice of Modelica as modeling language

(a) The input (speed) of the HTG Type 5

(b) The output (mechanical power) of the HTG Type 5

Figure 11. Comparison Modelica vs PSAT for the HTG Type 5’s responses with a perturbation at the speed reference  $w_{ref}$ .

Figure 12. Validation of the HTG model encapsulated using the FMI Toolbox for MATLAB

for this work was also motivated for its support of the FMI standard, which enabled the development of the RAPID toolbox.

#### 4.1 FMI Technologies

The Functional Mock-up Interface (FMI) standard was created as a tool independent format for model ex-

change and co-simulation. The full specifications of the standard, with a list of the supporting tools, are available in [22]. By opening the possibility of using a model in disparate simulation environments, the standard allows to benefit from functionalities offered by different programs.

As another part of the FP7 *iTesla* project, a parameter identification MATLAB toolbox was also developed. This toolbox was built with FMI technologies and uses the Modelica models presented above. The power system models used are test models including an device to be calibrated against some reference signals. An example of using the toolbox for calibrating the parameters of a generator model is presented next.

### 4.2 Example

This parameter identification example computes seven of the generator model parameters using reference measurement from the simulation of an EMT model (4 outputs: the voltage magnitude, the rotor speed, and the active and reactive powers). The reference model in this case was built in MATLAB/SIMULINK-SPS. The authors attempted to substitute the complex dynamics of the EMT generator model with a simplified third order generator model. The other components of the system were assumed to be known and modeled with the same components. For this experiment the FMI Toolbox from Modelon AB [28] has been exploited. The reasons for that are the following. First, MATLAB was chosen for the development of the RAPID toolbox. Second, the authors decided to use the Modelica language for power system modeling purposes [3]. The Modelica model with two different test scenarios was constructed (Fig. 13). In both test scenarios the reference signals are perturbed, the nominal torque value in the first and the field voltage in the second.

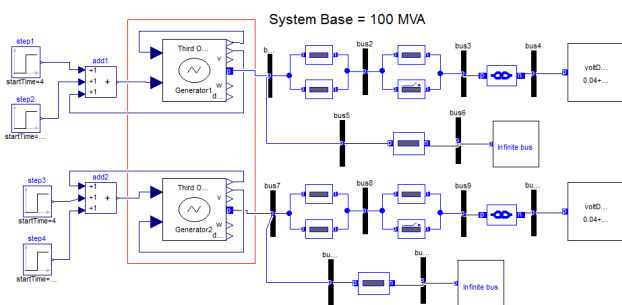

Figure 13. Modelica model used in the parameter identification process (component to be identified bounded in red)

The algorithm of the identification process is the following:

lowing:

1. Collect measurement data from the reference SIMULINK model.
2. Create the power system model to be identified in Modelica. The Modelica model requires a power flow solution, in this case the results of the power flow were obtained from PSAT.
3. Compile an FMU from the Modelica model in Dymola.
4. Create a SIMULINK model using the FMU block from the FMI Toolbox for MATLAB, see Fig. 14. The only blocks required in order to carry out the simulation are: *FMUme* and *To Workspace*. All data inputs and the scopes are included only to monitor the process interactively.
5. Start the RAPID Toolbox.
6. Provide RAPID with appropriate settings (algorithm, parameters, variables, etc.).

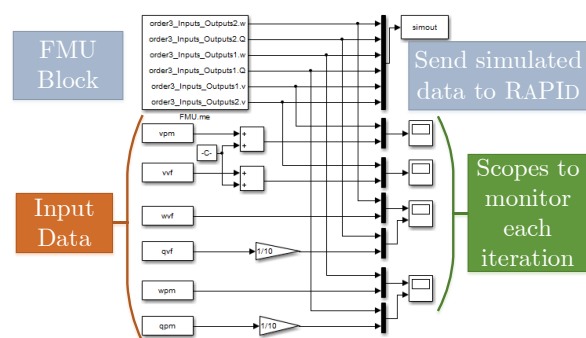

Figure 14. SIMULINK model used by RAPID with the FMU of the Modelica model

### 4.3 Results

The results of identification experience are presented in Fig. 15 and Table 1. The values of the identified parameters are shown in Table 1.

The numerical values for all the parameters were constrained before running the optimization algorithm to a valid range of real valued numbers, typical of synchronous machines. Thus, the resulting parameters are within practical and realistic values. Figure 15 shows the graphical comparison between the simulations in MATLAB/SIMULINK-SPS and Modelica. It

Table 1. Generator parameter estimation results

Parameter	Value
Armature resistance ( $R_a$ )	0.0010156
Direct axis reactance ( $X_d$ )	4.2924
Direct axis transient reactance ( $X'_d$ )	1.37
Direct axis transient time const. ( $T'_d$ )	2.6156
Quadrature axis reactance ( $X_q$ )	5.3994
Inertia coefficient ( $M$ )	14.9005
Damping ratio ( $D$ )	0.0088415

shows that the responses match with an acceptable error. The key here is to remember that a reference signal (from a high order model (MATLAB/SIMULINK-SPS)) is matched to a low-order model. The differences in reactive power (Fig. 15(a)) and in the voltage magnitude (Fig. 15(b)) are acceptable if one takes into account the difference in complexity of the mathematical presentation of high order dynamics by the simplified model. In order to validate the identification results, the simulations in both MATLAB/SIMULINK-SPS and Modelica were repeated using perturbations two-times larger than the original experiments used for identification. Similar results as those reported above were obtained.

## 5 Conclusion

This article introduced the work performed by SmarTS Lab and other collaborators within the FP7 *iTesla* project for developing a library in Modelica for power system component models. This library is already quite versatile as it enabled to carry out model calibration experiments within work package three of the FP7 *iTesla* project.

But the library is still not complete, additional models are being developed at KTH SmarTS Lab to continue populating it. To this aim, the method for developing and validating new models described in Section 3 is used. As such, the newly developed models can be integrated in the library after a successful Software-to-Software validation step.

The overall motivation for the development of such library in the Modelica language was briefly presented in Sections 1 and 4. The potential of model exchange across different tools is indeed of great importance. This is especially true for future power system tools [13], which will require more advanced simulation methods that the currently available in domain-specific tools. For example, unambiguous model exchange will allow for the development of model-driven

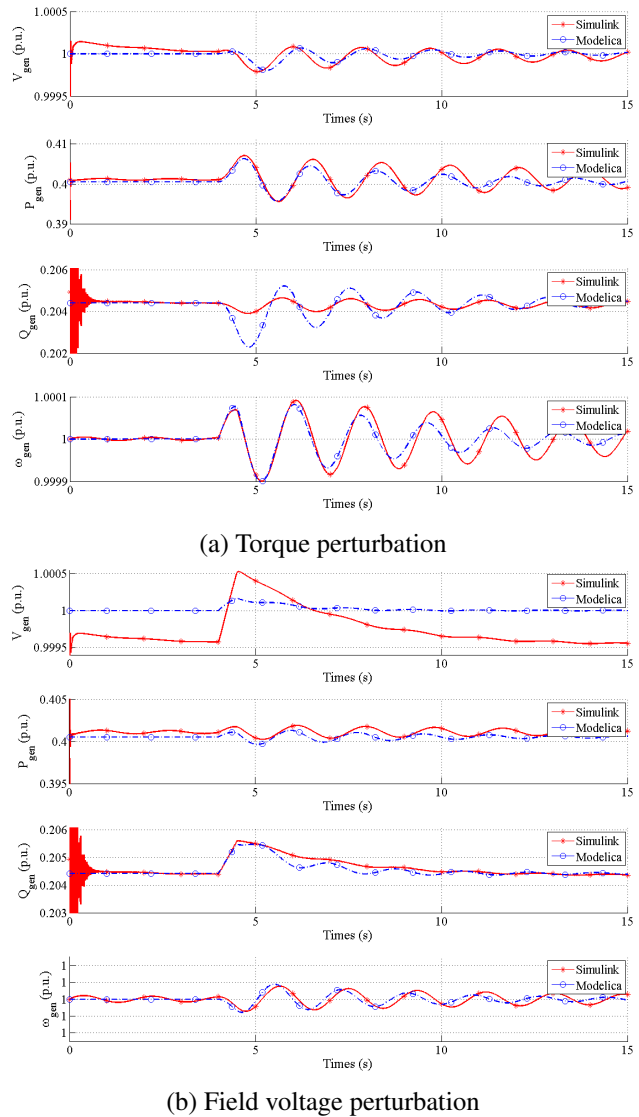

Figure 15. Comparison between the reference (Simulink) and the identified (Modelica) model responses with a perturbation at  $t = 4sec$ .

design of wide-area controls, which will require the use of a cyber-physical modeling language and appropriate solvers.

# Modelica Model for the youBot Manipulator

Rhama Dwiputra Alexey Zakharov Roustiam Chakirov Erwin Prassler  
Bonn-Rhein-Sieg University of Applied Sciences, Department of Computer Science  
Grantham-Allee 20, 53757 Sankt Augustin

## Abstract

This paper presents the development of Modelica model for the youBot manipulator. Whereas other robotic simulations focus on the robot interaction with its environment, Modelica allows the modeling of the manipulator controllers and motors. The model was developed with a Modelica library for the manipulator's components which provides modularity, reusability and abstraction. A comparison test with the actual system is performed to ensure the model accuracy. The test result shows promising result and provides possible future work. The Modelica model of the youBot manipulator is freely available.

*Keywords:* Control; Manipulator; Modelica; youBot

## 1 Introduction

Models and simulation tools are crucial in robotic research. Although there have been major improvements in the electronic and mechanical field, robots are still expensive equipments. The use of models and simulation tools overcome this problem. Models and simulation tools allow researchers and university students to experiment with different robots. Furthermore, experimentation with models is cost-efficient and time-efficient due to its ability to be automated, conditioned and accelerated.

The *youBot* is a mobile manipulator designed to serve as the reference platform for industry, research and education [1]. Due to its frequent use as a test subject for educational purpose or investigation of new methods in research institute, a model of the youBot is highly advantageous. Robotic simulation tools which has a model of the youBot are VREP [2], We-bots [3] and Gazebo [4]. Like most robotic simulation software, these software focus on simulating the robot interaction with its surrounding environment (navigation, object manipulation) and have its limitation when simulating the robot's internal components (mechanical, electrical, and control system).

Modeling the robot's internal component requires multi-domain capability such as provided by the Modelica<sup>1</sup> description language. Modelica is a non-proprietary, object-oriented, description language for multi domain modeling. Modelica is maintained by the non-profit Modelica association. As such, Modelica is suitable for use in education and research. The work in this paper is influenced by the existing manipulator model in the Modelica Standard Library or MSL [5].

The youBot standard configuration consists of an omnidirectional mobile platform and a five DOFs manipulator with a two finger gripper. In this paper, the manipulator model is developed by dividing the system into several smaller components. The component models are stored in a new Modelica library and categorized in different packages based on its functionality. This approach enables the user to experiment with the manipulator model on the component level.

A model is a representation of the actual system and the benefit of having a model only holds true when the model is accurate. Simulation can result in wrong conclusion when the researcher forget the limitations and condition under which the simulation is valid [6]. Therefore, the development of the manipulator model is followed by a test with the actual system. The test compares the behaviors of the actual system and the model throughout a point-to-point motion. The model accuracy along with the influence of estimated values and approximation is analyzed in the comparison test.

This paper is organized as follows. After this introductory section, Modelica related robotic research is presented in Section 2. Section 3 presents the specification of the youBot manipulator and Section 4 describes the Modelica Library for the youBot manipulator. Afterward, section 5 presents the evaluation of the developed model. Finally, section 6 summarizes the work and provides possible future work.

## 2 State of The Art

Modelica has been used for modeling spider robotic arm [7], 6-axis industrial robots [8, 9, 10], 3 DOFs parallel Gantry-Tau robot [11], 5 DOFs manipulator [12] and mobile platforms [13, 14]. In most cases, a robot model in Modelica is used for investigating the manipulator's motion control especially in the domain of optimization and system dynamics. Such research requires the repetition of motions and adjustments to the controller which can have damaging effect when being executed on a real robot.

[9] performed optimization through iteration to find a compromise between acceleration, velocity and energy consumption and [10] solved the minimum time optimization problem for an industrial robot. [8] derives the inverse dynamic model of a manipulator using algorithms for differential-algebraic equation available in the Dymola<sup>1</sup> software. Dymola was also used in [12] to design a picking manipulator for agriculture purposes. [11] develops method for kinematic calibration with the Modelica model of parallel Gantry-Tau robot. Aside in the field of motion control, Modelica robot models have also been used for tele-manipulation [7], robot communication [14] and teaching tools [13].

As shown from the work presented in this section, there is a wide range of research with robot models in Modelica. The Modelica model of the youBot manipulator will enable such research to be performed. Since the youBot is designed to be the reference platform for academic institute, a Modelica model of the youBot manipulator is of high importance.

## 3 The youBot Manipulator

The specification of the manipulator is acquired from the following sources:

- official youBot website<sup>2</sup>,
- email communication with the official distributor of the youBot<sup>3</sup> and
- discussion with researchers from BRICS<sup>4</sup> who were involved in the development of the youBot's software.

<sup>1</sup>[www.3ds.com/products-services/catia/portfolio/dymola](http://www.3ds.com/products-services/catia/portfolio/dymola)

<sup>2</sup><http://youbot-store.com/>

<sup>3</sup>[info@locomotec.com](mailto:info@locomotec.com)

<sup>4</sup><http://www.best-of-robotics.org/>

This section consist of two subsections, *kinematic chain* and *control system*. Due to the nature of the robot which is actively being developed, the description presented is subject to changes.

### 3.1 Kinematic chain

The youBot manipulator is a serial chain manipulator with five revolute joints (shown in Figure 1). The manipulator is equipped with a two-finger gripper as its end-effector and each finger weights 0.01 kg. The fingers' body, position and motion has insignificant influence to the system dynamic when compared to the overall manipulator system. Therefore, the gripper is modeled only for the visualization purpose.

Figure 1: The youBot manipulator

The manipulator is 65.5 cm high when fully extended, weights 6.3 kg and has a payload of 0.5 kg. Each joint is actuated by brushless DC motors and gearboxes with different specifications. The kinematic chain, joint ranges and dynamic properties of the manipulator are presented in appendix A.

### 3.2 Control System

The control system accommodates position, velocity and current control in each joint. For each joint, the control system consists of: 1. three cascaded *proportional-integral-derivative* or PID controllers, 2. a velocity ramp or v-ramp generator and 3. a space vector pulse width modulation (SVPWM). Two modes are available for joint position control, *PID* and *v-ramp* mode. The PID mode calculates the joint velocity in a PID controller whereas in the v-ramp mode, a trapezoidal velocity profile will be generated by the v-ramp generator for the joint velocity. In this paper, the developed model is based on the joint position control in PID mode. Figure 2 shows the overview of the manipulator's controller.

Figure 2: Controller overview

Where  $\theta$  is the joint angle,  $v$  is the joint velocity and  $i$  is the motor current. The *set* variables ( $\theta_{set}$ ,  $v_{set}$ ,  $i_{set}$ ) are the input values for the PID, the *actual* variables are the values from the manipulator's sensors and the *input* variables are the user defined values. When controlling the joint position, a user provides the  $\theta_{input}$  for the controller and the *Velocity PID* receive the output of the *Position PID* as its  $v_{set}$ . When controlling the joint velocity, a user provide the  $v_{input}$  for the controller which is directly forwarded as  $v_{set}$  to the *Velocity PID* (the output of the *Position PID* in such cases will be ignored). The *Position PID* is replaced with the v-ramp generator in v-ramp mode. The PID controllers for position, velocity and current have similar architecture. As a representative of the PID controllers, Figure 3 shows the overview of the PID controller for velocity (*Velocity PID*).

Figure 3: Velocity PID overview

Where  $e$  is the difference between the set value and the actual value.  $K_p$ ,  $K_i$ , and  $K_d$  are the gain parameters for the controllers. The output of the *Velocity PID* is forwarded to the *Current PID* as  $i_{set}$ . As observed in Figure 3, the *Velocity PID* controller is similar to the text book PID as follows:

$$C = K_p e(t) + K_i \int_{t-\Delta t}^t e(t) dt + K_d \frac{d}{dt} e(t) \quad (1)$$

Where  $C$  is the controller output and  $\Delta t$  is the PID period. However, the gain parameter in the velocity PID adjusts itself based on the motor velocity as follows:

$$k = \begin{cases} k_2 & \text{if } |v| \geq a \\ k_1 + \left(\frac{|v|}{a} * (k_2 - k_1)\right) & \text{if } |v| < a \end{cases} \quad (2)$$

Where  $k$  is the gain parameters ( $K_p$ ,  $K_i$  or  $K_d$  in Equation 1),  $k_1$  is the lower boundary of the gain parameter, and  $k_2$  is the upper boundary of the gain parameter value,  $v$  is the motor velocity and  $a$  is the threshold value for the motor velocity. The *Position PID* has the same characteristic as the *Velocity PID*. Therefore, the *Position PID* and the *Velocity PID* are referred as the non-linear PID. The non-linear PID enables the user to set different control behaviors for low and high velocity. Similar to the gain parameters, limiters in the position and velocity controller have non-linear characteristic where the limit value is defined by the motor velocity.

## 4 The youBot Modelica Library

The Modelica library for the youBot manipulator in this paper is developed with Dymola. The library is developed using a “divide and conquer” principle with emphasize on modularity, re-usability and abstraction. This approach enables components exchange and component-based experiment. Additionally, a template model is provided for components which are frequently used in the manipulator model. In such cases, the model has adjustable parameter sets to be configured based on its implementation. Finally, the manipulator model is developed in different abstraction layers (Figure 4). The lower layer provides a more detailed information in each component and the upper layer provides the general overview of the system.

Figure 4: Abstraction layer in a manipulator model

In every modeling process, using estimated values and approximation is unavoidable mainly due to the following reasons:

- *Limited knowledge.* Many parameter set of a dynamic system are estimated through system identification (friction, inertia tensor).
- *Restricted information.* Many manufactures do not provide complete information about their product.

The use of estimated values and approximation is presented in the description of each package. The youBot Modelica library consists of four packages which are:

- *Controller* package,
- *Axis* package,
- *Body* package and
- *System* package.

The library is developed with the use of several packages in MSL such as Modelica.Blocks.Math for standard mathematical functions and Modelica.Mechanics for 3-dimensional mechanical systems. This paper follows the Modelica convention in describing the models. Model's name or package's name begins with capital letter. When necessary, the model includes its package name. The model *Modelica.Blocks.Interfaces.RealInput* refers to the model *RealInput* which is inside the package *Interfaces*. The *Interfaces* package is inside the *Blocks* package and the *Blocks* package is inside the MSL. An instance of a model is written in lower case aside from a few exceptional cases (e.g. *V* is used for voltage to differentiate from *v* for velocity).

### 4.1 Controller Package

The *Controller* package consists of the components for the manipulator control system. The *Controller* package is divided into three packages which are the *Components* package, the *PIDs* package and the *Modes* package. The *Controller.Components* package consists of models which are in the lowest level of abstraction layer. Figure 5 show the models in the *Controller.Component* package.

(a) *Limiter2* (b) *Gain2* (c) *DisDer* (d) *P2V*

Figure 5: The *Controller.Component* models

Following the Modelica convention, the instance's name of a model is placed on the upper part of the symbols in blue color. The model *Limiter2* and *Gain2* (Figure 5b and 5a) perform the calculation for non-linear PID controller (Equation 2). The model *DisDer* (Figure 5c) produces the derivative value of a specific time period from a discretized continuous input. The model *P2V* (Figure 5d) converts PWM rate to voltage rate. The *P2V* model is an approximation of the SVPWM component in the controller.

The *Controller.PIDs* package consists of three different PID models which are the *Position*, *Velocity* and the *Current* model. As the name suggests, the models are the PID controllers for position, velocity and current in the youBot manipulator (Figure 2). As a representative, Figure 6 shows the *PIDs.Velocity* model.

Figure 6: *PIDs.Velocity*

Where  $v_{set}$ ,  $v_{actual}$  and  $i_{set}$  represent  $v_{set}$ ,  $v_{actual}$  and  $i_{set}$  in Figure 3 respectively. The additional component  $N$  in the model produces the output in mA to mimic the readings of the actual system.

Finally, the *Controller.Modes* package is for different types of control mode. Currently, the available model in the *Modes* package is the *Position* model. Figure 7 shows the *Modes.Position* model.

Figure 7: *Modes.Position*

The *Modes.Position* model consist of all three PID models from the *Controller.PIDs* package.  $V_{set}$  represent the voltage value which will be connected to the motor's power supply unit. Using the same approach, the model for other control mode explained in Section 3.2 can also be developed.

### 4.2 Axis Package

The *Axis* package consists of the model for joint actuator (motor and control system). The package is named *Axis* because the model will be connected to the rotating axis of the manipulator's joints. The *Axis* package consists of the *Position* model shown in Figure 8.

Figure 8: *Axis.Position*

Where *DCPM* represents the brushless DC motor model, *PSU* represents the power supply unit model, *R* represents the gearbox model, *F* represents the friction model, *controller* is the *Modes.Position* model (Figure 7), *sens\_v* represent the joint’s velocity sensor, *sens\_theta* represent the joint’s position sensor and *joint* is the connector to the manipulator’s joint model. The *controller* output (*V\_set* in Figure 7) is connected to *PSU* and its input is extended for the model input as *theta\_set*. The output of *sens\_v*, *sens\_theta* and the value of *DCPM*’s current is connected to the control system (*theta\_actual*, *v\_actual* and *i\_actual* in Figure 7). Aside from the controller, the component in *Modes.Position* are from MSL.

### 4.3 Body package

The *Body* package consists of models for the rigid body model of the manipulator’s kinematic chain. The *Body* package has three models which are *Gripper*, *Link* and *Manipulator*. The *Body.Gripper* model is the rigid body model of the youBot two finger gripper. Figure 9 shows the *Body.Gripper* model.

Figure 9: *Body.Gripper*

Where *RF\_rot* is the gripper’s reference frame rotation, *frame\_a* is the connector to the previous link model, and *gripper*, *left\_finger* and *right\_finger* are the rigid body model of the gripper body, left finger and right finger respectively. *marker* is a weightless body model to visualize the path of the manipulator’s end effector in simulation and *RF\_vis* provides the visualization of its reference frame.

The *Body.Link* model is the rigid body model of a manipulator link. Figure 10 shows the *Body.Link* model.

Figure 10: *Body.Link*

Where *joint* represent the link’s joint which is connected to the actuator model through the connector *motor*, *frame\_b* is the connector to the next link model and the *body* represent the rigid body of the link. *frame\_a*, *RF\_rot* and *RF\_vis* represent the same components as in *Body.Gripper* model.

The *Body.Manipulator* model represent the rigid body model of the youBot manipulator’s kinematic link. Figure 11 shows the *Body.Manipulator* model.

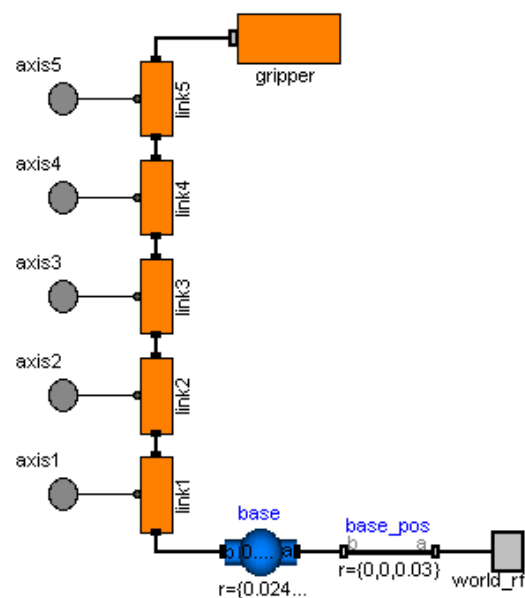

Figure 11: *Body.Manipulator*

Where *link1* represent the first link of the manipulator (*Body.Link*, Figure 10), *gripper* is the manipulator’s gripper model (*Body.Gripper*, Figure 9), *base* represent the rigid body of the manipulator’s base. The component *base\_pos* is for defining the manipulator position in the world reference frame. The *Body.Manipulator* model has five connectors (*axis1* to *axis5*) for each joint model and one connector (*world\_rf*) for the world reference frame.

### 4.4 System package

The *System* package consists of the manipulator ready-to-use models. The *System* package has two models which are the *Position* model and the *Dummy* model. The *System.Position* model is the rigid body model of youBot manipulator’s kinematic chain and its actuators. Figure 12 shows the *System.Position* model and its visualization in Dymola whereas Figure 13 shows the parameter set configuration for the velocity controller in the manipulator’s fifth joint.

(a) *System.Position*

(b) Model visualization

Figure 12: The youBot manipulator model

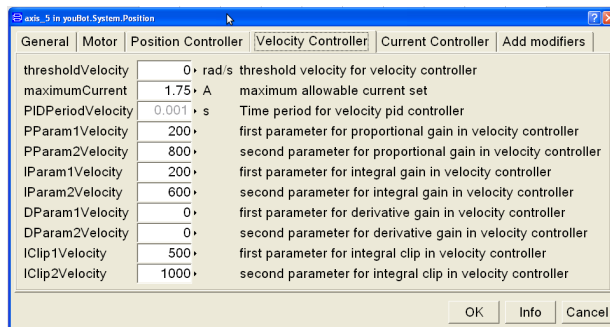

Figure 13: Parameters configuration

In Figure 12a, *KL* represents the rigid body model of the youBot manipulator’s kinematic chain, *theta\_5* represents the user defined joint angle and *axis\_5* represents the actuator (Figure 8) for joint 5. The parameter names in Figure 13 are consistent with the existing driver and firmware. The *System.Dummy* model is the rigid body model of the youBot manipulator (*Body.Manipulator*, Figure 11) connected to dummy actuators (*Modelica.Mechanics.Rotational.Speed*). The user can set the velocity of each joint directly in the *System.Dummy* model. The *System.Dummy* model is used for comparison test in Section 5.

## 5 Comparison Test

A comparison test with the actual system is performed after the development of the manipulator model. The test purpose is to evaluate the model accuracy and identify the major components which require further development. The test involves the comparison of the joint position and the joint velocity throughout a point-to-point motion. For the actual system, the joint velocity is recorded while performing the motion. The sensor measurement of the joint velocity is assumed to be accurate. Afterward, the recorded joint velocity is used as input for the *System.Dummy* model. In the same setting, the manipulator model (*System.Position*, Figure 12a) is also performing the same motion.

The manipulator’s joints in this test are set to be frictionless. The motion involves all joints moving 90°. Such motion was chosen so that the resulting error will be the accumulation of the estimated value and approximation in all joints. Figure 14a shows the end-effector paths during the motion (the gray-colored youBot manipulator is the starting pose of the motion.) whereas Figure 14b shows the error in joint position. As expected, the path generated by the model is smoother than that of the actual system as a result of the idealistic conditions in the simulation. The sum

Figure 14: Test result

of error from all joint peaked at the value of 0.55 radian. The error in each joint depends on the maximum velocity parameter ( $v_{max}$ ) in the controller. As shown in Figure 14b, joint 3 ( $v_{max} = 4.19 \text{ rad} \cdot \text{s}^{-1}$ ) has a considerably lower peak than joint 5 ( $v_{max} = 5.90 \text{ rad} \cdot \text{s}^{-1}$ ). The error in joint angle peaked at two points. Both peak points happened slightly after the velocity change (from stop to move and slowing down from a constant velocity). This is consistent with the error in joint velocity as shown in Figure 15.

The joint velocity in the actual system is less stable than in the simulation (Figure 15a). This is the result of the motor vibration which is excluded from the manipulator model. The ideal motor model results in the deviation on higher velocity (Figure 15b) which correspond to the higher error in joint position for joints with higher  $v_{max}$  value in its controller. Similar phenomena in joint velocity and joint position are also found in other joints. Other possible contributing aspects in the deviation between the model and the actual system are the inertia tensor estimation, gearbox elasticity/damping, SVPWM approximation and frictionless joints.

(b) Joint 5

Figure 15: Joint velocity comparison

## 6 Conclusion

In this paper, the development of Modelica model for the youBot manipulator is presented. The Modelica library for the manipulator components provides the user with modularity, reusability and abstraction. The model accuracy has been evaluated through a comparison test with the actual system. The test result shows that the model reflects the actual system within a reasonable deviation. Possible improvements for the developed Modelica library is the development of a more accurate motor model and a more comprehensive evaluation of the manipulator component (controller components, power consumption and dynamic properties of every rigid body model). The manipulator model is planned to be tested with other Modelica tools (OpenModelica, jModelica) and used for hardware-in-the-loop experiments. The development or design of other manipulator models is also possible through the reusability of the components model in the Modelica library. The library is publicly available<sup>1</sup> to be used for education or research involving manipulator dynamics, load identification, fault analysis and motion control.

## Abstract

In order to enhance the performance of modern computers, the current development is towards placing multiple cores on one chip instead of increasing the clock rates. To gain a speed-up from this architecture, software programs have to be partitioned into several independent parts. A common representation of these parts is called a task graph or data dependency graph. The authors of this article have developed a module for the OpenModelica Compiler (OMC), which creates, simplifies and schedules such task graphs. The tasks are created based on the BLT (block lower triangular)-structure, which is derived from the right hand side of the model equations. A noticeable speed-up for fluid models on modern six-core CPUs can be achieved.

*Keywords: modelica; openmodelica; parallelization; BLT, task graph*

## 1 Introduction

Modelica has become a widely used standard to describe physical simulation models. Compiling such a model into binary code can be performed by applications like Dymola, SimulationX or OpenModelica. However, all these tools only create a single thread simulation code out of standardized Modelica models, which does not allow for a speed-up with modern multi-core CPUs. This is due to the dependencies among the model equations which have to be considered in order to distribute the tasks amongst several threads.

The approaches to parallelize Modelica models can be divided into manual and automatic parallelization. Manual approaches comprise the *parModelica* language extension [1] or the TLM technique [2]. In this paper, manual parallelization shall not be pursued further as it is not suitable for parallelizing existing models. A lot of effort has been spent on automatic parallelization methods. Peter Aronsson [3] presented a method based on fine grained task graphs

which were derived from the expressions of the model equations. Later, this approach was adapted by other authors (see for example [4], [2] and [5]), to perform simulations on Cell- and GPU-Architectures. Handling fine grained task graphs is a complicated and time consuming topic. Therefore additional work was required to reduce the graph complexity, for example with the help of a graph rewriting system [3]. This paper follows the ideas of Casella [6] who suggested to build a task graph parallelization based on the BLT representation of a model. He then also showed that, in case of fluid applications, this approach will lead to task graphs which can be well parallelized. Therefore, this paper explores the implementation of the ideas of [6] into the OpenModelica compiler. To evaluate the efficiency of the implementation, the idea of the *Maximum Theoretical Speedup* is introduced. Afterwards, different scheduling algorithms are presented which are required to assign each task to a thread. It is followed by a number of benchmarks which compare the effectiveness of the different scheduling algorithms and reveal further properties of different domains with respect to parallelization.

## 2 Parallelization of model equations

The equations of a simulation model are typically described as a set of Differential Algebraic Equations (DAEs). Equation 1 shows the basic definition of such a DAE.

$$F(\mathbf{x}, \dot{\mathbf{x}}, \mathbf{v}, t) = 0 \quad (1)$$

The value  $t$  represents the time. The vector  $\mathbf{x}$  holds all variables of the system whose derivatives with respect to time appear inside the equations. The derivatives itself are stored in  $\dot{\mathbf{x}}$ . In addition,  $\mathbf{v}$  contains all other algebraic variables. By applying index reduction, (1) is converted into a DAE with index one or zero. The Underlying Ordinary Differential Equation (UODE) contains all equations and variables necessary to calculate the reduced state set  $\dot{\mathbf{y}} \subseteq \dot{\mathbf{x}}$  of the model (see equation

2) and other equations (see equation 3) [6].

$$\dot{\mathbf{y}} = \mathbf{f}(\mathbf{y}, t) \tag{2}$$

$$\mathbf{v} = \mathbf{g}(\mathbf{y}, t) \tag{3}$$

The equations and variables of the ODE system can be organized as an incidence matrix, with each matrix-row representing one equation and each column one variable [7]. If a variable is part of an equation, the matrix entry is filled with a value. A simple electric circuit, containing a power supply and two resistors as well as a capacitor, is displayed in figure 1. It can be described by the equations below. The rows and

$f_1 : v_s =$	<i>offset</i>
$f_2 : v_{R1} =$	$R_1 \cdot i_c$
$f_3 : P_{R1} =$	$v_{R1} \cdot i_c$
$f_4 : v_{R1} =$	$v_s - v_{R1n}$
$f_5 : i_c =$	$C \cdot \dot{v}_c$
$f_6 : v_{R2} =$	$R_2 \cdot i_c$
$f_7 : P_{R2} =$	$v_{R2} \cdot i_c$
$f_8 : v_{R2} =$	$v_{R1n} - v_c$

Figure 1: Simple model of an electrical circuit

columns of the incidence matrix can be arranged in a way that the matrix forms a block lower triangular matrix (BLT). Thus, the blocks of equations can be solved from the top to the bottom via forward substitution. First, the power supply voltage  $v_s$  is calculated from equation  $f_1$ . After that, the equations  $f_4, f_8, f_6$  and  $f_2$  of the circuit cannot be calculated as single equations, as they have two unknown variables. More precisely they are forming a circular dependency, because the variable  $u_{R1}$  is solved in equation  $f_2$ , which requires variable  $i_c$ , solved by equation  $f_6$ , for calculation. Furthermore, the calculation of  $f_6$  depends on the equation  $f_8$  which depends on equation  $f_4$ . And

Figure 2: A bipartite graph representing the circular dependency between the equations  $f_2, f_4, f_6$  and  $f_8$

finally the equation  $f_4$ , solving variable  $u_{R1n}$ , requires  $u_{R1}$ , still solved by  $f_2$ . This fact is shown in Figure 2. That is why they have to be handled in an equation system which combines all equations into one block (see figure 3, gray coloured box). As shown in the example, blocks can be very simple, containing just one single equation or they can be really complex, containing hundreds of equation stored in an equation system. In order to solve the system efficiently, the block size

Figure 3: BLT-Matrix of the example on the left, derived task graph on the right side

should be as small as possible. To find the smallest blocks of the system, Tarjan's algorithm [8] can be used. A complete algorithm to get the blocks from the DAE-System is presented in [6].

### 3 Task Graph representation

A task graph or data dependency graph is a widely used technique to describe the different parts of a program and their relationships among each other. The graph contains nodes representing the tasks and directed edges. If an edge goes from node  $n_1$  to  $n_2$ , the task  $n_1$  has to be executed before the task  $n_2$  can start.

Parallel branches of such a graph can be calculated in parallel, because there are no direct dependencies between them and thus they could be handled by different threads.

To get a task graph out of the BLT-structure, all blocks of the matrix are converted into a node of the graph. After that, the calculation dependencies between the blocks have to be inserted. An edge between the nodes of the blocks  $n_i$  and  $n_j$  is added to the graph, if the BLT-matrix has an entry at position  $(i, j)$ , with  $i > j$  and  $(i, j)$  representing the row and column index of the blockmatrix, respectively.

The task graph of the given example circuit is displayed in figure 3. The notation inside the nodes is  $\{equation\ index : variable\ index\}$ . For the given example, the last three tasks could be handled in parallel by three different threads. In order to evaluate the simulation speed, both execution and communication costs for the tasks and processors have to be known. The execution cost of a task is the number of cycles or the time span required to calculate it. Communication costs are the time to transfer all required variables from one thread to another. To measure these values, two benchmark programs were developed. To estimate the communication costs, a standalone benchmark has been created which copies different sized data arrays of 64 bit long floating point value from one thread to another. By analyzing the task equations, the number of variables, which are transferred by each edge in the task graph, can be obtained. Thus a communication cost estimate can be assigned to each edge. The execution costs are being measured with the help of the OpenModelica *measure time* functionality for a serial calculation run, which creates a xml-file containing execution times for each block. This approach has still some drawbacks. First, it cannot be exact, as it is not possible to predict the occurrence of cache misses or context switches between different processes. Second, one serial execution of the model is required, which may cause a severe overhead, before the estimates are available.

Execution costs are displayed on the bottom right corner of the nodes on a yellow background while communication costs are displayed near the edges, see Figure 3.

## 4 Graph simplification

Complex Modelica models may lead to complex task graphs with thousands of nodes and edges. Scheduling these graphs (see section 5) is a time consuming

process, which can, depending on the scheduling algorithm, scale superlinear with the number of nodes and edges. Therefore the authors have implemented two rules to simplify complex task graphs, based on the ideas of [3]. The first one is a simple rule to merge chains of nodes with a maximum of one successor and one predecessor into one, as there is no point in calculating these nodes by different threads. The rule is called "mergeSimpleNodes" and an example is displayed in figure 4. The second rule, which is more

Figure 4: Example of the "mergeSimpleNodes" rule. Node four and five are merged into one.

complex, is called "mergeParentNodes". It consolidates a node with its parents, if this leads to an decreasing execution time. See figure 5 for an example. If the nodes 11 and 13 are handled by different threads than task 12, the execution time increases compared to the serial execution. To prevent this, the nodes are merged into task 13'.

Figure 5: Example of the "mergeParentNodes" rule. Node 11, 12 and 13 are merged into one.

## 5 Task Graph Scheduling

Based on the derived task graph, the different tasks can be dispersed among different threads, which can later be distributed on different processors or processor-cores. This is called Scheduling. In the presented work the Scheduling is performed during compile time (static scheduling). If the mapping between tasks and threads is set during run time, it is called a dynamic scheduling.

In order to achieve a proper mapping, most of the static scheduling algorithms use the information about the execution and communication costs to load the threads evenly and with shortest idle time. Finding the ideal schedule is a NP-hard problem [9]. Thus, different heuristics are used which have been implemented into the OpenModelica compiler module. To analyse the scheduling of a task graph several evaluation parameters can be obtained. First, some basic definitions shall be given. The *serial time*  $t_S$  of a model is the sum of all execution costs of all tasks  $T$

$$t_S = \sum_{i \in T} t_i \quad (4)$$

The *minimum parallel time*  $t_{Pmin}$  is equal to the sum of the execution costs along the critical path, denoted as *crit'*

$$t_{Pmin} = \sum_{j \in \text{crit}'} t_j \quad (5)$$

This definition neglects all communication costs and corresponds to the case where all tasks of the critical path are assigned to the same thread. Further, it is assumed that all other tasks are handled in parallel by other threads not causing any delays. Clearly, this would require a sufficiently large number of computing cores. The *parallel time*  $t_P$  accounts for a limited number of computing cores and denotes the time required to calculate all tasks of a task graph given a schedule (assignment for each task to a thread or computing core) considering both execution as well as communication costs. The *Maximum Theoretical Speed-up*  $n_{max}$  can be obtained by dividing the serial time by the minimum parallel time

$$n_{max} = \frac{t_S}{t_{Pmin}} \quad (6)$$

assuming that an infinite number of computing cores is available. The *Theoretical Speed-up*  $n_t$  provides the expected speed-up for a given schedule. It is defined as the serial time divided by the parallel time

$$n_t = \frac{t_S}{t_P} \quad (7)$$

This quantity shall be used to compare different scheduling algorithms and to evaluate the implementation of the parallel code. In the following, different scheduling algorithms which will be compared are presented.

### 5.1 Level Scheduling

The simplest implemented scheduling algorithm is the level scheduling, which divides the graph into several layers. All tasks of one layer have just dependencies to tasks of previous layers. Thus, no direct dependencies between tasks of the same layer are allowed. The tasks of each layer are calculated in parallel until the algorithm proceeds with the next layer. Figure 6 shows a small graph example. Each layer is implemented as one OpenMP-Sections-Region and each task is handled in one OpenMP-Section. An example is displayed in listing 1.

Listing 1: Level scheduling code for graph in figure 6

```
static void solveODE(data) {
  //Level 1
  #pragma omp parallel sections {
    #pragma omp section {
      eqFunction_12(data);
    }
    #pragma omp section {
      eqFunction_11(data);
    }
    #pragma omp section {
      eqFunction_4(data);
    }
  }
  //Level 2
  #pragma omp parallel sections {
    #pragma omp section {
      eqFunction_13(data);
    }
    #pragam omp section {
      eqFunction_5(data);
    }
  }
  //Level 3
  #pragma omp parallel sections {
    #pragma omp section {
      eqFunction_14(data);
    }
  }
}
```

Therefore, OpenMP takes care of the concrete mapping between tasks and processors. This approach is following the ideas of a breadth-first-scheduling [10]. An eminent advantage of this scheduling method is that no information about execution and communication costs is needed. The scheduling is only based on the task dependencies. Thus, this algorithm is not fully static, but a hybrid of static and dynamic scheduling.

### 5.2 List Scheduling

The authors have also implemented a simple list scheduling algorithm [11], which can handle the tasks from root-nodes to leaf-nodes or vice versa. The list scheduling algorithm performs in the following way.

Figure 6: Example of level scheduling.

The root-nodes of the task graph are collected in a so-called 'ready list'. These tasks are distributed to all available threads. Before the first task assignment, every thread has a ready time of zero which means it is considered to be idle. If a task is assigned to an idle thread, the execution costs of the task will be added to its ready-time. The assignment of tasks enables the scheduling of their successor nodes which will be appended to the ready-list. The tasks from the ready list will be distributed successively to the thread with the earliest ready time. If the predecessor of an assignable task is scheduled to the same thread, the communication costs between these tasks are not taken into account. Otherwise, they have to be added to the ready time of the thread. The algorithm terminates when the ready list is empty.

### 5.3 Modified Critical Path Scheduling

Static scheduling algorithms are reviewed thoroughly. There is a multiplicity of approved scheduling heuristics and each performance depends on the structure of the graph, the dispersal of the costs etc. As an exemplary method, the 'Modified Critical-Path Scheduler' (MCP) by Wu and Gajski [12] has been implemented since this one is well-established as a reference heuristic[13]. The MCP distributes the tasks successively like the list scheduling to the thread that allows its earliest execution. The prioritisation of the assignable tasks is based on their ALAP-binding. The ALAP-binding stands for the as-late-as-possible start time and is computed as the longest path from the task to the finishing time of the last executed task.

### 5.4 External Scheduling

In order to understand and test the effect of different schedulings, the authors implemented a manual graph scheduler. The tasks can be assigned to the threads by hand on a graphical interface. For instance, the graph can be divided into vertical stripes, each handled by one thread like performed by libraries like metis [14].

### 5.5 Deadlock Detection

To check if a schedule is free of deadlocks, a transformation into a state / transition - petri net was developed. Every task of the graph is transformed into two states and one transition and every edge to one transition. An example for such a transformation is given in figure 7, where the task graph is shown on top and the petri net on bottom. The tasks of each thread are displayed one below the other. This kind of view gives more detailed information about the required locks between the different threads. If the final states of all threads are connected to a transition that is connected to the first states (not displayed in the figure), a petri net tool can check if the graph is free of deadlocks.

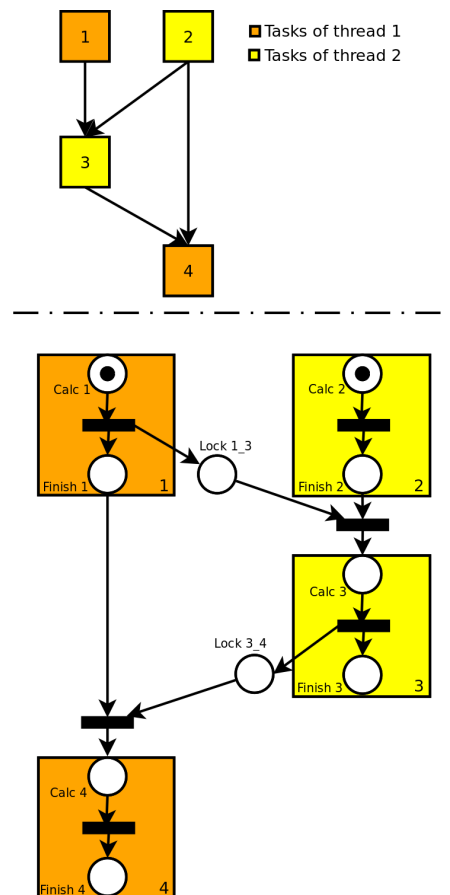

Figure 7: Example of state / transition net transformation

## 6 Benchmarks

To compare the different scheduling algorithms with the serial code, the simulation time of various models was measured. Three representative models from the domains Mechanics, Fluid and Electrics were selected out of the modelica standard library "MSL32". The first one is the engine V6 mechanic model. The second is the branching dynamic pipes example of the fluid domain. And the last model is the electrical cauer low pass sc model.

The test system was a computer with an Intel Core i7-3930K with six cores @ 3.20GHz and 32 gigabyte RAM running Windows 7 professional. All models were simulated from 0s to 1s using the dassl-solver.

In order to evaluate if it is possible to achieve shorter simulation times, the theoretical maximum speed-ups are displayed in table 1 for the three models.

The generated code of all scheduling algorithms, except the level-scheduling, is realized with pThreads using spin locks. Level-scheduling is based on an OpenMP implementation, as described in the previous section. Unfortunately, the results of level-scheduling were considerably slower than the other algorithms. Hence they were omitted from the diagrams for the sake of clarity.

Table 1: *Maximum Theoretical Speed-up  $n_{max}$*

Modell	$n_{max}$
Engine V6	1.11
BranchingDynamicPipes	13.09
CauerLowPass	5.97

For the mechanical model it is not possible to achieve a speed-up at the moment. This is due to the graph's structure. Every multibody system requires the solution of the following linear system [15]

$$\mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} = \mathbf{h}(\mathbf{q},\dot{\mathbf{q}}) + \mathbf{f}^a + \mathbf{G}^T(\mathbf{q})\mathbf{f}^c \quad (8)$$

$$\mathbf{0} = \mathbf{g}(\mathbf{q}) \quad (9)$$

The mass matrix  $\mathbf{M}$  is in general densely populated. Its number of rows and columns is equal to the degrees of freedom of all the *tree-joints*, see [15]. The authors have noted that a large portion of the calculation time is spent on solving this linear system which corresponds to a single node in the task graph. In case of the EngineV6 model this can be up to 95% of the entire execution time. To take advantage of the BLT approach for such a model, one would have to either find a way to split up this task into smaller ones or to solve the task itself in parallel. This will be a topic of

further research. For the fluid and electrical models, a speed-up is theoretically possible.

The benchmark results are displayed in the figures 8, 9 and 10. As already assumed, no speed-up with the mechanic model was found. The results of the fluid

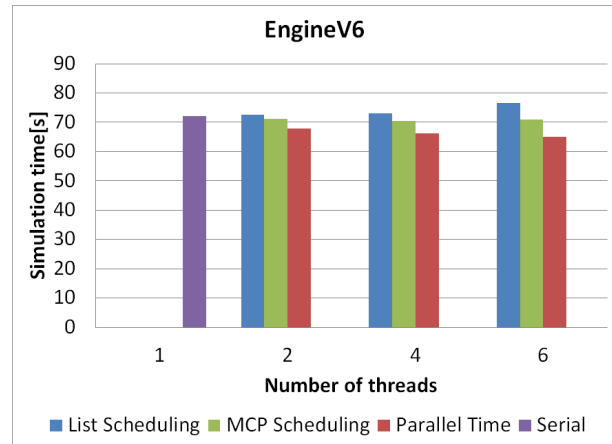

Figure 8: Benchmark of the engineV6 example

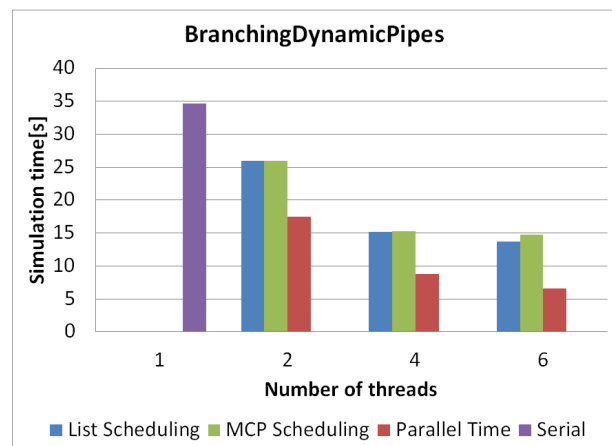

Figure 9: Benchmark of the dynamic pipes example

benchmarks indicates significant enhancement. The simulation showed a large step size, resulting in a lower number of calculations of the ODE functions. Carrying out such an ODE calculation takes a long time compared to the other examples. Moreover, the task graph has a lot of tasks which can be calculated in parallel. The trend of the Parallel Time indicates further potential. Additional research is needed in order to close the gap between predicted and measured speed-up. The low pass example shows currently no significant speed-up for the BLT parallelization, although the task graph has a lot of tasks in parallel, as can be seen in the behaviour of the Parallel Time. The issue appears to be the short execution time of the entire ODE system. The calculation of this sys-

Figure 10: Benchmark of the cauer low pass example

tem is about 30 times faster than the calculation of the branching dynamic pipes ODE system. The overhead of the parallel code seems to be too big to cope with such short calculation cycles. At the beginning of the presented work, the parallel code was solely implemented with OpenMP. In consequence of the bad measurements of the cauer low pass example, the OpenMP code was exchanged with pThreads code using spin locks. The execution time of the parallel code could be halved for the cauer low pass, but is still too large to achieve a significant speed-up for the model.

## 7 Conclusion

The implementation has shown that the BLT parallelization approach is able to reduce the simulation time for some models, especially if they are part of the fluid domain. To achieve speed-ups for various models, further research is required, especially to reduce the overhead of the parallel code and to handle one big task using multiple cores. The problem with the big tasks can be solved by applying parallel solvers or by splitting up the complex task into simpler ones.

Furthermore, some memory analysis needs to be performed to reduce the number of cache misses and invalidations between the threads. At the moment, the variables are stored regarding their types (real, int or boolean) in different arrays. To get some improvements, the variables have to be organized regarding their task affinity.

All in all the presented BLT approach looks promising for a parallelization speed-up on ordinary shared memory systems.

## Abstract

This paper deals with the implementation of a general methodology for modeling two-dimensional fluid flows in Modelica applying the Cascaded Digital Lattice Boltzmann Method. This approach models fluid flow as collective dynamics of fictitious particles on the nodes of a regular lattice. The various elements needed for simulation are described in Modelica and generic test cases are set up. The method is able to deal with simple scenarios where the powerful capabilities of advanced CFD tools are not needed.

## 1 Introduction

Calculating the dynamics of fluid flows is an important topic in the field of simulation. Common practice is to simulate complex scenarios by utilizing Computational Fluid Dynamics (CFD). Despite its capability of representing fluid flows in a very detailed way it has the drawback of compatibility. Coupling with other physical domain simulations is only possible by co-simulation. In this contribution a general methodology for modeling two-dimensional fluid flows in Modelica is shown. Whereas in [1] the Navier-Stokes equations are solved by a finite volume method, this work deals with modeling them with a Lattice Boltzmann Method (LBM).

## 2 Theory

The Lattice Boltzmann method is a relatively new simulation technique for fluid systems that has attracted interest as alternative to the discretization of

Figure 1: Lattice Boltzmann D2Q9 grid element

the Navier-Stokes equations. Instead of discretizing the Navier-Stokes equations to solve the conservation equations of macroscopic quantities (i.e., mass, momentum, and energy), LBM is a mesoscopic approach for modeling macroscopic fluid dynamics based on the Boltzmann kinetic equation which describes the statistical behavior of a non-equilibrium thermodynamic system. In the LBM, the fluid motion is based on the collective dynamics of fictitious particles on the nodes of a regular lattice. The dynamics of these particles is designed to obey the basic conservation laws ensuring hydrodynamic behavior in the continuum limit. The basic quantity is the particle distribution function  $f_i(\vec{x}, t)$  that represents the probability of finding a fluid particle density  $i$  at a location  $\vec{x}$  and at a time  $t$  traveling with a discrete speed  $\vec{c}_i$ .

The mass density  $\rho$  and the momentum density  $\rho\vec{v}$  are given by:

$$\rho(\vec{x}, t) = \sum_{i=0}^n f_i(\vec{x}, t) \quad (1)$$

$$\rho(\vec{x}, t) \vec{v}(\vec{x}, t) = \sum_{i=0}^n f_i(\vec{x}, t) \vec{c}_i \quad (2)$$

The motion of the particles is restricted to the node positions of a regular lattice. In 2D, commonly a 9-speed, quadratic lattice (D2Q9) with mesh spacing  $\Delta x$  is applied, where the discrete velocities  $\vec{c}_i$  connect lattice nodes to first and second neighbors and which has a rest particle  $f_0$ , see Figure 1. Here,  $c_x = [0, 1, 0, -1, 0, 1, -1, -1, 1]^T$  and  $c_y = [0, 0, 1, 0, -1, 1, 1, -1, -1]^T$ .

The spatial and temporal evolution of the particle distribution function is described by an explicit discretization of the Boltzmann equation, given by the following equation:

$$f_i(\vec{x} + \vec{c}_i \Delta t, t + \Delta t) = f_i(\vec{x}, t) - \omega (f_i(\vec{x}, t) - f_i^{eq}(\vec{x}, t)) \quad (3)$$

There, the left-hand side represents the molecular free streaming from one lattice node to the other, whereas the right-hand side represents the molecular collisions via a single-time relaxation towards local equilibrium  $f_i^{eq}$  on a typical timescale  $\tau = 1/\omega$ .  $\tau$  is related to the macroscopic kinematic viscosity  $\nu = c_s^2 \Delta t (\tau - 1/2)$ , where  $c_s = 1/\sqrt{3}$  is the speed of sound. Commonly  $\Delta t^{(LB)} = 1$  in lattice units, thus rendering the grid spacing  $\Delta x^{(LB)} = 1$ . Results in physical units can be obtained by applying the scaling  $u^{(phys)} = u^{(LB)} \sqrt{3} c_s^{(phys)}$ .

The local equilibrium is typically a second-order expansion in the fluid velocity of a local Maxwell distribution,

$$f_i^{eq} = w_i \left[ \rho + 3\vec{c}_i \cdot \vec{v} - \frac{3}{2} \vec{v}^2 + \frac{9}{2} (\vec{c}_i \cdot \vec{v})^2 \right], \quad (4)$$

where  $w_i$  is a set of weights normalized to unity. The single-relaxation-time (SRT) LBM, (3), recovers the weakly-compressible, athermal Navier-Stokes equations at low Mach numbers ( $Ma < 0.3$ ) with second order accuracy in space and time.

Nevertheless, the SRT-LBM method shows instabilities when the viscosity is reduced to small values, in order to reach high Reynolds numbers at low Mach numbers. To enhance the stability, the multiple-relaxation-times (MRT) collision operator was proposed by [2, 3]. Instead of relaxing the particle distribution functions themselves towards equilibrium, as in the SRT-LBM, in the MRT-LBM, they are transformed from velocity space into the corresponding moment space, where the moments are relaxed towards their equilibrium values. The moment space of the D2Q9 model has nine velocity moments. The conserved moments are the density (1) and the flow momentum

(2), the non-conserved moments include the energy, the stress tensor components, the energy square and the energy fluxes, for which different relaxation time scales are specified in order to decouple physical from higher order moments, thus improving the numerical stability. The post collision particle distributions  $f_i^{new}$  of the MRT-LBM are then given by the following expression:

$$f_i^{new} = f_i + M^{-1} S (m_i - m_i^{eq}), \quad (5)$$

where  $M$  is the orthogonal transformation matrix,  $m_i = M f_i$  are the moments of the system and  $S$  is a diagonal matrix of the relaxation rates.

A specific MRT variant, adopted in this work, is the Cascaded-Digital-Lattice-Boltzmann (CDLB) algorithm [4], that allows virtually any viscosity value without loss of stability within the low Mach number limit. It adopts central moments in the reference frame moving with the macroscopic velocity and a generalized local equilibrium which is a function of both conserved and non-conserved hydrodynamic moments. The post collision distributions  $\vec{f}^{new}$  of the CDLB are given by

$$\vec{f}^{new} = \vec{f}^{old} + K \cdot \vec{k} \quad (6)$$

where  $\vec{k}$  is the CDLB collision term and  $K$  is the orthogonal transformation matrix, that maps the moments into velocity space.

$$K = \begin{bmatrix} 1 & 0 & 0 & -4 & 0 & 0 & 0 & 0 & 4 \\ 1 & 1 & 0 & -1 & 1 & 0 & 0 & 2 & -2 \\ 1 & 0 & 1 & -1 & -1 & 0 & 2 & 0 & -2 \\ 1 & -1 & 0 & -1 & 1 & 0 & 0 & -2 & -2 \\ 1 & 0 & -1 & -1 & -1 & 0 & -2 & 0 & -2 \\ 1 & 1 & 1 & 2 & 0 & -1 & -1 & -1 & 1 \\ 1 & -1 & 1 & 2 & 0 & 1 & -1 & 1 & 1 \\ 1 & -1 & -1 & 2 & 0 & -1 & 1 & 1 & 1 \\ 1 & 1 & -1 & 2 & 0 & 1 & 1 & -1 & 1 \end{bmatrix} \quad (7)$$

As the collision term of the CDLB is rather complex, we refer to the original paper [4].

Using vector notation

$$K = [\vec{K}_0, \dots, \vec{K}_8], \quad (8)$$

$$\vec{f} = \begin{pmatrix} f_0 \\ \vdots \\ f_8 \end{pmatrix}, \quad (9)$$

the conserved moments are expressed as

$$\begin{aligned}
 \rho &= \vec{f} \cdot \vec{K}_0, \\
 \rho v_x &= \vec{f} \cdot \vec{K}_1, \\
 \rho v_y &= \vec{f} \cdot \vec{K}_2.
 \end{aligned}
 \tag{10}$$

### 3 Implementation

Lattice Boltzmann collision equations are usually written in terms of post-collision distributions  $f_i^c$ , i.e.,  $f_i(\vec{x} + \vec{c}_i, t + 1) = f_i^c(\vec{x}, t)$ .

In this contribution a formulation where the pre-collision distribution is described in terms of the post-collision distribution at the respective neighbor node, i.e.,  $f_i(\vec{x}, t) = \mathbf{pre}(f_i(\vec{x}, t)) \equiv f_i^c(\vec{x} - \vec{c}_i, t - 1)$  is used. The operator **pre** of Modelica makes this formulation convenient [5].

#### 3.1 Node element

All elements extend from a basic node element, the partial node model `PrtlNode_D2Q9`. There, all parameters and variables like the transformation matrix, weighting parameters etc. are defined. Furthermore the internal particle distribution variables are defined and initialization values are calculated. Collision and streaming of particles is based on an equidistant time step which is realized by a clock signal

```
clock := sample(dt, dt);
```

where `dt` is the width of one time step, taken equal to one (in lattice units). The  $f_i$  are time discrete quantities changing their values only at event instants which are triggered by the clock signal.

Each grid element has a rest particle and eight particles that are streamed to the first (horizontal and vertical) and second (diagonal) neighbors of the element. To link the elements, two kinds of connectors are implemented, a forward connector `f_fwd` and a backward connector `f_bwd`. Each consists of a Real input variable and a Real output variable to match its counterpart.

```
connector f_fwd
  input Real f_n;
  output Real f_p;
end f_fwd;
```

```
connector f_bwd
  output Real f_n;
  input Real f_p;
end f_bwd;
```

Figure 2: Schematic grid of four D2Q9 node elements including connections

Connectors are placed on the element models facing in all eight streaming directions. Connectors 2, 3, 6 and 7 are facing forwards and connectors 4, 5, 8 and 9 are facing backwards.

Various kinds of node elements extend from this partial model. They are explained in more detail in section 4.

#### 3.2 Collision and streaming step

At every time step and at each grid element, the particle distributions are received, collided and propagated. The receiving and propagating step are generally known as streaming.

In a conventionally implemented LBM, streaming affects only ports of the same direction. This means, a particle distribution with velocity  $\vec{c}_2$  exits port 2 and enters port 2 of the adjacent element. In Modelica, due to the connector concept, the case is slightly different. Port 2 of a grid element is connected to port 4 of the adjacent element, port 4 is connected to port 2 of the next element, and so on. To establish a correct streaming behavior the input, which holds the post-collision value at the last time step, must be mapped to the respective output, e.g., port 4 has to be mapped to port 2, port 2 has to be mapped to port 4. Then the particle distributions are collided. Then the post-collision values are written into the output variable of the respective connector. Propagation to the neighboring grid elements is done automatically by the connector, no additional commands are needed.

```

when clock then
  // mapping
  fold[1] := pre(f1);
  fold[2] := pre(f4.f_p);
  fold[3] := pre(f5.f_p);
  fold[4] := pre(f2.f_n);
  ...

  // collision
  fnew := ... fold;

  // output
  f1 := fnew[1];
  f2.f_p := fnew[2];
  f3.f_p := fnew[3];
  f4.f_n := fnew[4];
  ...
end when;

```

### 3.3 Mesh and connections – setting up the computational domain

In the example model, the 2D-flow model has to be described and the computational domain set up. Each model consists of sources, fluid nodes and boundary conditions. Two ways are possible to build up the model. The first is to build the model by dragging and dropping elements to the workspace and drawing connections by hand. Because the number of elements may be quite high and every element needs eight connects to its neighbours, the effort to set the model up like this is quite high. A more convenient method is proposed here. Providing the matrix `nodeType` that represents the LB discretized computational domain, all connections are generated automatically via nested loops.

The matrix can easily be set up in e.g. Microsoft Excel and then imported to the simulation example. A simple example of a two-dimensional duct model is shown below.

```

parameter Integer nodeType[:, :] =
  {{2, 2, 2, 2, 2, 2, 2, 2},
   {3, 1, 1, 1, 1, 1, 1, 4},
   {3, 1, 1, 1, 1, 1, 1, 4},
   {3, 1, 1, 1, 1, 1, 1, 4},
   {3, 1, 1, 1, 1, 1, 1, 4},
   {3, 1, 1, 1, 1, 1, 1, 4},
   {2, 2, 2, 2, 2, 2, 2, 2}};
...
CDLB.D2Q9 node[:, :] (nodeType=nodeType, ...);

```

The parameter `nodeType` is then propagated to the element `CDLB.D2Q9` which acts as generalized element representing all node types in conditional definition.

```

model D2Q9
  ...
  CDLB.FluidNode   fn if nodeType == 1;

```

```

CDLB.BounceBackNode bn if nodeType == 2;
CDLB.VelocityNode   vn if nodeType == 3;
CDLB.DensityNode    dn if nodeType == 4;
...
end model;

```

The user only has to define the matrix, all connections are established automatically. They are defined in multiple loops to interconnect every element with its eight neighbors. As example, the connections for connector 4 are outlined here:

```

// connect row 2:end and col 2:end
for i in 2:1:nrow loop
  for j in 2:1:ncol loop
    connect (node[i, j].f4, node[i, j-1].f2);
  end for;
end for;

// connect row 1 and col 2:end
for j in 2:1:ncol loop
  connect (node[1, j].f4, node[1, j-1].f2);
end for;

// connect col 1 to col end
for i in 1:1:nrow loop
  connect (node[i, 1].f4, node[i, end].f2);
end for;

```

These equations are repeated for all other connectors and are omitted here for sake of brevity.

## 4 Elements

### 4.1 FluidElement

The fluid element implements the collision, (6). To speedup symbolic pre-processing and compilation time, this is encapsulated in a function. To avoid reflections at the in- and outflow boundaries, sponge zones are implemented. There the relaxation factor  $\tau$  is gradually increased to 1, thus driving the fluid towards its equilibrium state at the boundary.

### 4.2 BoundaryElement

To implement a solid, non-slip boundary condition a local bounce-back rule is applied on the solid node  $\vec{x}_s$ :

$$f_{i'}^c(\vec{x}_s, t) = f_i(\vec{x}_s, t) \quad (11)$$

where  $i'$  denotes the link with reversed velocity of  $i$ , i.e.,  $\vec{c}_{i'} = -\vec{c}_i$ , pointing into the fluid. Incoming distributions functions at a wall node are reflected back to the original fluid nodes, with the direction rotated by  $\pi$ . The “bounce-back on the node” is purely local, thus being implementable in the current concept, but it has

been proven to be only first-order accurate in time and space.

Shifting the solid wall half-way between the two nodes, leads to the “bounce-back on the link” which is of second order accuracy:

$$f_i'(\vec{x}_l, t+1) = f_i^c(\vec{x}_l, t) \quad (12)$$

where  $\vec{x}_l$  is a fluid node next to the solid boundary and  $f_i^c$  is the post-collision value before propagation. Unfortunately it is not implementable in the current context, as each node element in Modelica cannot access its neighbors.

### 4.3 DirichletElement

Dirichlet boundary conditions can be set up based on the idea of bounce-back of the non-equilibrium part, as proposed in [6]. As an example, at a flow boundary having a normal vector into the fluid in positive  $x$ -direction, i.e.,  $f_2, f_6, f_9$  pointing into the fluid, these distribution functions are unknown after streaming. Equations (1) and (2) can be used to reconstruct the unknown distributions.

At a velocity boundary node, after streaming  $f_1, f_3, f_4, f_5, f_7, f_8$  are known and  $v_x, v_y$  are specified.  $f_2, f_6, f_9$  and  $\rho$  need to be determined. Equations (1) and (2) yield three equations. In order to close the system, it is assumed that it is admissible to bounce-back of the non-equilibrium part of the particle distribution normal to the boundary, i.e.,  $f_i^{neq} = f_i^{neq} \equiv f_i' - f_i^{eq} = f_i - f_i^{eq}$ . For a Dirichlet element pointing in positive  $x$ -direction this gives

```
rho := 1/(1-vx) * ((fo[1]+fo[3]+fo[5]) +
  + 2 * (fo[4]+fo[7]+fo[8]));
fo[2] := fo[4] + 2/3*rho*vx;
fo[6] := fo[8] + 1/2*(fo[5] - fo[3])
  + 1/2*rho*vy + 1/6*rho*vx;
fo[9] := fo[7] + 1/2*(fo[3] - fo[5])
  - 1/2*rho*vy + 1/6*rho*vx;
```

For a known inlet velocity  $v_{in,x}$ , this system serves as velocity inlet, `CDLB.VelocityNode`, or can be rearranged in terms of known density,  $\rho = \rho_{in}$ , into a density inlet, `CDLB.DensityNode`.

### 4.4 Initial Conditions

At start of the simulation run, a flow at rest is assumed, setting the distribution functions to their equilibrium value.

Figure 3: Profile of the magnitude of the flow velocity in lattice units in a fluid domain with one solid node at one quarter of the domain length and vertically centered. A periodic vortex occurs forming a von Karman vortex.

Figure 4: Profile of the magnitude of the flow velocity in lattice units in a fluid domain with an orifice at one quarter of the domain length. A jet is created which is amplified by aerodynamic effects.

Figure 5: Profile of the vorticity in lattice units in a fluid domain with an orifice at one quarter of the domain length. A jet is created which is amplified by aerodynamic effects.

## 5 Test cases and results

### 5.1 Flow past a cylinder

The first test case deals with the flow around a cylinder in a fluid stream, which is formed by one solid node. It is positioned at approximately one quarter of the domain length and vertically centered in the computational domain. The nodes at the upper and lower boundaries are also fluid nodes. As all boundaries are interconnected with each other, this constitutes periodic flow boundary conditions. The computational domain consists of  $258 \times 30$  grid nodes, leading to 570k equations, which is close to the maximum size manageable in Dymola.

Periodic vortex at the cylinder occurs forming a von Karman vortex street, see Figure 3 for a snapshot showing the velocity magnitude in lattice units. In order to obtain a high Reynolds number, the relaxation factor  $\tau$  was set to  $1/2$ , yielding a very low kinematic viscosity, which is only determined by numerical precision of the solver.

### 5.2 Flow through an orifice

The second test case is a flow through an orifice where a jet is formed. The orifice is modeled as solid with

non-slip walls and is positioned in a duct with slip-walls at one quarter of the domain length. The computational domain consists of 258 x 30 grid nodes, leading to 570k equations.

Figures 4 and 5 show snapshots of the velocity magnitude and the vorticity in lattice units. Velocity perturbations at the flow inlet trigger initial perturbations in the jet shear layers which are further amplified by aerodynamic effects due to the Kelvin-Helmholtz instabilities until the jet breaks up into discrete vortices.

## 6 Conclusions

An approach for simulating fluid flow with the Cascaded Digital Lattice Boltzmann method is proposed. With this approach fluid flow problems can be addressed in a multi physical modeling language like Modelica. The method works for small scenarios but reaches the boundaries of efficient simulation quickly. Nevertheless, the approach works for 2D flows and can be extended to 3D flows easily.

# FORM-L: A MODELICA Extension for Properties Modelling Illustrated on a Practical Example

Thuy Nguyen  
EDF R&D

6, quai Watier F-78401 Chatou Cedex, France

## Abstract

As systems engineering methodologies for complex systems make increasing use of modelling and simulation techniques, it has become important to extend the MODELICA language to also cover requirements, and more generally, properties modelling. The ITEA2 MODRIO project is currently developing an extension for that very purpose: the FORM-L language (FOrmal Requirements Modelling Language). This paper presents an overview of the FORM-L concepts, and illustrates them with examples based on a practical case study, the Backup Power Supply (BPS) system.

*Keywords: physical modelling; requirement modelling; systems engineering; methodology*

## 1 Introduction

Systems engineering methodologies for complex systems increasingly rely on, or could benefit from, modelling and simulation. For MODELICA to support activities such as functional validation of system requirements, design verification against requirements, testing, dysfunctional analyses and verification of operational procedures, the ITEA2 MODRIO project is developing extensions to the language. One of them concerns formal requirements and properties modelling, and is called FORM-L (FOrmal Requirements Modelling Language). This paper presents the main concepts underlying FORM-L, and illustrates them with examples taken from a MODRIO case study, the Backup Poser Supply (BPS) system.

Section 2 presents the main objectives assigned to FORM-L. Section 3 introduces briefly the BPS case study in order to provide a background context for the examples given in the following sections. Section 4 presents how FORM-L considers *functions*, *constants* and *fixed* variables. Section 5 introduces the notions of *condition* and *event*. Section 6 presents the

notions of *properties*, *requirements*, *assumptions* and *guards*. Section 7 presents the notion of *time locator*, continuous or discrete. Section 8 presents how FORM-L views *sets* and *arrays*. Lastly, Section 9 presents how *actions* are modelled in FORM-L.

## 2 FORM-L Overview

### 2.1 Motivation

Paper *Innovative Modelling Architecture for the Verification of Design against System requirements* presents how one of the methodologies developed by MODRIO (to verify the design of a system against its requirements) is supported by FORM-L.

This includes in particular a clear separation of models serving different purposes in the systems engineering lifecycle or the support to systems operation. In particular, there should be a well-identified model that clearly and formally specifies:

- The boundaries of the system under study.
- The interactions of the system with its environment (including human operators), including any assumptions made regarding this environment.
- The system requirements, including functional and timing requirements (concerning the interactions with the environment) and system operational requirements (including quality of service and fault-tolerance, and operational constraints aiming for example at reducing wear and tear of system components).

### 2.2 Main Notions

This is supported by the FORM-L with the notions of *property*, *requirement*, *assumption*, and *external* information (to be supplied either by other MODELICA models or by engineering databases).

The expression of a requirement or a desirable property needs to address four basic issues: WHAT, WHERE, WHEN (cf. EuroSysLib WP7.1 Property Modelling) and HOW WELL.

WHAT states what needs to be achieved or what must be avoided. This is expressed in FORM-L with the notions of *condition* (that must be satisfied), *event* (that must or must not occur), *function* and *action*.

WHERE states where in the system the WHAT needs to be achieved. This can be expressed in FORM-L by the explicit naming of objects, but also with the notion of *set*, in particular of set resulting from queries. Indeed, at the time system requirements are specified, early in the system lifecycle, the names, number, types, characteristics and locations of the objects concerned are often not known yet. They are determined at a later stage, the information being usually stored in one or more engineering databases.

WHEN states when the WHAT needs to be achieved. Possibly complex temporal logic is often needed when considering reactive systems such as the BPS. Such logic can be expressed in FORM-L using *continuous* or *discrete time locators*. FORM-L also includes the notions of *finite state automaton*, *statechart* and *time domain* (the latter being extremely useful, or even necessary, when considering hybrid systems).

HOW WELL states how well the WHAT needs to be achieved (as real life systems are bound to have failures). This is expressed in FORM-L using probabilistic properties. Extensive work is being done in the framework of MODRIO on stochastic issues and multi-mode modelling: FORM-L only addresses what concerns properties.

### 2.3 Readability

It is not sure that all aspects of requirements specification (in particular complex temporal logic) can be represented graphically without risks of misinterpretation from the part of readers, or even authors of models. Therefore, the clarity of the FORM-L language textual syntax is important, as the language is mainly intended to be used by application specialists rather than modelling experts. The syntax that is proposed here voluntarily includes significant amounts of "syntactic sugar" for this very reason.

## 3 A Brief Introduction to the BPS Example

### 3.1 BPS Objective

The objective of the BPS (Backup Power Supply) is to provide electric power to electrical components (e.g., pumps and valves in a thermohydraulic indus-

trial installation) that are considered essential, in case of loss of the Main Power Supply (MPS). Such components could be important to safety (e.g., in an industrial installation or in a hospital) or could be required to prevent unacceptable economic losses (in a semiconductor fab).

Figure 1 presents the overall organisation of the BPS from the standpoint of the requirements specifiers. Figure 2 presents a system architecture developed by designers as a possible answer to the requirements. The objective of the system requirements model and of the architecture model is to support the verification that the architecture indeed meets the requirements.

### 3.2 BPS Principles

As the levels of power required by the backed-up sets of components are assumed to be very high, and the duration of the backing-up to last up to several days, the BPS is based on a Back-Up Generator, or BUG. This generator has a number of constraints. In particular, it cannot power instantaneously all necessary components: if all 'client' components were connected simultaneously to the BUG, the BUG could be overloaded and stall, due to the fact that when electric power is restored to a given component, there is an important, transient call for current and power (see figure 3). Thus, much like a conventional car engine needs a gearbox, the BPS and its BUG need an active control system to ensure a progressive and orderly increase of requested power (hence the presence of circuit breakers).

Figure 3: Transient call for current when electric power is supplied to an electric component

Also, not all components powered by the backed-up electric panel have the same needs and functional roles. In the case study, six sets of backed-up electric components (SBC) have been identified:

- *SBC1* groups components that implement Context Specific Actions (CSA). Such actions are not always needed. However, if and when they are, then Set1 must be powered back within 20 seconds.
- *SBC2*, *SBC3*, *SBC4* and *SBC5* are redundant sets of components, and it is sufficient to power any two of them within 40 seconds.

- *SBC6* must be powered back within 60 seconds.

When in operation, the *BPS* can be in one of three main states:

- *Nominal* state: the *BPS* is available and ready to perform its missions.
- *Test* state: as *MPS* loss is rare and the *BPS* is seldom required, periodic testing is necessary to

- ensure that when needed, the *BPS* will indeed be able to perform its missions.
- *Maintenance* state: the *BPS* is under repair and is not able to perform its main mission, which is to provide electric power to the backed-up electric panel.

Figure 1: *BPS* and its environment as viewed by system requirements specifiers. The overall configuration corresponds to the case where the *MPS* is available

Figure 2: *BPS* and its environment as viewed by the system designers. Note the introduction of sensors (voltmeters, frequency meters, breaker position sensors), of the digital control system *GLS* (Generator Load Sequencer), of the splitting of certain *SBCs* into smaller Steps.

### 3.3 The BPS Models

The BPS case study considers 4 models (see figure 4):

- *BPS.REQ* is a property model specifying the functional and quality of service requirements applicable to the *BPS*. This property model also describes the environment of the *BPS*, and the interactions between the *BPS* and that environment.
- *BPS.ADS* is a property model describing an architectural design for the *BPS*. In particular, it identifies the components constituting the *BPS*, and puts requirements on these. One objective is to verify that this design will indeed satisfy the requirements stated by *BPS.REQ*.
- *BPS.ENV* is a behavioural model that simulates the system environment of the *BPS*, including operators' actions.
- *BPS.BEV* is a behavioural model that simulates the design specified by *BPS.ADS*.

Figure 4: The MODELICA models for the BPS

## 4 Functions, Constants and Fixed Values

### 4.1 Functions

Functions are features the value of which depend on time. In addition to functions already supported by current MODELICA, FORM-L has a few additional types:

- *Conditions* are combinations of Boolean and temporal logic. Their values can be *true*, *false* or *undefined*.
- *Finite state automata* are functions the values of which are in an enumerated set (see section 10 Discrete States - Finite State Automata).
- Probabilities are functions the values of which are real in the  $[0., 1.]$  range (see section 13 Probabilistic Properties).

### 4.2 Constants

Qualifier **constant** may be used to specify that a feature does not vary in time and has the same value for all simulation runs. This is not absolutely necessary (the FORM-L compiler should be able to detect that automatically) but may clarify authors' intentions.

```
constant real pi = 3.1416;
```

### 4.3 Fixed Values

Qualifier **fixed** may be used to specify that a feature has a value that is determined at the beginning of a run and does not vary during that run. However, it may be different in different runs. Here again, this is mainly to clarify authors' intentions.

```
constant duration CycleTime = ms50;
```

```
fixed duration Phase = random (0.0, CycleTime);
```

The GLS (Generator Load Sequencer, see Figure 2) is a digital, synchronous control system introduced by the architectural design. It operates in a discrete time domain, the *CycleTime* of which is 50 milliseconds (ms50). The *Phase* of the time domain is a random value that does not change once the system has started, but that will be different when the system is restarted.

Figure 5: The GLS time domain

## 5 Conditions and Events

### 5.1 Conditions

Conditions determine the evaluation of Boolean expressions restricted to time periods specified by *continuous time locators* (or CTLs). The general rule is that they are *true* when not in the time period, and take the value of the Boolean expression when in the time period. However, there are cases where they are undefined (see example below).

Conditions are used to specify so-called *condition-based properties*. The difference between the two is that properties express something that is desirable, required or assumed, whereas conditions are just building blocks to express properties, as it is often preferable to break the expression of complex properties into simpler, intermediate expressions.

```
condition C = duringAny s4 check Off;
```

This condition is used to specify when the MPS can or must be declared unavailable. In particular, to avoid activating the BPS for short MPS losses, it must have been off for at least 4 consecutive seconds (s4).

Condition *C* is evaluated at the end of each 4 second time window (**duringAny** s4): it is *true* if *Off* had been *true* during the complete time window. It is *false* otherwise. It is *undefined* during the first 4 seconds of the simulation run, since no 4 second time window has elapsed yet.

## 5.2 Events

An *event* characterises the occurrence of one or more facts that have no duration: each of these facts is an occurrence of the event. Events are used to specify so-called event-based properties.

```
external Boolean EndMaint;
event endMaint =
  when EndMaint becomes true;
```

The external Boolean *Endmaint* represents the time-continuous signal issued by one of the buttons at the disposal of the human operator. This signal is simulated by the behavioural model of the BPS environment. Transition from *false* to *true* (**becomes true**) denotes the end of the on-going maintenance operation.

## 6 Properties, Requirements, Assumptions, Guards

There are two types of properties: condition-based properties, and event-based properties. Two Boolean functions are attached to each property:

- *Violated* is initially *false*. It becomes *true* at the first instant where the property is violated, and remains so until the end of the simulation run.
- *Evaluated* is also initially *false*. It becomes *true* at the first instant where the *Violated* / *notViolated* status can no longer be modified in the course of the simulation run, and remains so until the end of the simulation run.

### 6.1 Condition-Based Properties

Like a condition, a condition-based property specifies a Boolean expression and a CTL: the Boolean expression should be *true* during the CTL.

A three-valued function (*satisfied*, *notSatisfied*, *notApplicable*) is attached to each condition-based property. During the CTL, the property is *satisfied*

when the Boolean expression is *true*, and *notSatisfied* otherwise. It is *notApplicable* at time instants not covered by the CTL or when the combination of CTL and Boolean expression is *undefined*. It becomes *Violated* at the first instant where it is *notSatisfied*.

```
property P2ce =
  after (BPSNeeded becomes true)
  within s60
  check SBC[6].Powered becomes true;
```

This property expresses the need to start providing electric power to the 6th SBC (SBC[6].Powered **becomes true**) at most 60 seconds after the BPS has been declared as needed.

### 6.2 Event-Based Properties

An event-based property specifies a constraint on the number of occurrences of an event during a given time locator.

A three-valued function (*belowLimits*, *withinLimits*, *aboveLimits*) is attached to each event-based property, indicating whether the number of occurrences is below, within or above the limits specified. The property becomes *Violated* at the first instant where it is *aboveLimits*.

```
property P2 = {P2a; P2b; P2c};
required property R7 =
  until (or{P in P2 | P.Violated})
  becomes true
  check no eFailure;
```

P2 is the set of properties stating when SBC1 (P2a), SBC2-5 (P2b) and SBC6 (P2c) must be powered by the BPS. When any one of the SBCs cannot be powered back within the allocated time, a failure signal (eFailure) must be sent to the operator.

Property R7 expresses the requirement that this signal must not be sent (**no eFailure**) spuriously, i.e., before any one of the P2 properties is violated.

### 6.3 Requirements,

A *requirement* is a property that **MUST** be satisfied: it is the objective of simulation to verify that it is not *Violated*.

### 6.4 Assumptions

An *assumption* is a property that is supposed to be satisfied: simulation scenarios assume / ensure that it is satisfied. Assumptions are usually made with respect to the environment or the boundaries of the system under study. They can also be made on sys-

tem aspects not fully determined yet, in preliminary stages of design.

```

assumed property
  during MPS.Unavailable
  check no eMaint;
  
```

This assumption concerns the human operator's actions. It states that when the MPS is not available, the operator will not launch a maintenance session (**no** eMaint).

### 6.5 Guards

A guard is a property that states the conditions that must be satisfied for a model to be valid. It is to be used for multi-modelling, when several models are available for the same system or components, each corresponding to specific situations.

## 7 Time Locators

There are two types of time locators in FORM-L: continuous time locators (CTLs) and discrete time locators (DTLs).

### 7.1 Basic Continuous Time Locators (CTLs)

A CTL specifies one or more time periods. Time periods have a duration and usually have a position in time (see Figure 6).

Figure 6: Time intervals

#### duringAny duration

This defines a sliding time window, i.e., any time period of a given duration (see Figure 7 and example in Section 5.1).

Figure 7: *duringAny* duration

Sliding time windows are a very distinct type of CTL and cannot always be used as the other types of CTL.

#### during condition

The time periods defined are those where condition is **true** (see figure 8).

Figure 8: *during* condition

```

property P4 =
  during not (BPSNeeded) // CTL
  check not (Active);
  
```

In this example, the CTL is specified in line 2. The property states that when the BPS is not needed, it should not be activate.

#### after event

The time periods defined begin with each occurrence of event and last until the end of the simulation run (see figure 9). There are as many periods as there are event occurrences: if there are more than one occurrence, they will overlap.

Figure 9: *after event*

```

event eMustAbortM =
  (after eMaint within s60)
  and MPS.eLoss;
  
```

In this example, the meanings of the named events and conditions are as follows:

- eMustAbortM is an event that signals that a BPS maintenance request previously raised by the operator needs to be cancelled.
- eMaint is an event raised by the operator signalling that maintenance will be performed on the BPS.
- MPS.eLoss is an event signalling that the MPS has been lost, and thus that the BPS is needed.

This event occurs when the MPS is lost 60 seconds or less after a maintenance request has been issued. In such cases, the maintenance request is expected to be aborted (see example below).

#### after event for duration

#### after event within duration

The time periods defined begin with each occurrence of event and last for the specified duration (see figure 10).

Figure 10: *after event for duration*

Both syntaxes have the same meaning, but whereas the expression with **for** is mainly used for condition-based properties (the condition must be true **for** a certain time period), the expression with **within** is mainly intended for event-based properties (an event must occur **within** a certain time period).

```

assumed property
  after eMustAbortM within s5
  check endMaint;
  
```

This statement assumes that within 5 seconds ( $s5$ ) after an occurrence of `eMustAbortM` (the event signalling that a BPS maintenance request should be cancelled), the effective cancellation event (`endMaint`) is indeed raised by the operator.

**after event1 untilNext event2**

The time periods defined begin with each occurrence of `event1` and last until the first strictly following occurrence of `event2` (see figure 11). There are as many intervals as there are occurrences of `event1`.

Figure 11: *after event1 untilNext event2*

```

condition Running =
  after eStart untilNext eStop;
  
```

This statement concerns the backup generator of the BPS. The generator can signal several events, including `eStart` (it has started) and `eStop` (it has stopped). The statement defines the time periods where the generator is Running.

**until event**

The time intervals defined all start at the beginning of the simulation run. There is one time interval per occurrence of `event`, and it ends with the occurrence (see figure 12).

Figure 12: *until event*

```

condition BPSNeeded =
  (MPS.Unavailable or after Op.eVTest)
  and not(Maintenance)
  and until Op.eVReset;
  
```

This statement specifies when the BPS is needed. It is a time period that begins when the MPS has become unavailable (`MPS.Unavailable`) or when the operator has initiated a periodic test (`Op.eVTest`), under the condition that the `BPS` is not under maintenance (`not(Maintenance)`). It ends when the operator issues a valid reset (`Op.eVReset`):.

**every duration1 for duration2**

This expression defines periodic time intervals (see figure 13). `duration2` should be shorter than `duration1`.

Figure 13: *every Duration1 for Duration2*

```

required property
  every s10 for s2 check eCheck;
  
```

This statement requires that periodically, every 10 seconds ( $s10$ ), event `eCheck` should occur in the first 2 seconds ( $s2$ ).

### 7.2 Combining / Transforming CTLs

The FORM-L offers various means for deriving new CTLs from already existing ones. These are summarised in figure 14. The only type of CTL that cannot be used in these expressions are sliding time windows: they can be neither transformed nor combined directly, but conditions based on sliding time windows can be used (with keyword `when`) to define CTLs that can be combined and transformed.

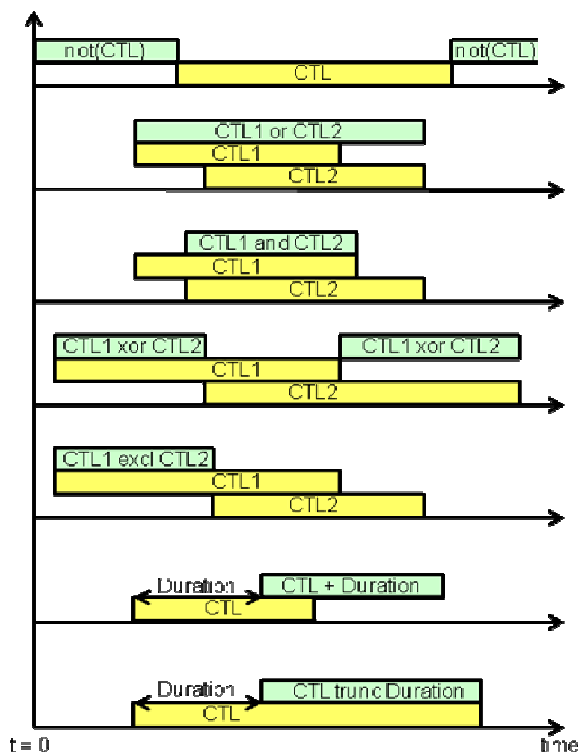

Figure 14: *Deriving new CTLs from existing ones*

### 7.3 Basic Discrete Time Locators (DTLs)

A DTL defines one or more positions in time and has no notion of duration.

- when condition becomes true
- when condition becomes false
- when condition changes

The DTL has a time position for each instant where condition becomes *true*, *false* or changes value (see Figures 15 and example of Section 6.1). In a discrete time domain, condition changes value when and only when its value at a given instant is different from its value at the preceding instant.

Figure 15a: when condition becomes true

Figure 15b: when condition becomes false

Figure 15c: when condition changes

- when fsa becomes state
- when fsa leaves state
- when fsa changes
- when integer changes

DTLs can be defined when a finite state automation (fsa) enters or leaves a given discrete state or changes state. They can also be defined when an integer function changes value.

when event

This expression simply denotes the DTL associated with an event.

every duration

This expression defines a periodic DTL, the period of which is duration (see figure 16).

Figure 16: every duration

```
constant duration CycleTime = ms50;
private fixed duration Phase =
  random(0.0, CycleTime);
dt1 = (every CycleTime) + Phase;
```

This example defines the discrete time domain associated with the GLS, which has a synchronous design: it sees its environment and acts upon it only at the instants defined by the specified dt1. The period

is defined by CycleTime (50 milliseconds). The time domain has a random phase defined by Phase.

7.4 Combining / Transforming DTLs

FORM-L offers various means for deriving new DTLs from already existing ones. These are summarised in figure 17.

Figure 17: Deriving new DTLs from existing ones or from CTLs

8 Sets, Subsets and Arrays

Sets are an essential ingredient of FORM-L, particularly when requirements and assumptions are stated at very early stages of a project, where the precise identifications and numbers of the objects constituting the system are yet unknown.

Sets are first divided into two main categories: *static sets* (the membership of which does not vary in time) and *dynamic sets*.

Static sets are either *enumerated sets* (their members are listed individually) or *queried sets* (their membership is defined in intention based on constraints on static attributes, and is obtained at the beginning of a simulation run through a query to an engineering database).

Dynamic sets are always subsets of static sets. Their membership is defined based on constraints involving dynamic attributes.

All sets are ordered, either explicitly or implicitly. In this sense, they are close to single dimension arrays (vectors) of the current MODELICA language.

However, there is one significant difference: an array contains its members and an object cannot belong to two different arrays; a set references its members, and an object may belong to several sets.

FORM-L has set operators (such as union or intersection), arithmetic operators (such as sum, minimum or maximum) and Boolean operators (such as and or or). It also provide a cardinal function that calculates the number of members in a set and that allows the expression of universal or existential quantifiers.

## 9 Actions

FORM-L provides the notion of action to support the modelling of designs.

### 9.1 Elementary Actions

Elementary actions belong to one of two types:

- Assignments to functions.
- Raising of events.

They are composed of two parts: an optional delay part (specified by a time locator) and an action specification (the effective event raising or function assignment).

### 9.2 Composite Actions

Composite actions regroup two or more actions that need to be performed in a coordinated manner at instants specified by a CTL or during time periods specified by a DTL. There are two types of coordination:

- Sequences, where the member actions are performed one after the other.
- Simultaneous actions, where all actions are performed at the instants specified by a DTL.
- Non-ordered actions, where the actions are performed at unspecified instants within the time periods specified by a CTL.

```
when State becomes Operational(Active;)
then sequence
  raise eStartDG;
  wait eDGReady
  then raise eOpenMPSBrk;
  wait eMPSBrkOpen
  then raise eShedAll;
do
  wait s1 then raise eCloseDGBrk;
  wait s5 then raise eReload;
end;
end;
```

This composite action specifies the elementary actions to be implemented by the GLS when the BPS is needed (see Figure 17).

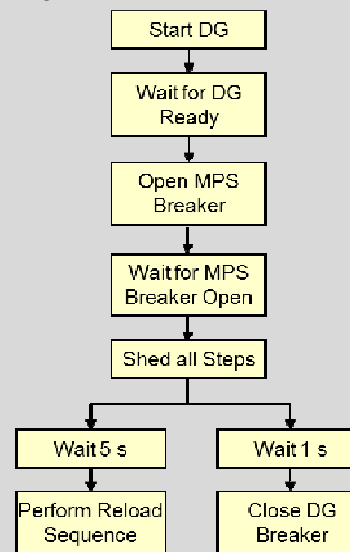

Figure 17: Beginning of the GLS sequencing

## 10 Probabilistic Properties

The MODRIO project is developing extensive stochastic modelling capabilities for MODELICA. These will not be addressed here: for requirements modelling, FORM-L needs only two simple notions.

### 10.1 Probability Function

The first notion introduced by FORM-L is a function of time: its value at a given instant is a Real number in the  $[0., 1.]$  range that represents the probability that a specified event occurred at least once before that instant.

```
property P3 =
  during not(BPSNeeded)
  check not(Active);

required property R3 =
  when SingleSensorFailure then P3;

required property R9 =
  probabilityFunction
  (P3.Violated becomes true)
  < 1-exp(-Y*time);
```

Property P3 states that the BPS should not be spuriously activated when it is not needed. Requirement R3 states that when there are no BPS component failures, or at most one sensor failure, then P3 must be satisfied. Requirement R9 puts a limit on the probability of spurious activation of the BPS (due to BPS components failures). This probability must be lower than what it would be if there was a constant occurrence rate of spurious activation, equal to Y.

## 10.2 Probability

The second second notion introduced by FORM-L is a Real constant or fixed value (not a function of time) in the  $[0., 1.]$  range that states the probability of an event occurring at least once during a given time period (possibly during the whole simulation run). This could be used for example to specify conditional probabilities, with the time period representing the condition. Application of conditional probabilities include probabilities of failure on demand or probabilities of common-cause failure.

```
property P2ce =
  after (BPSNeeded becomes true)
  within s60
  check SBC[6].Powered becomes true;
property P2e = {P2ae; P2be; P2ce};
required property R3a =
  probability (
    (card{P in P2e | P.Violated} == 1)
    becomes true)
    < 5*10-3;
```

Property `P2ce` states that `SBC6` (`SBC[6]`) should start to be powered within 60 seconds after the BPS is declared needed. There are similar properties for the other SBCs (`P2ae` and `P2be`). They are grouped in `P2e` which is the set of properties regarding the timeliness of providing power to the SBCs.

Requirement `R3a` specifies the maximum probability of not satisfying any single one of these properties.

## 11 Conclusions

A number of tasks remains to be achieved, mainly:

- Finalizing the FORM-L concrete syntax, in order to bring it closer to the current MODELICA syntax when this is not at the cost of clarity and conciseness.
- Deciding on an implementation path in the existing tools environments. It is likely that integration with other existing tool environments (in particular with Computer Aided Design and Product Life Management environments and their data bases).
- Developing the methodological aspects to better support systems engineering and systems operation activities.

## Abstract

This article introduces a new feature of LMS Imagine.Lab AMESim that allows users to define plant model controllers. We start by reviewing some challenging aspects of hybrid state machine handling in asynchronous Modelica-based physical simulation environments. We then describe the implementation available in AMESim, focusing on user interaction and especially static error checking and reporting.

*Keywords:* Statechart; Modelica; LMS Imagine.Lab AMESim

## 1 Background

Models of physical systems can be built out of equation-based entities (submodels) whose interaction through a connection structure yield the behavior under consideration. This way of defining physical models puts emphasis on *technological* and/or *phenomenological* aspects of modeling: one typically defines entities representing fundamental phenomena (e.g., energy storage), or entities representing technological assemblies (e.g., a cooling system), or any combination of both, as modeling ‘bricks’. However, this is not the only nor always the most appropriate way of defining models. For instance, one sometimes prefers to put emphasis on *states* and *transitions* between states. This is typically the case when building controllers used to drive models. These controllers feature operating modes that can be conveniently represented as states of a certain finite state machine (consider for instance a controller having modes *start*, *run* and *stop* with transitions between these states indicating possible mode transitions).

To make the picture complete however, real-world controllers actually also feature *state variables*, leading to infinite (often uncountable) hybrid state ma-

chines. Nevertheless, the state-and-transition view is still the preferred one in most situations: this observation motivated the introduction of a new user interface feature in AMESim, allowing users to define controllers by means of a finite set of states and transitions, yet offering state variables and equations as a means to specify not only actions to be performed during state transition but also constraints to be verified in a given state.

Figure 1 shows a simple counter model expressed in the new state-and-transition view, which has been highly inspired by Harel’s statechart language [1]. The corresponding user interface has been built on top of AMESim’s Modelica translation chain to benefit from its automatic code generation feature.

Figure 1: A simple counter statechart

## 2 Why statecharts?

Variants of Harel’s statecharts are today by all means one of the most popular approaches used to describe state machines in Control tools. On the other hand, LMS Imagine.Lab AMESim, which is a Physical System Modeling tool, used to favor the technological and phenomenological aspects of models—which are often the most natural ones in its application area. However, models do not necessarily classify as “pure control” or “pure physical”: some of them involve a *mix*

of physical and control aspects (e.g., aircraft models including aircraft missions, vehicle models including driving manoeuvres, etc.). If we want to handle such models in a simulation tool, we basically have two options: either we choose a unified representation, or we offer the ability to work with both the state-and-transition view and the technological-and-phenomenological view—and then possibly translate heterogeneous parts to a common representation under the hood. In the following we explain the reasons that have driven the choice made in AMESim, whose last release implements the second option.

## 2.1 Control in AMESim by means of native components

Early attempts to mix control with physics in AMESim naturally made use of the versatile native *component* concept. An AMESim component can be seen as a generic “basic brick” having one or several implementations called *submodels*, each of them specifying the *causality* attached to each of its port signals. In this paradigm, there is no fundamental difference between control signals and physical signals (i.e., signals held by *power variables* in corresponding bond graph models): it follows that native submodels can be used to implement control. However, while monolithic controllers (i.e., implemented as single submodels) can be made reasonably safe,<sup>1</sup> controllers built out of *smaller bricks* suffer from two weaknesses inherited from the submodel composition operation:

- the resulting flow of events is not synchronized and
- some control flow defects (resulting, for instance, in blocking models) cannot be detected at compile time.

As a consequence of the former, *cascades of events* are typical of models that deal with discontinuous—not necessarily piece-wise constant—signals. For instance, if a submodel’s job consists in converting its real piece-wise constant input to an integer, it will trigger a fresh event each time its output changes,<sup>2</sup> even if in this case—the input is piece-wise constant—we know that instants corresponding to output changes form a *subset* of those corresponding to

<sup>1</sup>We’ll come back to them in subsequent sections when talking about automatic code generation for controllers.

<sup>2</sup>This is necessary in order to notify a change to possible listener submodels.

input changes.<sup>3</sup> This has unfortunate consequences over resulting models: for instance, it is not possible to know, when a bunch of events fire, whether these events trace back to the same cause or not. Consider our real-to-integer converter example: since each jump in the output signal slope triggers a fresh event in disregard of the reason that made the jump necessary (actually another jump, so another event) we end up having to deal with *two simultaneous* events.<sup>4</sup> Even if consequences over performance are generally negligible, models have to figure out somehow that, given a bunch of events, some of them are “duplicates” of others to avoid treating each of them as independent events, yielding wrong results in some circumstances (see [2] for concrete examples of such wrong models). So to avoid practical synchronous issues, some form of collaboration between submodels—a *design pattern*—must be implemented by *library developers* and, moreover, *understood* and *correctly used* by end-users. Indeed, this collaboration scheme is unknown from the modeling tool which is then of no help to track down misuses of the submodels. This is arguably too much to require from both library developers and end-users, who should ideally focus on physics and control, rather than on low-level implementation details.

Also, it would be desirable to be able to statically (i.e., before execution) catch modeling errors resulting in *non-deterministic models* and *fragile models*.<sup>5</sup> Alas, the technological-and-phenomenological approach is again of no help here: in this paradigm, such modeling errors can only be detected—if they ever are—at runtime. As a consequence, development of models involving many discrete states can become cumbersome: it requires extensive testing to gain confidence in the correctness of the design, and whenever an error is detected, the location of the faulty submodels can be quite challenging. On the other hand, modeling with discrete states is precisely where the state-and-transition approach shines: when the state-and-transition graph of (part of) a model is explicit, it is possible to detect *at compilation time*, as we shall explain in subsequent sections, non-deterministic and

<sup>3</sup>In synchronous language terminology, we say that the *clock* corresponding to output changes is a *subclock* of the clock corresponding to input changes.

<sup>4</sup>This example will be further discussed in subsection 4.1.

<sup>5</sup>Fragile models are models whose correct execution relies on a property that escapes the automatic checker’s proof capabilities. Some of those models are actually correct, but some others are not: we prefer to reject *all* suspicious models, forcing users to disambiguate correct ones (disambiguation is often easy) rather than accepting wrong models that may be hard to debug.

fragile *patterns* that may lead to runtime errors.

Clearly, the technological-and-phenomenological approach, despite its versatility, reaches its limits when complex discrete state submodels such as those involved in Control applications come into play. This observation has motivated the extension of AMESim’s submodel description capabilities, which now feature a state-and-transition perspective.

## 2.2 Statecharts: an intuitive yet expressive graphical language

The general adoption of (variants of) statecharts in Control tools is due to their ability to concisely express complex finite state machines, making them reasonably understandable by humans.

Conciseness is mainly achieved thanks to the nice concept of *composite state*, which can be seen, at least in the original proposal by Harel [1], as a kind of “pseudo-abstraction” in the sense that this construct effectively allows some details of the equivalent, un-factored, flat machine to be abstracted away, but it is nevertheless necessary to reveal some contents to allow inner transitions. Statecharts also feature discrete state variables (updated in *actions*), which makes them suitable to describe even infinite state machines. Actually, Harel’s statecharts come with many appealing features, so they constitute a very good starting point for our targeted applications. However, since they are historically strongly rooted in the discrete control world, they lack the concept of continuous state variable. So, like many others did before us, we have extended statecharts to support hybrid modeling. We have designed this extension so that it remains simple and intuitive, yet powerful enough to handle many practical applications.

We will review in the next section some theoretical aspects of timed systems that have guided integration of statechart modeling capabilities in AMESim. We will then dive in important technical achievements such as validation and automatic code generation before presenting the final result from an end-user point of view.

## 3 A variant of the statechart language

The graphical language implemented in AMESim is very similar to the original statechart language: a statechart is essentially a set of *states* represented with rectangular boxes (labelled `count` and `reset` in the

example of Figure 1) and a set of possible *state transitions* represented with labelled arrows.

A transition can be associated with a *trigger*, a *guard* and *actions*. A transition is taken when an event corresponding to its trigger occurs if its guard evaluates to true. In that case, the actions—which are *state variable* assignments—are executed. For instance, the transition from `count` to `reset` in Figure 1 labelled

```
e [counter == 10] /
  counter := 0;
  reset_count := reset_count + 1
```

means that when an event associated with `e` occurs while `count` is active and the state variable `counter` is equal 10, a transition from `count` to `reset` is taken, `counter` is set to 0 and `reset_count` is incremented.

Triggers, or event generators, are defined at statechart creation time by boolean expressions that create events on their rising edges.

In addition to these general features, a statechart can be augmented with inputs from and outputs to AMESim. An output can either refer to a state variable, i.e. a discrete variable, or to a continuous signal controlled by state activations.

## 4 Theoretical aspects of statecharts integration in AMESim

When Modelica-based tools *simulate* the dynamic behavior of a system, they actually try to find a reasonable approximation of the solution of a system of equations that is supposed to capture the behavior of interest. This system of equations generalizes the so-called state space representation: it roughly consists in inputs, outputs and internal variables constrained by sets of equations whose (possibly dynamic) activation determine the trajectories of the model. This form constitutes the actual *denotation* of the corresponding *desugared program*<sup>6</sup> from which tools need to deduce the desired approximation. Now, given a desugared program, how is this approximation actually obtained? Of course, at some point, it depends on design choices made in the simulation tool.<sup>7</sup> But, given a common model description language like Modelica, any implementation is supposed to follow the same *operational semantics* which state *how to compute the solution—not an approximation—of any well-behaved program*:

<sup>6</sup>“Flat program” in Modelica.

<sup>7</sup>A tool may favor one or several classes of problems (e.g., marginally stable problems, discrete problems, etc.). This contributes to the tool’s added value.

this is somewhat the “reference implementation”—although a “virtual” one<sup>8</sup>—of a correct interpreter of the modeling language. Unfortunately, in practice, defining sound operational semantics for a physical system modeling language is such a huge work that, for most languages available today (including Modelica), only *informal semantics* (i.e., given in written human language) are available. Consequently, many inconsistencies simply cannot be spotted, because, contrary to formal descriptions, informal descriptions do not easily allow *reasoning* about the semantic model itself. This partly explains why, as pointed out in, e.g., [3], physical simulation tools experience difficulties in correctly handling some hybrid problems.

In AMESim, we had to take this fact into consideration when designing the new state-and-transition mode (which interacts with continuous behavior) so that we practically avoid most issues encountered in an unchecked implementation.

In the following subsections, the issues involved with coupling statecharts with AMESim models and the design choices made to circumvent them are discussed.

#### 4.1 Synchrony vs. Simultaneity issues

Statecharts describe systems that *react* to the environment, i.e., they respond to external *triggers* by executing state transitions according to their internal state and their inputs. In other words, a statechart merely describes a function that computes a new internal state from a previous state and a set of inputs while the environment is responsible for providing the inputs and for deciding *when* this function should be used to compute a new state.

A first source of non-determinism originates from the fact that the execution of a statechart can sometime be triggered by several different event sources *at the same time*. The issue is then to tell if the corresponding events are actually one and the same, i.e. they are dependent, or *synchronous*, events, or if they are unrelated, i.e., *asynchronous*, and actually occur in sequence but just seem to be simultaneous due to numerical approximations.

As an example, let us consider the simple statechart of Figure 2.

It simply says that

- if the event  $e1$  occurs while in state  $s0$ , the statechart transitions from  $s0$  to  $s1$ ,

Figure 2: A simple statechart

- if the event  $e2$  occurs while in state  $s1$ , the statechart transitions from  $s1$  to  $s0$  and
- the statechart starts with  $s0$  being active.

If the statechart is executed because only one of  $e1$  or  $e2$  has occurred, the computation of the new state is quite straightforward. But what should happen if, for example,  $s0$  is active and both  $e1$  and  $e2$  are sensed simultaneously? Different interpretations are possible.

A first interpretation might be to assume that events that occur simultaneously are *exactly* the same, i.e. that they originate from the same *primary* external source and should consequently only be taken into account once. In the example this means that the new active state should be  $s1$ .

Another interpretation could be that  $e1$  and  $e2$  are *independent* and that the fact that they appear simultaneous is just a numerical artefact. In that case, the statechart would need to be executed twice according to the sequence in which  $e1$  and  $e2$  have occurred. If  $e1$  happens first,  $s1$  would become the active state after the first execution and  $s0$  would again be after the second one. It should be noted that in this interpretation it is not enough to know that the events are independent: the order in which events occur needs to be determined as well.

Both interpretations can be perfectly valid depending on the external context. Let us reuse examples similar to those presented in [2] to illustrate this fact.

Let us assume that the events  $e1$  and  $e2$  occur when some external signals  $i1$  and  $i2$  respectively become larger or equal to zero.

Figure 3 shows an AMESim model where the same signal source is connected to both  $i1$  and  $i2$ . The source defines a piece-wise constant signal that is  $-1$  when  $t < 1$  and  $1$  when  $t \geq 1$ . As a result, events  $e1$  and  $e2$  happen simultaneously when  $t = 1$ . In that

<sup>8</sup>This guarantees implementation independence.

case, it would make sense to consider that  $e_1$  and  $e_2$  refer to the same events and to adopt the corresponding interpretation in the statechart.

Figure 3: Dependent event sources

Let's now consider the model shown in Figure 4. The same statechart model is fed the outputs of position sensors attached to two identical mass with viscous friction models. If the velocities and positions of the masses are initialized to the same values, both positions will become non-negative simultaneously (if they ever do). However, it does not make sense to consider that these events are related as the models that generate them have nothing to do with each other. It seems much more natural to take them into account one after the other as if they had been sensed in sequence. The order of this sequence is not that important here as there is absolutely no reason to favor one model over the other. Actually, in real life, two seemingly identical systems submitted to the same inputs will always behave slightly differently at some scale because of uncontrolled parameters.

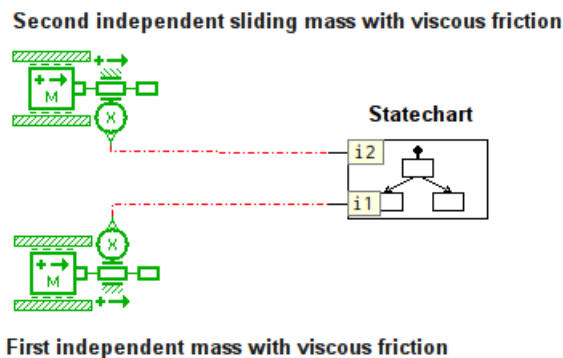

Figure 4: Independent event sources

A third way of using the statechart of Figure 2 is presented in Figure 5. This model illustrates the idea expressed in Subsection 2.1 about cascading events: a piece-wise constant signal is fed to  $i_1$  while its integer part is fed to  $i_2$ . Both inputs cross zero at the same time, generating simultaneous events. One could consider that they are the same events, as in the model in Figure 3, but one could also consider that  $e_2$  is a *consequence* of  $e_1$  and should then be handled *after*  $e_1$ .

Figure 5: Independent event sources where order matters

The examples presented above show that very different meanings can be given to simultaneous events. Unfortunately, a continuous-time modeling environment is unable to give any insight about which is the expected one, the information being simply unavailable. This shortcoming is particularly critical when executing a statechart as making wrong decisions in a discrete model can radically alter the course of a simulation compared to continuous-time detailed physical models where energy conservation principles make models more robust with regard to non-determinism.

## 4.2 Observability of state transitions

In AMESim, just like in Modelica, discrete states can only be assigned *once* when a continuous-time event occurs.<sup>9</sup> This makes up another obstacle in the way of coupling a statechart with a continuous-time model. Indeed, a statechart may need to execute several transitions *without increasing the elapsed time in the model*, thus updating its state multiple times as a response to a unique continuous-time event.

Let us consider for example the statechart of Figure 6 featuring an input  $i$ , a discrete real output  $o$  and an event generator  $e$ . The statechart starts in state  $s_0$ . When  $e$  generates an event, state  $s_1$  is entered and  $o$  is set to 1.0. Besides, if the guard  $i > 0.0$  is satisfied at that time,  $s_2$  directly becomes the new state and  $o$  is set to 2.0, *without awaiting a new event*.

This clearly contradicts the assumptions stated above. In Modelica, for instance, something like the partial Modelica code in Listing 1 would need to be written, which is invalid as the second when clause introduces an algebraic loop involving  $s_1$  and because  $s_1$  and  $o$  are potentially constrained by two equations at once when  $e$  occurs.

Listing 1: Invalid Modelica code for the statechart of

<sup>9</sup>The values of certain states can actually be changed by a Modelica simulator as part of a solving process, but these intermediate values should never be relied upon in a model.

Figure 6: A statechart involving a potential double assignment

Figure 6

```

when initial() then
  s0 = true;
  s1 = false;
  s2 = false;
  o = 0.0;
elsewhen e then
  if pre(s0) then
    s0 = false;
    s1 = true;
    o = 1.0;
  end if;
end when;

// when state s1 is entered...
when s1 then
  if i > 0.0 then
    s1 = false;
    s2 = true;
    o = 2.0;
  end if;
end when;
  
```

One could, of course, think of working around these obstacles by “inlining” the intermediate transition, i.e. by rewriting the statechart with a direct transition from 0 to s2 as done in Listing 2.

Listing 2: Modelica code for the statechart of Figure 6 using “inlined” transitions

```

when initial() then
  s0 = true;
  s1 = false;
  s2 = false;
  o = 0.0;
elsewhen e then
  if pre(s0) then
    if i > 0.0 then
      s0 = false;
      s2 = true;
    end if;
  end if;
end when;
  
```

```

o = 2.0;
else
  s0 = false;
  s1 = true;
  o = 1.0;
end if;
end if;
end when;
  
```

This is valid Modelica, but the behavior is not exactly the expected one. Indeed, from an external point of view, *o* jumps from 0.0 to 2.0 directly without ever taking the 1.0 value. This may seem harmless for one used to physical continuous-time modeling, but what if this output was fed to another discrete part, e.g. another statechart, that relies on it to significantly alter its behavior? Figure 7 shows an AMESim model that depends on the intermediate value being taken. Event *e* is fired when the input becomes positive which at the same time satisfies the guard  $i > 0.0$ . The output is connected to a discrete subsystem that increments a counter when it gets exactly equal to 1.0. This means of course that the counter will only be incremented if the intermediate value is properly observed.

Figure 7: A model exposing observability issues

It should be noted that using Modelica algorithms to rewrite the model as shown in Listing 3 exposes the same issue as *o* is only equal to 1.0 during an intermediate step inside the algorithm.

Listing 3: Modelica code for the statechart of Figure 6 using an algorithm

```

algorithm
when initial() then
  s0 := true;
  s1 := false;
  s2 := false;
  o := 0.0;
elsewhen e then
  if pre(s0) then
    s0 := false;
    s1 := true;
    o := 1.0;
  end if;
end when;

// when state s1 is entered...
  
```

```

when s1 then
  if i > 0.0 then
    s1 := false;
    s2 := true;
    o := 2.0;
  end if;
end when;

```

### 4.3 Design choices

When designing the statechart extension to AMESim, the main focus was placed on the robustness, reliability and usability of the solution. That is why special care was taken to avoid as much as possible the issues presented above. This necessarily lead to additional rules in our variant of the statechart language that will be justified in this section.

First, it was decided to avoid the simultaneity issues described in Subsection 4.1 altogether by making sure that the execution of a statechart is always independent of the interpretation given to simultaneous events. This means that if any two events occur at the same time, assuming that they are synchronous or asynchronous should not change the upcoming computation. In the language described in this paper, events triggering a statechart simultaneously are simply forbidden.<sup>10</sup>

This rule is partially enforced by the statechart environment of AMESim by statically checking that a transition cannot generate an event that would conflict with the one that triggered the transition in the first place. What is more, simultaneous external events are detected at runtime and result in aborting the simulation. This guarantees the deterministic execution of a statechart provided that no dependent event sources are created by directly connecting—without inserting a continuous or discrete state variable as a buffer—an output to an input.<sup>11</sup>

One may argue that another solution might have been to stick to one interpretation anytime events occur simultaneously. But what if the only interpretation that makes sense is precisely the other one like in the model of Figure 4, where assuming that the events are dependent is clearly not expected? That is why signaling ambiguous situations was favored over making arbitrary choices behind the scene. As a side note, the “independent events” interpretation brings its lot of additional questions. How can the ordering of events be determined? How can several events be processed without

<sup>10</sup>This rule may be made less restrictive in the future if it turns out that it significantly enlarges the range of valid models.

<sup>11</sup>Avoiding this is the responsibility of the environment and cannot be enforced locally in a statechart.

increasing the continuous time and without encountering the issues of Subsection 4.2?<sup>12</sup>

Similarly, to avoid the observability issues presented in Subsection 4.2, the decision was made to enforce that the *effect* of every taken transition can always be observed from outside a statechart. This means that an *output* cannot be set more than once during one execution of a statechart. This property can be checked statically assuming that the first rule about simultaneous events is enforced.

## 5 Practical validation of statecharts

To ensure the safe execution of a statechart definition, the fulfilment of the aforementioned constraints has to be statically checked before generating code. Beside trivial checks such as making sure that the state machine contains a unique initial state or that at least one event generator is present (to ensure time progression), a few non-trivial checks have also been implemented. These checks are presented hereafter.

### 5.1 Transition expression checking

Writing correct transition expressions is error-prone: as in any other textual language, one can easily make syntax and semantic errors such as referring to a non-existent variable or event generator, or combine incompatible expressions.

Figure 8: A statechart with a typo in an identifier

In order to avoid runtime errors due to unknown identifiers, each input, output and event must be declared before use. All local variables have to be initialized, and thus implicitly declared, on the initial transition of a statechart. These rules imply that all variables are known at compile time and allow rejecting the statechart of Figure 8 where `my_sped` is not a valid variable name.

<sup>12</sup>For instance, a state transition may change an output that in turn invalidates an event that has already been placed in the processing queue.

Avoiding element misuse requires a more complex solution: a static type system. This type system was designed to avoid the need for user provided type annotations, which would make writing transition expressions cumbersome. The Hindley/Damas/Milner type inference algorithm [4, 5] is used to type check all transitions without type annotations.

The basic idea of type inference is to traverse all expressions of a program to gather various typing constraints and correlations and then to resolve all those constraints in a second pass, thus attributing their final types to variables.

Let us consider for example the following expression

$$e / v := 2 + v; x := \sin(v) + x$$

and the primitive type definitions below.

$$\begin{array}{l|l} \sin & \text{Real} \rightarrow \text{Real} \\ 2 & \forall \alpha \in \{\text{Integer}, \text{Real}\}, \alpha \\ (+) & \forall \alpha \in \{\text{Integer}, \text{Real}\}, \alpha \rightarrow \alpha \rightarrow \alpha \end{array}$$

The first step to perform type inference on the example expression is to attribute free type variables to the variables in use, i.e.  $v$  will get type  $\beta$ ,  $x$  type  $\delta$  and  $e$  type  $\gamma$ .

As  $e$  is used in the trigger section of the expression, the typer can deduce the constraint  $\gamma = \text{Event}$ , which gives the final type for  $e$ : Event.

In the first action, the type of the  $(+)$  operator implies that both its operands must have the same type, which can be either Integer or Real. This means that the type of variable  $v$  must satisfy the following constraint:

$$\beta \in \{\text{Integer}, \text{Real}\}.$$

On the other hand, the type constraint for  $2$  matches exactly the one for the operands of  $(+)$  and can then be omitted in the next equivalences as it brings no additional information.

Similarly, the use of the  $(+)$  operator in the second action yields the following constraint:

$$\delta \in \{\text{Integer}, \text{Real}\}.$$

The presence of the  $\sin$  function generates tighter constraints, as it bounds the types of the input and output variables, yielding:

$$\begin{array}{l} \beta = \text{Real}, \\ \delta = \text{Real}. \end{array}$$

Gathering all the inequalities together gives the following final typing equation system:

$$\begin{array}{l} \beta = \text{Real}, \beta \in \{\text{Integer}, \text{Real}\}, \\ \delta = \text{Real}, \delta \in \{\text{Integer}, \text{Real}\}. \end{array}$$

It can then be simplified to deduce that  $v$  has type Real and that  $x$  also has type Real. An impossibility to simplify type equations, like obtaining  $\text{Integer} = \text{Real}$  would have meant a type error which should be reported to the user.

### 5.2 Activation chain analysis

Transitions that have no trigger section do not necessarily stop the execution of a statechart; they are taken as far as their guards allow, without waiting for another event.

Figure 9: An activation chain

The execution of the statechart of Figure 9 exhibits such a behavior: when the event  $e1$  is raised while in  $s0$ , the state machine will take the transition to  $s1$  as  $x$  is equal to 0, then take the transition to  $s2$ , as the transition has no trigger, and finally to  $s3$ . To an external observer, the visible state activation will go from  $s0$  to  $s3$  directly. A path made of transitions that can be taken globally during an execution of a statechart is called an activation chain.

This behavior can result in infinite looping if not handled carefully, like in Figure 10. The semantics of our statechart language imply that the execution will continue indefinitely between  $s0$  and  $s1$  (highlighted in red), without ever resuming continuous-time simulation.

To ensure that a statechart will never stall a simulation, activation chain cycling is forbidden, hence forcing users to break cycles with triggers. For example, fixing the statechart of Figure 10 requires the addition of a trigger on the transition between states  $s1$  and  $s0$ .

The possibility to take several transitions in a single execution leads to potential duplicated assignments of variables, as in Figure 6 where variable  $o$  is assigned

Figure 10: A cyclic activation chain

twice, once on the transition from  $s_0$  to  $s_1$  and once on the transition from  $s_1$  to  $s_2$ .

As explained in Subsection 4.2 about transition observability issues, this behavior is undesired and the implementation prevents it by analyzing the assignments along every activation chain and rejecting the activation chains that assign a variable more than once.

### 5.2.1 Practical chains analysis

The algorithm used to check the invariants mentioned above is mainly a depth-first search coupled with memoization. Each state is visited to compute its activation chains and forward assigned variables while the set of visited states in the current activation chain and the set of already assigned variables are maintained. Any intersection with the visited values and the ones already stored results in an error.

Another possibility would be to use a data-flow framework and express activation and assignment as liveness information to be propagated by the framework.

## 6 Code generation strategy

In this section, an overview of a code generation strategy leveraging the existing AMESim Modelica tool chain is presented.

### 6.1 Describing statecharts in Modelica

Modelica fits well to our purpose as a statechart that passes the validation stages discussed in the previous section can be described by a Modelica model that is:

- *valid*, i.e., is guaranteed to compile without error, thanks to the syntax and type check phases, and

- *sound* with respect to mixed discrete/continuous semantics as all ambiguous models are filtered out by the restrictions regarding simultaneous events.

Listing 4 shows how Modelica code can be generated to describe the statechart of Figure 1.

Listing 4: Code generated for the statechart of Figure 1

```
e = pulse > 0.0;
when initial() then
  reset_count = 0;
  counter = 0;
  st2 = true;
  st1 = false;
elsewhen e then
  if pre(st2) then
    if pre(counter) == 10 then
      counter = 0;
      reset_count = pre(reset_count) + 1;
      st2 = false;
      st1 = true;
    else
      counter = pre(counter) + 1;
      reset_count = pre(reset_count);
      st2 = true;
      st1 = false;
    end if;
  elseif pre(st1) then
    counter = pre(counter) + 1;
    reset_count = pre(reset_count);
    st2 = true;
    st1 = false;
  else
    counter = pre(counter);
    reset_count = pre(reset_count);
    st2 = pre(st2);
    st1 = pre(st1);
  end if;
end when;
```

Each event generator is associated with an `elsewhen` clause with the logic to handle this specific event as the body of the clause. This logic is encoded as cascading `if` statements representing the various transitions, the transition priorities being used to order the conditions. The equations describe the accumulated content of the action part of every transition and of the state activation updates.

Activation chains are generated recursively, for each level of the chain, the final body standing for the concatenation of all the actions. For instance, adding a transition from `reset` to `count` with the expression `[reset_count > 2]` and a priority below the existing one in the example counter statechart would create an activation chain resulting in the code shown in Listing 5.

Listing 5: Code generated for the statechart of Figure 1 augmented with an activation chain

```
...
```

```

if pre(st2) then
  if pre(counter) == 10 then
    if pre(reset_count) > 2 then
      counter = 0;
      reset_count = pre(reset_count) + 1;
      st2 = true;
      st1 = false;
    else
      counter = 0;
      reset_count = pre(reset_count) + 1;
      st2 = false;
      st1 = true;
    end if;
  else
    counter = pre(counter) + 1;
    reset_count = pre(reset_count);
    st2 = true;
    st1 = false;
  end if;
elseif pre(st1) then
  ...

```

## 7 Graphical user interface aspects

AMESim provides an editor to let users easily create statecharts and statically validate them, highlighting erroneous parts in red as seen in Figure 11.

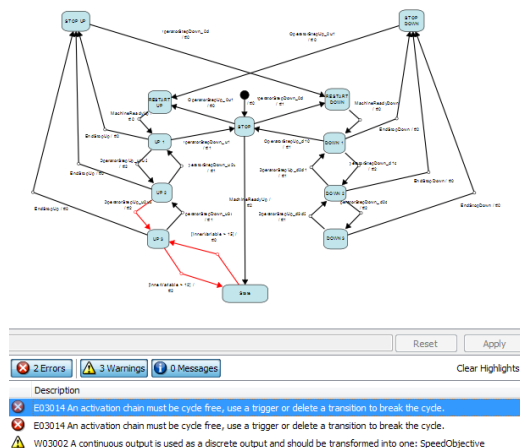

Figure 11: A statechart with a structural error highlighted in red

The editor also serves as a debugger as it is able to replay the behavior of a statechart during simulation, highlighting the active states and showing the values taken by all variables. Additional post-processing features are available, such as the possibility to easily jump between state changes. Timing diagrams representing state activations can be obtained using the regular AMESim data plotting facilities by displaying the activation variable associated with every state.

## 8 Conclusion and perspectives

In this paper, a few challenging issues associated with modeling and simulating hybrid models in an asynchronous environment are discussed.

A practical solution implemented in AMESim to avoid those issues and to offer a reliable and usable user interface is presented. This solution is built on top of the AMESim Modelica tool chain and demonstrates how a specific language can be implemented in terms of a more general language. The condition is, of course, that any model expressed in the specific language can somehow also be expressed without loss of meaning in the base language, which demands special care. However, the advantages of this approach are appealing as it is then possible to combine the convenience associated with a user friendly dedicated language with the power of a more general underlying language allowing to connect models expressed using different paradigms together. A core language can thus be extended to new applicative domains without being altered, retaining its generality.

Future work involves extending the supported subset of the statechart language, for example to allow parallel states. Developing practical and scalable means of building statecharts by composing smaller ones is another interesting perspective.

## Abstract

In this paper we present the work done to integrate OpenModelica into the Ptolemy II framework for modeling large-scale concurrent systems. To this end a dedicated computational model for OpenModelica has been defined in Ptolemy II, and support for tool-interaction has been implemented. This implementation will allow to simulate existing Modelica models by the OpenModelica compiler in a heterogeneous context together with models from other computational domains.

*Modelica, Ptolemy II, hierarchical system modeling, concurrent systems*

## 1 Introduction

Distributed, concurrent systems are becoming increasingly common. However, they are complex to develop. Therefore a large number of computational models and tools for modeling and developing such systems has emerged. The Ptolemy project aims to support such heterogeneous modeling in Ptolemy II[1], an open-source software framework for modeling, simulation and design of large concurrent real-time systems. This framework is a system-level design environment that provides the possibility of combining several variants of models of computation (MoCs) in one hierarchical heterogeneous model. Ptolemy II also supports an actor-oriented view of a system where the basic building blocks of a system are concurrent components called actors which communicate through messages sent via interconnected ports.

Ptolemy II currently supports numerous concurrent programming models, such as process networks, discrete event or continuous time models and interfaces with other simulations tools such as Matlab [2]. In this paper we present the integration of Modelica models in Ptolemy II through an integration with the OpenModelica tool.

Modelica[3] is a non-proprietary, object-oriented,

equation based language aimed at modeling complex multi-domain physical systems. Moreover, this language is supported by a number of free and commercial tools, in particular by OpenModelica [4], an open source compiler and tool suite, complete with a text and graphical modeling editor (OMEdit) for modeling and simulation of cyber-physical systems.

The Modelica Standard Library contains a large number of models and functions from multiple domains. Integrating Modelica in Ptolemy would enable the use of these models in concurrent system modeling, as well as models from many other existing libraries.

In this paper we present the integration process of OpenModelica into the Ptolemy II framework, and illustrate use of Modelica models from within Ptolemy II on a simple example.

The paper is structured as follows, Section 2 presents the basic blocks of the integration between OpenModelica and Ptolemy, Section 3 discusses the simulation mechanism, Section 4 presents the performances of the proposed implementation, Section 5 highlights some related works and finally Section 6 briefly sums up the contents of the paper.

## 2 Integration Architecture

Ptolemy II is composed by a number of different domains and supports an actor-oriented modeling paradigm. Actors are the main building blocks of the system. They are concurrent components that communicate through interfaces called ports. Relations define the interconnection between these ports, and the communication structure between actors. Viewing a system as a structure of actors emphasizes its causal structure and its concurrent activities, along with their communication and data dependencies. A consequence of an actor-oriented view of a system is the decoupling of the transmission of the data from the transfer of control [5].

## 2.1 OpenModelica director

Ptolemy II is modular and relies on a well-organized package structure where the core packages support the data model, or abstract syntax, of Ptolemy II design. These packages also support the abstract semantics that allows domains to interoperate with maximum information abstraction. The user interface packages provide support for our XML file format, called MoML, together with a visual interface for constructing models graphically. The library packages provide actor libraries that are domain polymorphic, meaning that they can operate in a variety of domains. Additionally, the domain packages provide domains, each of which implements a model of computation. Some of which provide their own, domain-specific actor libraries.

A model of computation (MoC) is defined as a set of rules that governs the interactions between components and determines the semantics of a model. Moreover, these rules determine when actors perform internal computation and update their internal state. The semantics of the computation model are implemented through the concept of *Director*.

In order to integrate OpenModelica into Ptolemy II, it is necessary to create a dedicated computation domain with the corresponding director. Since Modelica is a language designed for continuous and discrete event modeling modeling of physical systems and variables described using DAEs, the continuous-time domain in Ptolemy II which models physical processes and supports mixtures of discrete and continuous behaviors is considered the most suitable for the Modelica language. Therefore the OpenModelica domain extends the continuous time domain already present in Ptolemy. Figure 1 shows the OpenModelica director with its parameters, such as the number of iterations or the solver to be used .

The integration work described in this paper involves three sub-packages of the domain package: `kernel`, `demo` and `lib`. The kernel package provides the software architecture for the Ptolemy II data model, or abstract syntax. This abstract syntax has the structure of clustered graphs. The classes in this package support entities with ports, and relations that connect the ports.

## 2.2 OpenModelica actor

Actors, the basic building blocks of a system, are the executable entities used to build the models. The OpenModelica actor reads one or more inputs from

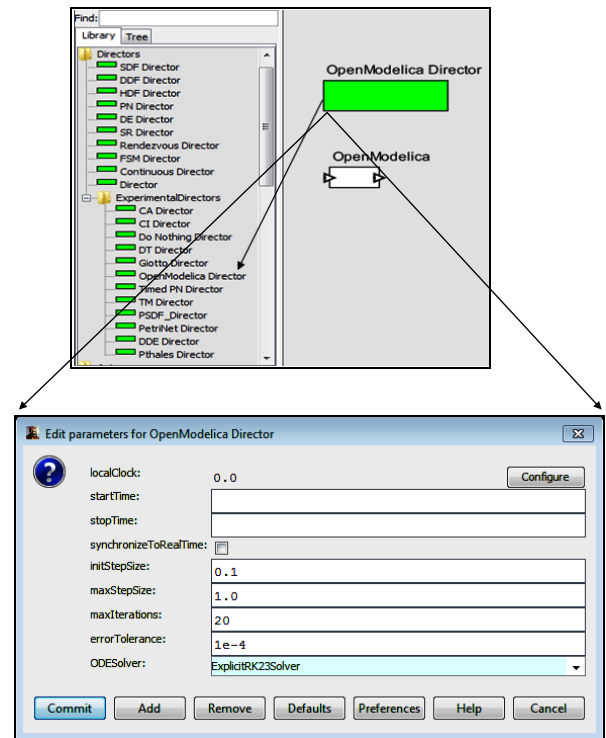

Figure 1: OpenModelicaDirector is provided on the left menu under the Directors → ExperimentalDirectors.

other actors and simulates the Modelica model. This simulation can be done in either batch or interactive processing mode. The results of the simulation can then be passed to Ptolemy II actors, to be displayed or modified.

An execution in Ptolemy II is divided into the following phases: setup, iterate, and wrap-up. The setup phase is divided into two phases, preinitialize and initialize. The preinitialize sub-phase usually handles structural information, such as constructing dynamically created actors, determining the width of ports, and creating receivers. The initialize phase initializes parameters, resets local states, and produces initial tokens. The preinitialization and initialization of an actor are performed exactly once during the actor’s life cycle.

To organize the interactions among actors, an iteration is divided into **prefire**, **fire**, and **postfire**.

1. Prefire checks if the preconditions are fulfilled for the actor to execute, such as the presence of sufficient inputs to complete the iteration.
2. Most of the actions are taken place in the fire phase, which involves reading the inputs, processing data, and producing outputs. Some MoCs

Figure 2: We can see that the model to be loaded is contained in the file *dcmotor.mo*. We can also set the simulation parameters (in red), the parameters of the model (green), such as for instance the resistance of the resistor and apply a filter to select the variables that should be displayed (in yellow).

```

model dcmotor

  Modelica.Electrical.Analog.Sources.SignalVoltage signalVoltage1;

```

Figure 3: The parameters for the Modelica model can be set through the graphical interface in Vergil.

like synchronous reactive models and CT differential equations support fixed-point iteration which enables the computation of the fixed point of actor outputs while keeping the state of each actor constant.

3. Invocation of `fire()` several times prior to the invocation of `postfire()` results to updating the state of an actor at the time of reaching the fixed point. At the final stage, `wrapup()` is invoked to release resources that were used during execution.

The domain specific OpenModelica actor is defined in the `lib` sub-package. It is an atomic actor which is visible in Vergil [6], the graphical editor for the Ptolemy II framework.

In this paper, we illustrate the use of the OpenModelica actor to simulate a simple DCMotor example. When looking inside the actor, all the simulation parameters are displayed, as illustrated in Figure 2. When this model is parametrized through the Vergil interface, this will initialize the corresponding Modelica model (Figure 3).

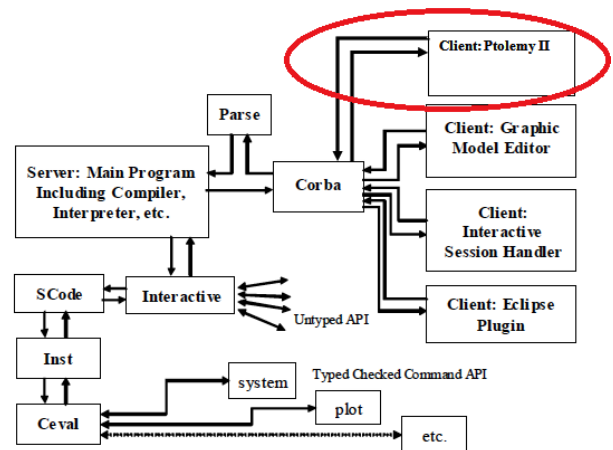

Figure 4: Client-Server interconnection structure of the compiler/interpreter main program and interactive tool interfaces after adding new Ptolemy II as a new client.

### 3 Simulation

To simulate Modelica models in Ptolemy II, it is necessary to invoke the OpenModelica Compiler (OMC). OMC provides a CORBA interface for remotely invoking the compiler from client applications. This interface is used to communicate with OMC from Ptolemy II (see Figure 4).

An OpenModelicaDirector (Figure 1), which extends the ContinuousDirector, is implemented in the Kernel package. The key function of this actor is `postfire()`, a method that will be invoked exactly once during an iteration, after all invocations of the `fire()` method in that iteration. However, in this integration, when `postfire()` is invoked in OpenModelicaDirector it returns false in order to stop/halt the invocation of `fire()` after firing once.

The communication between OpenModelica and Ptolemy follows the following pattern:

1. The OpenModelica actor starts the OpenModelica Compiler(OMC) server in the `initialize()` method, by invoking `startServer()`.
2. In the next step, value(s) of the Modelica parameter(s) are modified by Ptolemy IIs' actor(s) prior to the simulation of the Modelica model through OMC.
3. After simulation of the Modelica model, the retrieved result back from OMC server is plotted/displayed through Ptolemy IIs' actors.
4. Finally, OpenModelica actor sends the result to

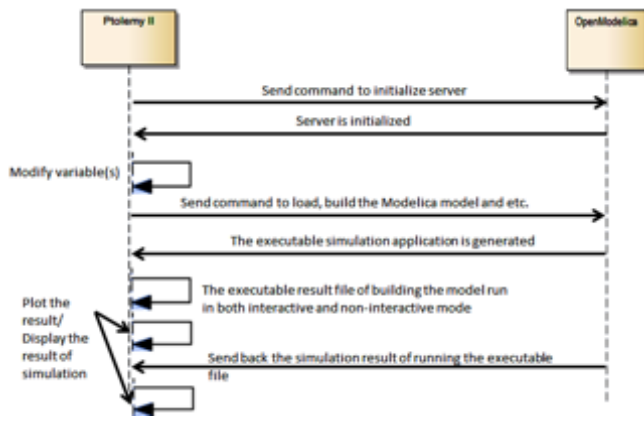

Figure 5: The interactions between Ptolemy II and OpenModelica can be summarized by the following diagram.

the output port which enables using the generated result by other Ptolemy IIs' actors.

All these actions are invoked in the `fire()` method. In the final step, the OMC server is halted through invoking `stopServer()` in the `wrapup()`. These steps are summed up in Figure 5.

The `OMCCCommand` class provides the implementation for all the functionalities required by the `initialize()`, `fire()` and `wrapup()` methods, except for modifying the component values after simulation. This functionality is provided by the `UntilSocket` class. Figure 6 presents the class diagram of the implementation, which contains around three thousand lines of code. `OMCCCommand` is the largest class, containing over a thousand of code lines. Since the Ptolemy II framework is written in Java, the `OpenModelica` extensions are also done in Java. Appendix A includes a code snippet that shows the implementation of the `fire()` method.

In order to integrate the `OpenModelica` actor with components for displaying the simulation results in ptolemy, a composite actor is constructed. Figure 7 shows the Composite actor that is used for plotting CSV format, the `OpenModelicaDirector` that controls the execution order of the `OpenModelica` actor and the `RunCompositeActor`, and `SDF` director which is known as the inside director of `RunCompositeActor` controls the execution of `CSVReader`, `RecordDisassembler` and `XYPlotter` whenever `RunCompositeActor` is executed.

In the current implementation both batch and interactive simulation are possible.

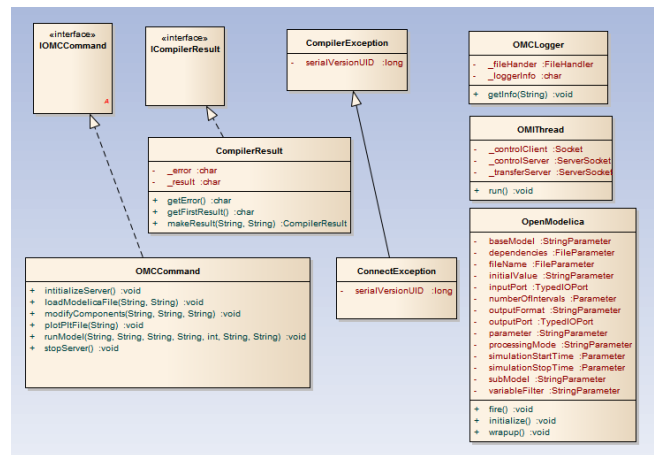

Figure 6: The class diagram for the current implementation.

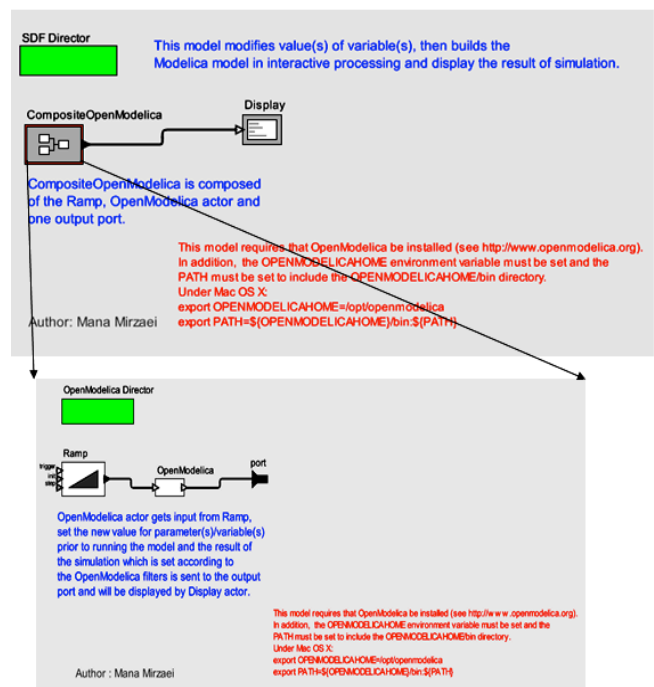

Figure 7: OpenModelicaXYPlotter model is composed of OpenModelica actor and RunCompositeActor.

### 3.1 Interactive Simulation

OpenModelica offers a user-interactive and time synchronous simulation known as OpenModelica Interactive (OMI). OMI is part of the simulation runtime core. The output of OMI is an executable simulation application, running the executable file in an interactive processing mode that enables users to govern the simulation runtime behavior.

The integration of OMI with Ptolemy is implemented through the following two modules, illustrated in Figure 8:

**Control module** is the interface between OMI and Ptolemy II which is implemented as a single thread to support parallel tasks and independent reactivity. The Control module is considered the major controlling and communication instance during the simulation initialization phase as well as for managing simulation properties throughout the simulation runtime. The Control module also reacts to the feedback from other internal OMI components and sends some messages back to Ptolemy II including error and status messages.

**Transfer module** gets simulation results from a result manager and sends them to Ptolemy II upon launching a simulation. Additionally, the module employs a filter mask allowing the user to select the variables whose result values are significant to Ptolemy II.

At the moment only the step by step simulation of the OpenModelica models is possible, however the next step in the development process is to implement cosimulation. Figure 9 illustrates the results of an interactive simulation, new value(s) for variable(s) of the Modelica model can be set in the *initial value(s)* parameter or the Ramp actor parameter which can be customized in the same way as the OpenModelica actor. The value of the *init* parameter of the Ramp actor overrides the value of *initial value(s)* parameter of OpenModelica actor.

The step time of the simulation in interactive processing is calculated by following formula:  $Simulation\ step\ time = (Simulation\ stop\ time - Simulation\ start\ time) / (Number\ of\ intervals)$ .

According to the above formula, the step time is 0.0002 [ (1.0 - 0.0)/500] in this example. The calculated step time results in the start of the simulation at 0.0002 and completion at 0.0998, as shown in red in Figure 9.

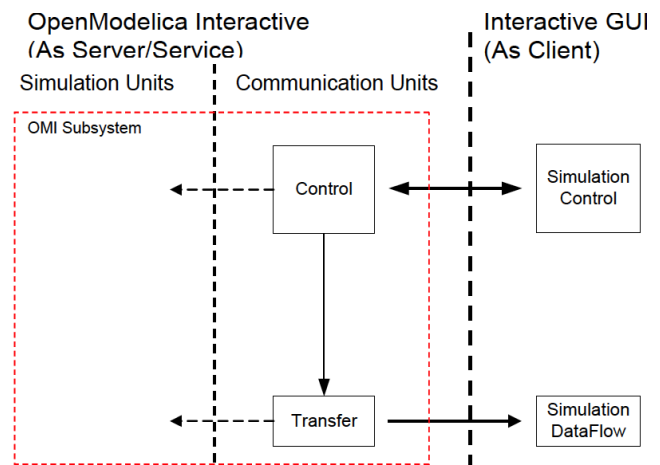

Figure 8: Interactive simulation mechanism.

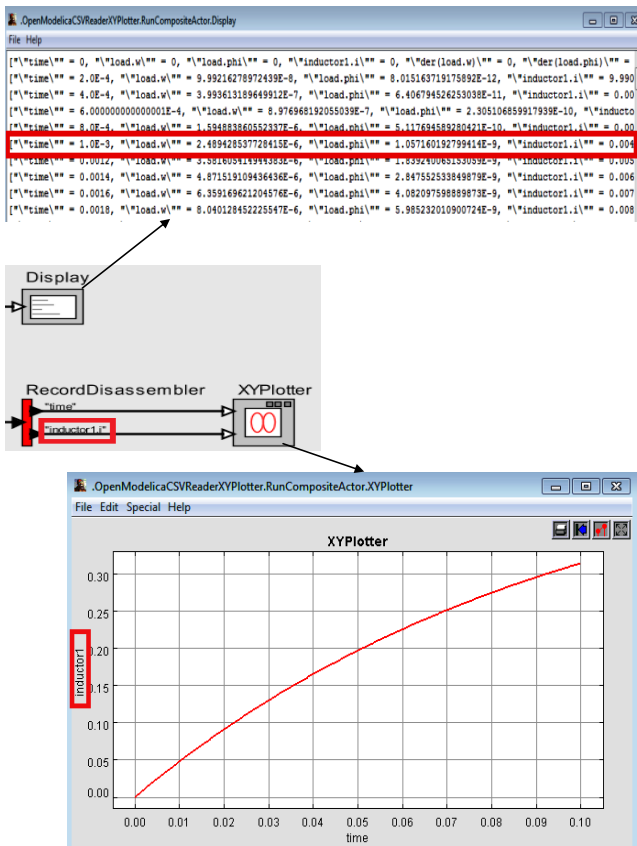

Figure 10: The generated output is displayed in XY-Plotter as well as in textual format by the correspond- ing actors.

### 3.2 Non-interactive simulation

There is also the possibility of running the executable simulation application which is generated by OMC in a non-interactive simulation runtime. In contrast to Interactive Simulation, this method does not offer any user-interactive simulation. Running the executable file in batch processing mode allows to generate the whole simulation result in CSV or PLT file formats (Figure 10) that can be displayed and used by other actors in Ptolemy II.

## 4 Performance

In this section we compare the simulation times of two test models in OpenModelica and when simulating them through Ptolemy, to estimate overhead. The following table compares the two:

Use Case	in Ptolemy II	in OpenModelica
OMXYPlotter	25021ms	30ms
OMPltPlotter	28673ms	12ms

As simulating the models in Ptolemy involves establishing a connection with the OpenModelica compiler and exchanging data, some overhead is to be expected. However it is the tradeoff for simulation in a heterogeneous environment.

## 5 Related Works

An integration between Dymola, one of the commercial tools for Modelica modeling and simulation, and Ptolemy II through a software environment known as BCVTB4 has been developed [7]. In this approach, Ptolemy II acts as the middleware for implementing BCVTB and actors in Ptolemy II are responsible for starting a server that uses the BSD5 socket utilized for exchanging data between the simulator and the actor as well as implementing the inter-process communication. This approach is implemented by adding BCVTB block to the Dymola library and it is necessary to include this block in the Modelica model in order to enable co-simulation.

FMI (Functional Mockup Interface) is an evolving standard for composing model components designed using distinct modeling tools that can also be used in the cosimulation of models [8].

## 6 Conclusion

In this article we have presented the integration of Modelica models in the Ptolemy II framework for modeling large-scale heterogeneous concurrent systems. This will allow the simulation of Modelica models through the use of the OpenModelica compiler within the Ptolemy II network.

Moreover the current architecture can serve as a base for further integration efforts, such as the bisimulation of Modelica models in conjunction with other formalisms.

## Appendix A

The following code snippet shows the implementation of the `initialize()` method:

```

/** Invoke the fire() of the super class. Then, Modelica library and model(s) are loaded.
 * Upon modifying the value of variable(s) and parameter(s) by input port or actors'
 * parameters,
 * the Modelica model is built in <i>non-interactive</i> or <i>interactive</i> mode.
 * <p>After building the model in an interactive mode, the simulation result
 * is calculated step by step according to the parameters of the OpenModelica actor.
 * The result is sent in the string format to the output port of the OpenModelica
 * actor to be
 * displayed by Display actor.</p>
 * @exception IllegalArgumentException If the evaluation of the expression
 * triggers it, or the evaluation yields a null result, or the evaluation
 * yields an incompatible type, or if there is no director.
 */
public void fire() throws IllegalArgumentException {
    super.fire();

    // Load Modelica library and model(s).
    try {
        _omcCommand.loadModelicaFile(fileName.getExpression(),
            subModel.getExpression());
        // If the model is inherited from a base model,
        // that base model should be loaded in advance to the derived model.
        // Otherwise, the derived one could not be built.
        if (!(dependencies.getExpression().isEmpty() && baseModel
            .getExpression().isEmpty()))
            _omcCommand.loadModelicaFile(dependencies.getExpression(),
                baseModel.getExpression());
    } catch (ConnectException e) {
        throw new IllegalArgumentException(
            "Unable to load Modelica file/library!" + e.getMessage());
    }

    // There is a value to be passed to the OpenModelica actor's port.
    if (input.getWidth() > 0) {
        // Get the token from input port of OpenModelica actor.
        IntToken inputPort = (IntToken) input.get(0);
        try {

# On Extending JGrafchart with Support for FMI for Co-Simulation

Alfred Theorin    Charlotta Johnsson

Department of Automatic Control, Lund University, Lund, Sweden

## Abstract

Grafchart is a graphical programming language which extends Sequential Function Charts (SFC), the PLC standard languages for sequential, parallel, and general state-transition oriented automation applications. SFC is widely used and accepted for industrial automation. Grafchart adds higher level features to SFC such as hierarchical structuring, reusable procedures, and exception handling to make it convenient to implement and maintain large applications.

Functional Mock-up Interface (FMI) is a standard to combine dynamic system models for technical system developed in various tools. Tools can export models as Functional Mock-up Units (FMUs) which can be combined with other FMUs to compose the whole system.

In this paper adding *FMI for Co-Simulation* support to JGrafchart, a free implementation of the Grafchart language, is conceptually evaluated. It is discussed how JGrafchart fits into the *FMI for Co-Simulation* framework and potential ways to implement this are discussed. *Keywords: Grafchart; FMI; Co-Simulation; FMI for Co-Simulation; Modelica*

## 1 Introduction

Grafchart is a graphical programming language which extends Sequential Function Charts (SFC), one of the IEC 61131-3 [1] PLC standard languages for sequential, parallel, and general state-transition oriented applications. SFC is supported by most large industrial automation systems, for example 800xA by ABB, SIMANTIC S7 by Siemens, RSLogix 5000 by Rockwell Automation, DeltaV by Emerson, and CENTUM CS by Yokogawa. SFC is widely used and accepted for industrial automation, but is a low level programming language and thus implementing larger applications in SFC is inconvenient. Grafchart adds high level features such as hierarchical structuring, reusable procedures, and exception handling which makes it convenient to implement large applications that are

overviewable and maintainable [2].

Functional Mock-up Interface (FMI) is a recent standard [3] which aims at combining dynamic system models developed in various tools. Modelica [4], the state of the art language to express dynamic behavior of technical systems, promotes this standard and the number of tools supporting FMI is growing rapidly. A tool can export a model as a Functional Mock-up Unit (FMU) which can then be combined with other FMUs to compose the whole system. The FMI standard consists of two parts, namely *FMI for Model Exchange* and *FMI for Co-Simulation*. The difference is that for *FMI for Co-Simulation* a FMU also includes an individual solver to simulate its behavior.

In this paper adding *FMI for Co-Simulation* support to JGrafchart, a free implementation of the Grafchart language, is conceptually evaluated. In Section 2 *FMI for Co-Simulation* is described, in Section 3 the Grafchart and JGrafchart basics are covered, and Section 4 motivates the need to connect JGrafchart to *FMI for Co-Simulation* and discusses possible ways to implement this. Finally, future work is discussed in Section 5.

## 2 FMI for Co-Simulation

*FMI for Co-Simulation* is a standard which enables simulation of coupled technical systems with focus on time-dependent problems. It is designed for both standalone FMUs and FMUs which are FMI wrappers for simulation tools.

A co-simulation is executed from a given starting time to a stop time which is not necessarily pre-specified. There is an FMI *master* which coordinates the co-simulation and there are FMU *slaves*, each corresponding to one model or subsystem. Each *slave* has a pre-specified set of inputs and outputs which are known by the *master*. The *master* is responsible for initialization of the *slaves* and for handling the coupling between them by getting and setting their inputs and outputs.

The co-simulation is executed for one time interval at a time, known as a *communication step*, during which each *slave* executes independently. Between the *communication steps* are the *communication points* where the *master* communicates the inputs and outputs between the *slaves*. *Slaves* can specify their desired *communication step* size and the *communication step* size may also vary during the co-simulation provided that all *slaves* support this. A *communication step* may also fail. Then a new *communication step* of different size may be attempted if all *slaves* support redoing *communication steps*. It is the *master* which decides the *communication steps* and what to do when one fails.

The standard does not define an FMI *master* algorithm, and the level of sophistication is decided by the one who implements the *master*. What the standard does define is the API, a set of *slave* capabilities, and rules for how these may be used.

An FMU is described by an XML metadata file which primarily contains the inputs and outputs and co-simulation capabilities such as support for redoing *communication steps* and support for variable *communication step* size.

### 3 Grafchart

Grafchart has the same graphical syntax as SFC with steps and transitions, where steps represent the possible application states and transitions represent the change of application state. Associated with the steps are actions which specify what to do. Associated with each transition is a Boolean guard condition. It is a state machine related language which has been developed particularly with automation in mind and with focus on scalability.

A part of a running Grafchart application is shown in Figure 1. Here two steps are connected by a transition and there are two variables, namely *var* and *cond*. In the left part of the figure, the upper step has just been activated which involved executing its *S* action, thus setting *var* to 7. An active step is indicated by a black dot, known as a token. The upper step will remain active until the guard condition of the transition becomes true, that is, until *cond* gets the value 4. When the guard condition becomes true, shown in the right part of the figure, the upper step is deactivated and the lower step is activated which means that *var* is set to 12.

Steps also have additional properties, namely *x*, *t*, and *s*. *x* is true if the step is active and false if the step

Figure 1: A piece of a running Grafchart application. The left part shows one application state and the right part shows a later application state.

is inactive. *t* is how many scan cycles the step has been active since the previous activation if the step is active. For inactive steps *t* is 0. *s* works the same as *t* but counts seconds instead of scan cycles.

Grafchart supports basic SFC functionality such as alternative and parallel paths, see Figure 2. At any time only one alternative path may contain active steps. On the other hand, parallel paths are executed in parallel and will contain active steps at the same time. To create alternative paths a step is connected to several transitions. To create parallel paths a Parallel Split is added to split the execution. A Parallel Join is used to merge the execution again when the parallel paths are completed.

Figure 2: A Grafchart application showing how to express alternative and parallel paths.

In Figure 1 only the S action type is used. S actions are executed on step activation. SFC also supports several other action types (action qualifiers) which have other semantics. Grafchart supports fewer action types. However, these are more general and can, among other things, be used to implement the semantics of all action types of SFC. The main action types in Grafchart are S (executed on step activation), P (executed periodically while step is active), X (executed on step deactivation), and N (sets a boolean variable to true (false) on step activation (deactivation)).

Additional constructs such as hierarchical structuring, reusable procedures, and exception handling have been added in Grafchart which makes it convenient to implement large applications that are overviewable and maintainable [2].

With reusable components, code duplication is avoided. Reusable code can be put in a Grafchart Procedure which can then be called from any number of Procedure Steps and Process Steps, see Figure 3. The difference between Procedure Steps and Process Steps is that Procedure Steps wait for the call to complete before the application can proceed while Process Steps do not.

Figure 3: A Procedure can be called from Procedure Steps and Process Steps. Each Procedure Step and Process Step specify which Procedure to call when activated.

### 3.1 Execution Model

Grafchart has a well defined execution model which ensures sufficiently deterministic execution behavior. A transition is *enabled* when all immediately preceding steps are active. An *enabled* transition is *fireable* if

its condition is true. *Firing* a transition involves deactivating the immediately preceding steps and activating the immediately succeeding steps.

Grafchart applications are, like SFC, executed periodically, one scan cycle at a time. The execution model of a scan cycle is described by the following sequence:

1. Read inputs.
2. Mark fireable transitions.
3. Remove mark for conflicting transitions of lower priority.
4. Fire marked transitions.
5. Update step properties  $t$  and  $s$ .
6. Execute P actions.
7. Mark variables subject to N actions.
8. Update marked variables.
9. Sleep until the start of the next scan cycle.

The execution model has the property that an activated step always remains active for at least one scan cycle. Note that the execution model does not give a completely deterministic execution. For example the firing order of transitions affects which step's S and X actions are executed first. Another example is which step's P actions are executed first. The application is not allowed to depend on the execution order in these cases.

## 3.2 JGrafchart

JGrafchart is a free Java based integrated development environment for the Grafchart programming language which can be downloaded from <http://www.control.lth.se/Research/tools/grafchart.html>. It is a research tool used in for example the EU/GROWTH project CHEM for control in process industry [5], the EU FP7 project ROSETTA for robotic assembly [6], and a master's thesis for modeling of avionics systems [7].

### 3.2.1 Inputs and Outputs

JGrafchart can be connected to external environments through a multitude of customizable input/output (I/O) integration capabilities and can thus be used to control external real and simulated processes. This is used in education, for example in laboratory exercises on sequential and batch control, and to control real industrial processes.

One I/O possibility in JGrafchart is the *CustomIO*, that is, the I/O elements Digital In, Digital Out, Analog In, and Analog Out as well as inverted variants

for the Digital In/Out. At the beginning of each scan cycle each In I/O is read from the external environment. An Out I/O is written to the external environment whenever assigned. How the I/O interact with the external environment depends on the chosen I/O implementation. A custom I/O implementation is created by implementing a set of Java interfaces. With a custom implementation it is possible to communicate with practically any external environment. However, it is limited to Boolean and Real values.

There is also generic support for communicating with Devices Profile for Web Services (DPWS) devices using the DPWS4J toolkit [8]. Devices and their supported operations are automatically discovered and can be called directly.

Another I/O possibility is the *SocketIO* elements. JGrafchart then connects to a TCP server and communicates Boolean, Real, Integer, and String values over a socket with the message protocol: `<identifier> '|> <value> '\n'`. The TCP server is responsible for the interaction with the external environment. *SocketIO* is often powerful enough to allow creation of external adapters to other communication protocols. It has for example been used to integrate JGrafchart with a multitude of tools and protocols, among others prototypes for Simulink [7], DPWS [9], LabComm, and OPC UA support.

It would be useful to also support code generation to be able to export JGrafchart applications as FMUs. Code generation has previously been added to JGrafchart [10, 11] but, due to the current JGrafchart code base design, the results have been limited and fragile.

Currently JGrafchart only supports interpreted execution. To execute an application it must first be compiled. The compiler checks if the application is valid and prepares it for execution by attaching additional data. Applications are then executed directly in an interpreted manner using the same Java instances as the editor. JGrafchart is currently being split into three standalone parts, namely editor, compiler, and executor. This makes it possible to add robust code generation capabilities.

## 4 JGrafchart with FMI Support

### 4.1 Motivation

In one of our laboratory exercises, JGrafchart is used to control both a simulated and a real batch tank. The simulated process is implemented as a simpli-

fied model in Java. It is also possible to implement simulations of simple processes directly in JGrafchart [12]. However, there is much potential for improvement in terms of effort for specifying the simulated model, quality of the models, support for inspecting simulation results, and time required to simulate, especially for more complicated physical systems. Extending JGrafchart with support for *FMI for Co-Simulation* gives more and better opportunities to connect JGrafchart to other tools.

There is also a need to efficiently develop and test JGrafchart control applications before using them to control the real system. This may save a lot of time as many industrial systems have slow dynamics and running a simple test on the real system could take days. With a good model of the system the development time could be considerably reduced, and the quality of the control application will be higher as there is less resistance in the development process. Industrial systems are often dangerous and running a proper simulation first could be essential for safety reasons. For the batch tank in our laboratory exercise, the simulated process is 10 times as fast as the real process. Special code is required to add support for this which both makes it fragile and susceptible to errors as it is possible to run the control application in the wrong mode, for example in simulation mode against the real system. With a simulation environment that does not run according to wall clock time, it can be run faster and without the special code.

It is also important to verify that the system behaves properly when controlled by a JGrafchart application. JGrafchart executes periodically and only sees the sampled behavior. When controlling a continuous system, the behavior between the sampling points may also be of interest. Also, currently JGrafchart applications are always executed according to wall clock time. With a large or complex simulated system the JGrafchart application might execute faster than the rest of the system can be simulated.

Support for state machines were introduced in Modelica 3.3 [13] providing a proper way to implement hierarchical state machines directly in Modelica. On one hand, JGrafchart does not provide the mutual hierarchical structuring property with data flow that Modelica state machines do [13], but on the other hand it supports powerful high level language features such as object orientation, hierarchical structuring, code reuse, and exception handling. Additionally it is based on an industrial automation language.

## 4.2 Integration

JGrafchart supports the data types Real, Integer, Boolean, and String which correspond to the FMI data types `fmiReal`, `fmiBoolean`, `fmiInteger`, and `fmiString`. Both variables, lists (arrays), and I/O in JGrafchart use only these data types. The state of a JGrafchart application is described by the variable, list, and I/O values as well as which steps are active, how long they have been active, and currently active procedure calls. The number of simultaneous procedure calls and the list sizes are not limited and there are no semantics to limit this. However, there are no list I/O and procedures are not allowed to contain I/O so this is not an issue for *FMI for Co-Simulation*.

As the I/O in the JGrafchart application are the means of connecting it to external components, these would ideally be the FMU inputs and outputs. The mapping for *CustomIO* and *SocketIO* is straightforward. DPWS on the other hand is based on method calls instead of data and need some configuration to be able to expose the methods as data instead. Thus it is best to exclude DPWS, at least during prototyping.

JGrafchart applications are executed periodically, one scan cycle at a time, as described in Section 3.1. The execution can be modeled as discrete events at the beginning of each scan cycle. During the rest of the scan cycle nothing happens. Ideally, there would be *communication points* just before and just after the beginning of each scan cycle. With a sufficiently small *communication step* size this should work fine for all JGrafchart applications, regardless of scan cycle time. This could be requested by setting the `stepSize` attribute of the `DefaultExperiment` element in the FMU XML.

JGrafchart applications are currently always executed according to wall clock time and it is not possible to get and set the execution state as there has been no need for this before. However, it should be possible to extend JGrafchart with the possibility to get and set the current execution state to support redoing *communication steps*.

## 4.3 Architecture

This section discusses various ways to connect a JGrafchart application to an FMI *master*.

### 4.3.1 Hardware-in-the-loop

The simplest way is to consider the JGrafchart application as a hardware-in-the-loop, see Figure 4. Then the

JGrafchart application executes as usual, with the FMI *master* getting and setting its I/O. As discussed before, the co-simulation must then be able to keep up with and synchronize with JGrafchart's wall clock time execution. The main advantage with this approach is that no modifications to JGrafchart are necessary, it would be sufficient to create an FMU compatible *CustomIO* or TCP server for *SocketIO*. This is a suitable approach for FMU integration prototyping but it does not improve matters for systems with slow dynamics.

Figure 4: Overview of connecting JGrafchart as a hardware-in-the-loop.

### 4.3.2 Generic FMI Wrapper

Another approach is to implement a generic FMI wrapper for JGrafchart and extend JGrafchart with support for external clocks, see Figure 5. It is a small effort to add this feature. The same FMI wrapper would be possible to use with all JGrafchart application but the wrapper would expose different inputs and outputs to the FMI *master* depending on the JGrafchart application. This approach only requires slightly more effort than the hardware-in-the-loop approach and gives more benefits as the co-simulation no longer executes according to wall clock time. For this approach it is suitable to also add support for playback and to be able to inspect individual scan cycles of the JGrafchart application during the co-simulation. To add these features should only be a moderate effort, it could be as simple as trace printouts or as advanced as interactive scan cycle stepping. Compared to the hardware-in-the-loop case, the main drawback is that modifications to JGrafchart are required. However, these additions are great additions in general and are not solely useful for *FMI for Co-Simulation*. For example they open up possibilities for integration with other tools and improves JGrafchart's debugging capabilities.

Figure 5: Overview of connecting JGrafchart with a generic FMI wrapper.

### 4.3.3 Standalone FMU

The last approach discussed in this paper is to generate a standalone FMU for a JGrafchart application, see Figure 6. The FMU is then self-contained and does not rely on JGrafchart running in parallel. This is a clean and portable approach but requires the most effort and might make it harder to inspect the co-simulation results. Until the JGrafchart compiler is standalone, the implementation would also be fragile.

Figure 6: Overview of using code generation to create a standalone JGrafchart FMU.

A hybrid approach is to use a generic FMI wrapper with both JGrafchart and the JGrafchart application embedded as additional FMU *resources*, see Figure 7. Then the FMU is standalone but no code generation is required. The main drawback with this approach is that the FMUs would be roughly 20 MB larger.

Figure 7: Overview of exporting a standalone FMU with integrated JGrafchart and JGrafchart application.

## 4.4 Implementation

The FMI API is defined for C and FMUs are distributed with C source code and/or binary executables for supported platforms. JGrafchart is written in Java and is platform independent. However, the FMU itself can be implemented in any language which is able to interact with C code, that is, practically any language. There are language specific wrappers for FMI, for example PyFMI for Python [14] and JFMI for Java [15] which uses JNA [16] to interface with native code. Which language is chosen is less important and up to the one who implements the FMU. However, the *CustomIO* implementation must be written in Java.

## 5 Future Work

Extending JGrafchart to support *FMI for Co-Simulation* is only conceptual so far. It looks promis-

ing and there are several alternative ways that it could be implemented.

The next step is to implement a prototype to verify that it works in practice. A suitable first attempt would be a hardware-in-the-loop approach using an unmodified version of JGrafchart and utilizing its *CustomIO* and/or *SocketIO* capabilities. However, this does not improve matters for slow systems. A desirable future solution would either be the Generic FMI Wrapper or the Standalone FMU.

## Abstract

Development of customized workflows and interfaces to deploy Modelica Functional Mockup Units (FMUs) with the various FMU tools has been gaining traction in the industry – both with tool vendors as well as end users.

The FMI Add-in for Excel (FMIE) is a commercial product from Modelon AB that enables the deployment of FMUs in Microsoft Excel. FMIE enables the user to programmatically control the add-in through Visual Basic code in Excel. This allows the implementation of custom workflows and interfaces for the user to interact and automate the tasks involved in loading, simulation and analysis of FMUs.

In this paper we present a workflow in FMIE for an automobile thermal management model FMU. The workflow utilizes Visual Basic scripts for automation and user-forms for user interaction.

## 1 Introduction

The Functional Mock-up Interface (FMI) defines an interface to be implemented by an executable called the Functional Mock-up Unit (FMU) to describe, evaluate and simulate models of dynamic systems defined by differential, algebraic and discrete equations in different simulation environments [1][2]. The FMI standard has greatly facilitated the transfer, exchange of dynamic models between component suppliers and Original Equipment Manufactureres (OEMs) and enabled export and import of models between multiple simulation platforms that have FMI export/import functionality.

The FMI standard as a result, is gaining traction in the industry as the technology of choice in the ex-

change of dynamic models between suppliers and OEMs. As a result, there have been a large number of FMU deployment tools of which the FMI Add-In for Excel (FMIE) [3] developed by Modelon AB is a popular choice among customers.

The FMIE integrates FMI-based parallel simulations in Excel. The add-in offers the following features:

- Simulation of compiled dynamic models, FMUs generated by any FMI-compliant tool such as Dymola, OPTIMICA Studio or Simulation X.
- The add-in takes advantage of powerful features in Excel to set up and perform batch simulations for parameter sweeps and simulations driven by data series.
- Perform dynamic simulations or solve initialization problems, in parallel.
- The FMI add-in supports FMU for Model Exchange 1.0 and FMI for Co-Simulation 1.0.

Due to its application in multiple engineering domains and across several organizations, FMIE provides a general interactive environment through the Microsoft Ribbon interface. From version 1.2 onwards, FMIE enables the user to programmatically control the add-in through Visual Basic code in Excel. This has opened up interesting possibilities to create custom workflows to automate several tasks in the loading, simulation and analysis of FMUs in Excel with FMIE.

The workflow includes both scripting automation and a customized graphical user interface (GUI). The automation includes filtering of variables to set-up experiments, loading values for these filtered variables for simulation and scripts for plotting the output response to these experiments. Additionally, macros to do the same for Design of Experiments (DoE) and Monte-Carlo analysis where many hundreds of simulation cases are to be generated in a single experi-

ment possibly with statistical distributions for multiple parameters/variables. The workflow presented in this paper allows all of these steps to be performed in just a few mouse clicks interactively and improves efficiency and ease of use.

Further, for visualization of results, a customized GUI is presented as a Visual Basic for Applications user form within Excel. It presents a streamlined interface for plotting experiment trajectories to the end user. This allows the user to quickly find available trajectories and generate default charts for visualizing and comparing the results.

## 2 The FMIE Interface

The FMIE provides a general graphical interface through the Microsoft Ribbon interface and appears as one of the tabs in the Ribbon interface of Excel and labeled as 'FMI' as shown in Figure 1. The FMI tab contains four different groups of buttons.

Figure 1: The FMIE Native Interface

The FMI tab in the ribbon is divided into four groups: **Load**, **FMU**, **Experiment** and **Info** as highlighted in Figure 1 and respectively have buttons to load, create and set-up, simulate and analyze results of FMU's. In addition to these buttons, the functionalities of these buttons are mirrored with API function calls that are listed in Table 1. These functions are written in Visual Basic and the code for these is accessed from opening Visual Basic from the Developers tab.

### 2.1 Structure of loaded FMU and experiment sheets

The FMIE follows a pre-defined structure to how the information about input, output variables and parameters from the FMU are displayed in Excel. The loaded FMU displays meta-data containing general information of the FMU model e.g. model name, FMU kind, number of state variables etc. The list of input, output variables and parameters are displayed under the Variables section in the same worksheet. The variables are identified by the name, variability, start value, unit, description etc. and there is a column to indicate if the variable in the corresponding row is to be included in an experiment. This Boolean is set to "TRUE" if the variable is to be selected for analysis in an experiment. Each of these columns has a search filter associated with which the variable list can be parsed to select the appropriate variable set for analysis. This process gets tedious and inefficient when the number of variables in an FMU or the number of variables to be selected in an analysis is huge. As a result, any workflow to be developed should provide an easy and efficient way to filter out these variables for analysis.

Once the analysis variables are filtered and an experiment sheet created, the input variables and parameters are separated automatically by FMIE from the output variables in the experiment sheet. The nominal values of the inputs and parameters are also displayed and 3 default simulation cases already set-up. The user is to then create as many simulation cases as needed within the experiment by creating new columns adjacent to the 3 already created. The next step before simulating the FMU is to load the parameter, input values for the experiment. This is also to be done manually in the native interface and can be automated to improve efficiency. The next section describes a template for entering the variable list and parameter values for experiments that would enable the workflow created to automatically load these into the experiment sheet.

## 3 Workflow

A typical workflow involved in the set-up, simulation and analysis of FMUs is illustrated in Figure 2. At a higher level, the workflow follows a sequential procedure to load the FMU, filtering the relevant input, parameter and output variables for the study, create experiments and loading the input data for simulation, plotting and analysis of results.

To standardize the interface for user input and to facilitate data exchange between model developers and end-users, we present a simple front-end template for user input of information or data pertaining to the analysis to be performed. We present two templates – one for batch simulations involving parameter sweeps and the other for DoE and Monte Carlo studies. The proposed workflow is demonstrated in this paper with the example of a Co-Simulation FMU of a automotive thermal management system proposed in [4].

### 3.1 Batch Simulations

Batch simulations include parameter sweeps and experiments where one or more variables are changed individually or simultaneously and studying the effects of these on certain output variables. As a result, the batch simulation sheet needs to include sections for including the names of the input, parameter and output variables along with a description of each variable. Columns for entering user data are then classified according to the names of the experiments as shown in Figure 3.

Figure 2: A typical workflow in the set-up, simulation and analysis of an FMU.

### 3.2 Design of Experiments and Monte-Carlo Analysis

Similar to the batch simulation template, a template for Monte-Carlo analysis is also set-up as shown in Figure 4. This template includes fields to enter the type of statistical distribution and arguments for each statistical distribution. Figure 4 shows an example

where the efficiency multiplier of the heat exchanger stack is varied according to a Gaussian distribution with mean 1 and standard deviation 0.1. The current implementation of the workflow supports Gaussian, uniform and triangular distributions and can be easily extended to other Excel-supported statistical distribution functions.

Both templates provide a standardized structure for user-input of data for the workflow and enable convenient exchange of information between model developers and end users of the FMU.

Additional fields like the base class have been included in the template for model developers to provide a short description or a snapshot of the base class in which the variable is used, so as to give the end-users some insight into the variable.

### 3.3 Load FMU and Filter Variables

With the batch simulation or DoE template filled up with a set of variables and their corresponding input data like that shown in Figure 3-4, the next step in the workflow is to filter these variables and create an experiment sheet. A sample (partial) Visual Basic code shown in Table 2 is an example that loads an fmU and prompts the user to choose variables for filtering and creates an experiment with 7 cases with these variables.

```

Public Sub FMIE_Filter_vars()
Dim fmuFile As String
On Error GoTo ErrFileNotFound
' Path to FMU
fmuFile = Application.ActiveWorkbook.Path &
"\DriveCycleVTM.fmu"
' Load FMU into Excel
FMILoadFMU fmuFile, True, vbNullString
' Select & Filter variables to create experiment
Dim data As Range
Set data = Application.InputBox(Prompt:=
"Please select range", Title:="Range Select",
Type:=8)
<<Add VB code to set the Include attribute of
selected data to True>>
' Create Experiment sheet with 7 simulation cases
FMICreateExperiment ActiveSheet,vbNullString ,7
Exit Sub
ErrFileNotFound:
MsgBox "Error: FMU not found!"
  
```

Table 2: Sample VB code for loading FMU and filtering variables

The above code loads the fmU named 'DriveCycleVTM.fmu', and then prompts the user to select the names of the variables from the batch simulation or the DoE template sheet to be added to an experiment.

Enter Data in this sheet to perform Batch Simulations on FMU's				Modelon															
<b>Instructions:</b> 1. Load the FMU 2. Enter data for batch simulations for the parameters/variables of interest into the respective rows. <i>Max Limit: 16372</i> entries per variable. 3. Ensure the naming convention is consistent between this & the FMU sheets. 4. Set up the Experiment sheet by filtering the variables/parameters of interest. 5. Call the LoadData macro from the <i>experiment sheet</i> and use the user form to choose the variables and data entered in this sheet. For a full factorial sweep of all variables, check the permute option. 6. The data are now loaded in the experiment sheet and the experiments are ready to be simulated using FMIE.

Figure 4: Template for user-input for DoE and Monte Carlo analysis in FMIE.

The number of simulation cases to be set-up in the experiment sheet is also stated explicitly as shown in Table 2.

### 3.4 Loading Data into an Experiment

As noted in 3.1 above, the batch simulation template sheet includes fields to include the data for inputs and parameters to be set in experiments. Figure 3 includes data for two experiments labeled ‘Exp DC Batch’ and ‘Exp Const Speed’ where the model is simulated with different drive cycles in the former and a sweep over different speeds with a constant speed drive cycle in the latter.

To allow a more general way for users to load input data into the experiment sheets involving multiple parameter sweeps in the same experiment either as a full factorial or independent study, the user form shown in Figure 5 is used. A similar form for data input for Monte-Carlo Analysis is shown in Figure 6.

These user forms contain private sub-routines for processing the selected input and based on the options chosen, load the input data into the experiment sheet.

Figure 5: User form for data input for batch simulations

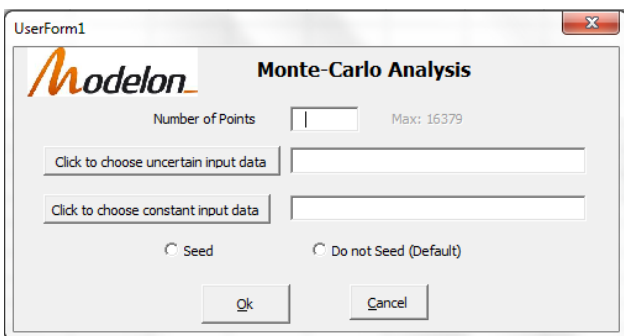

Figure 6: User form for data input for Monte Carlo analysis.

The user form for batch simulation for example lets the user choose a range of values for each variable and gives the option to run a full factorial sweep of

all values for all the parameters or input variables and also the option to choose a particular set of data points for exclusion from simulations. The user form for Monte-Carlo analysis has fields to enter the number of simulations cases to be performed in the study and options to choose the uncertain parameters and their corresponding attributes (statistical distributions and the corresponding arguments) and also the option to set input data for variables that remain constant throughout the simulation study. The option to seed gives the user the ability to repeat the simulation by generating the same set of randomly generated points as from a prior experiment.

The userforms described in this section along with the private subroutines that process the user input and load the data into the FMIE experiment sheet can be combined with the VB code shown in Table 2 to seamlessly integrate the entire FMU and experiment set-up procedure into a single macro for execution. And when combined with the analysis tools for plotting that are described in the next section, provide the user with an efficient and easy-to-use workflow in working with FMUs.

### 3.5 Plotting simulation results

When an end user chooses the option ‘‘Create Results’’ from an experiment sheet, FMIE will create a new ‘‘Result’’ worksheet. In general this will be the same name as the experiment sheet with the prefix ‘‘Res’’. The structure of these result worksheets are column oriented data of the selected output trajectories sequentially ordered by experiment case. From there the user is free to generate charts of this data as they would with other Excel data. To further increase usability for end users, custom GUIs can also be created to manage and generate these charts. An example of this is shown in Figure 7.

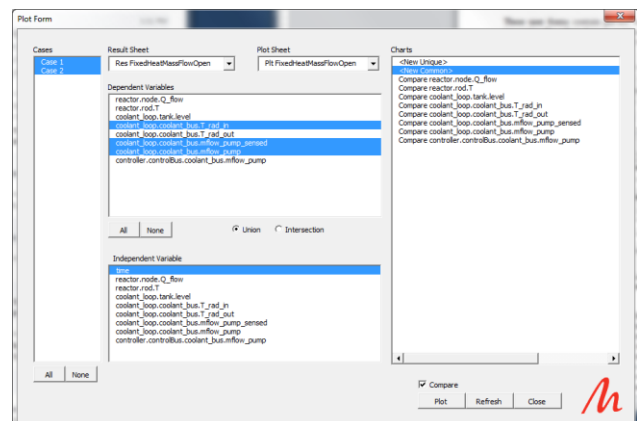

Figure 7: Illustration of the plotting GUI

The GUI maintains multiple lists relevant to plotable data from experiments. The first is a list of re-

sult sheets within the workbook. This allows the user to select which set of results they wish to use. When a particular result sheet is selected, the “Cases” list is updated with all the cases within the result sheet.

The user is then free to choose any combination of cases they wish to work with. As the case list selection changes the lists of dependent and independent variables also changes to match the corresponding variables for the selected cases. The user also has the option of choosing either the union or intersection of the set of variables for each selected case.

The user then chooses any combination of dependent variables and a single independent variable. By default time is selected. Next the user can choose an existing “Plot Sheet” or define a new sheet directly within the drop down list. The Chart list is updated to reflect existing charts on the sheet. This allows the user to add the selected trajectories to existing charts or to create new charts with the selected signals.

When new charts are chosen they are automatically added to the sheet without needing any user intervention on placement or style. The user is however free to manually modify the chart properties after it is created.

## 4 Conclusions

In this paper, an approach for implementing a workflow to deploy FMUs with the FMI Add-In for Excel was presented. A typical workflow in the set-up and analysis of FMUs was presented along with a general template in Excel of a front-end with which the end-user interacts. The macros created with the user forms for loading data and the FMIE API functions can be used as the back-end which enable the end-user to quickly and efficiently simulate and analyze FMU models with relative ease. They can also be used as the front-end interface for generating charts of simulation data for quick and simple visualization of results.

## Abstract

Investigating the use of different fluids and their advantages in new energy systems has increased the need for faster and more robust simulation models. The need to explore the potential of new fluids in different systems requires dynamic simulations for longer periods of time. In this paper, developing and improving a medium model for propane is discussed. Besides being fast and accurate, the propane model should also be stable in different dynamic simulation scenarios.

First, existing libraries are tested and in some cases modified to increase the stability. Since the simulation speeds were not in an acceptable range in the existing models, a new propane model based in the refrigerant models in HelmholtzMedia Library is introduced. The new model is then tested as a refrigerant in a direct exchange heat pump system. A comparison between an existing propane model and the new model shows that much faster simulations, up to 35 times, are possible with the new propane model.

*Keywords: Media Library; Propane; Refrigerant; Helmholtz Media*

## 1 Introduction

To address the main challenges arising from an ever increasing energy demand worldwide and its associated environmental impacts, it is not only essential to optimize the existing energy landscape but is also necessary to develop new approaches. One of these approaches is to utilize low-exergy heating and cooling systems.

A well-known method is by the use of heat pumps to extract energy stored in the ground. A conventional combination of a heat pump and a heat-

ing/cooling unit consists of three different hydraulic cycles, a primary cycle (energy source), a secondary cycle (energy sink) and a refrigerant cycle in between. For dynamic analysis of a complete heating or cooling system using a heat pump, the refrigerant cycle is usually considered as a black box model. This means that the thermal behavior of the refrigerant under different conditions is considered to be known without knowing the actual state of the refrigerant. Although this will reduce the accuracy of such a simulation, in larger scales, its great impact in the simulation speed is of higher importance.

To improve the affordability of heat pumps and reduce thermal losses in the heat exchangers between each cycle, the concept of direct exchange heat pumps is considered. This means that instead of having a heat exchanger between the energy source (ground) and the refrigerant cycle, the refrigerant flows directly inside the ground source. In simulations of such systems, a black-box model cannot be used and the whole behavior of the refrigerant should be simulated without compromising the simulation speed.

There are different methods of simulating different refrigerants. C. Heinrich et al. [1] have developed models for household refrigerant appliances using R600a, T. Pfafferott et al. [2, 3] have developed refrigerant models with CO<sub>2</sub> and R134a and I. Bell et al. [4] have created an open-source fluid library available for many different platforms using the Helmholtz equation of state. These methods use either internal or external functions. Although these methods can be expanded to different refrigerants, a separate propane model is not developed and the accuracy of the models was the main subject and not the simulation speed. Since simulation speed is of great concern, external media functions are not considered in this study. In the next chapter an available method of describing the behavior of refrigerants

internally is discussed. For further simplifications, only one refrigerant is considered.

Because of its low environmental impact, propane is chosen as the refrigerant and the modeling of this refrigerant is described in this paper.

## 2 Available Refrigerant Model

The design and simulation of heat pumps or power cycles require an accurate representation of the working fluid. In general a fluid is described by the equation of state and additional transport properties. The equation of state defines all thermodynamic properties in terms of two independent thermodynamic state variables. Usually these two variables are pressure ( $p$ ) and enthalpy ( $h$ ), temperature ( $T$ ) and density ( $\rho$ ) or, in case of one phase only, pressure and temperature. Today fundamental equations of state (EoS) in terms of Helmholtz energy are the most accurate method available for this purpose [5].

### 2.1 Helmholtz Energy Equation of State

As described in detail by [6], the Helmholtz EoS uses temperature and specific volume or density of the fluid as the independent variables. Other variables such as specific enthalpy, specific entropy as well as partial derivatives of several thermodynamic state variables can be calculated directly from these independent variables. Additional ancillary equations express the vapor pressure and the saturated densities in terms of the temperature and thereby define the boundary between single-phase and two-phase. Transport properties like surface tension, viscosity and thermal conductivity however are not part of the equations of state and have to be supplied for with additional independent correlations.

The Helmholtz energy equation of state excludes the two-phase region. Here all the remaining properties can be calculated under the condition of mechanical and chemical equilibrium for the liquid and the vapor phase. With this assumption, all thermodynamic properties can be calculated as a function of the dew and bubble state properties and the resulting steam quality.

A comprehensive explanation of the Helmholtz energy equation of state for the refrigerant propane can be found in [7].

### 2.2 HelmholtzMedia Fluid Properties Library

The HelmholtzMedia Fluid Properties Library is an open-source Modelica library. The library is devel-

oped to be expandable and contains several different refrigerants. The library covers a wide variety of applications since the implemented EoS are valid for a wide range of state variables.

As mentioned in [6], since the EoS are implemented in their general form, the library is not optimized for speed. Also because the fluid library is designed for all conditions, it may be unstable in certain complex combination of different components, such as complex energy systems that include closed fluid circuits, which should be avoided in large scale simulations.

## 3 Methods of Calculation of EoS

### 3.1 Inverse Calculation of EoS

Common variable combinations for engineering applications often are  $(p, T)$ ,  $(p, h)$  or  $(p, s)$ . The reason for choosing these independent state variables is on the one hand an improved computational stability and on the other hand the fact that changes of state are usually expressed via these variables. There are two ways to calculate the inverse of the equations of state. The first way is to use an implicit description which was done in the HelmholtzMedia Fluid Properties Library. The second solution is to do it explicitly which is done in the new propane model discussed later on.

### 3.2 Implicit Calculation of Inverse EoS

In order to compute all other thermodynamic properties from the chosen state variables, the corresponding  $(T, \rho)$  must then be determined iteratively, since the fundamental equation of state in terms of Helmholtz energy is non-reversible.

The iteration is a root finding algorithm available in the base library of Modelica. The two-phase boundary of the fluid is described by the vapor liquid equilibrium. The dew and bubble states are then calculated by solving two out of three conservative equations: the thermal equilibrium, the mechanical equilibrium and the chemical equilibrium. Ancillary equations for the saturation pressure and the dew and bubble densities help finding these states giving start values for the iteration. They also serve for a first region check for the inverse equation of state calculation. In the close proximity to the saturation line however, the exact values must be calculated by solving the vapor-liquid-equilibrium. The vapor-liquid-equilibrium represents a state where the rate of evaporation and the rate of condensation are the same on a molecular level. It is characterized by

three conditions: thermal equilibrium, mechanical equilibrium and chemical equilibrium [8].

### 3.3 Explicit Calculation of Inverse EoS

Due to the high computational effort for the implicit calculation of state an alternative way for expressing the state variables in terms of  $(p, T)$ ,  $(p, h)$  or  $(p, s)$  is implemented in Modelica. For these calculations, polynomial fit functions were developed for a predefined region. The maximum and minimum values were chosen according to the approximate range of operation of the application. Here a temperature region between  $-10^{\circ}\text{C}$  and  $70^{\circ}\text{C}$  and a pressure region between 0.5 bars and 30 bars was chosen (see Figure 1).

For this purpose, the inverse of the whole EoS was calculated numerically. The resulted data-set was then divided into six different sets (sub cooled liquid and superheated steam for density, specific enthalpy and specific entropy). Then a surface was fitted to each data-set separately. The outcomes of this fitting were six polynomial functions of order  $5 \times 5$ .

Figure 1: Range of validity for the inverse EoS

## 4 Implementation in Modelica

For all the necessary parameters, surface equations are added to the new media library. An example of such a surface is illustrated in Figure 2. The implemented media library is an extension of PartialTwoPhaseMedium which itself is an extension of PartialMedium in the Modelica Standard Library. This means that the simple propane model is also compatible with all the existing components in the Fluid library.

Moving from one region to the other makes the system not continues resulting in instabilities in solving the system of differential equations and therefore the whole simulation. To avoid these certain functions are developed for the smooth transition between each state of the fluid. These functions not

only include the correct value for the properties of propane at the discontinuous point, but also include the derivative so that smooth transitions are possible. Although this method will improve stability, since it is only applied in one point, the discontinuity of the functions can still be observed in the results.

Figure 2: Illustration of the fitted surfaces in a predefined region for pressure, temperature and specific enthalpy

## 5 Results and Discussion

### 5.1 Accuracy of the Fitted Functions

As discussed earlier, it is important for the model to be accurate. For this purpose, the Sum of squared errors (CSE), coefficient of determination (RSQUARE), number of evaluated points (DFE) and root mean square error (RMSE) are calculated for the fitted curves and are shown in Table 1. The low error values indicate a very fine fitting of the data.

Table 1: Accuracy of the inverse equations

Function	SSE	RSQUARE	DFE	RMSE
$\rho(p, T)_G$	0.009132	1.000000	296656	1.7545e-4
$\rho(p, T)_L$	0.185102	1.000000	104686	0.001330
$T(p, h)_G$	0.073031	1.000000	296656	4.9616e-4
$T(p, h)_L$	2.2526e-4	1.000000	104686	4.6387e-5
$T(p, s)_G$	1.171992	1.000000	296656	0.001988
$T(p, s)_L$	7.9326e-4	1.000000	104642	8.7067e-5

For comparison between the HelmholtzMedia and the fast propane model, both fluid models are simulated at different temperature and pressures in Modelica. The relative error between the two simulations is then calculated and is shown in Table 2. The relative error in all cases is close to zero. For all the simulation parameters, this error is much smaller than the uncertainty in the system.

Table 2: Relative error between propane in HelmholtzMedia and the fast propane

$T$ K	$\rho$ mol/cm <sup>3</sup>	$p$ Rel. Err.	$C_V$ Rel. Err.	$C_P$ Rel. Err.	$w$ Rel. Err.
200.0	14.0	-2.1e-8	3.9e-8	2.9e-8	1.4e-10
300.0	12.0	-5.2e-8	1.0e-7	5.0e-8	1.3e-8
300.0	0.4	3.2e-8	8.8e-8	9.4e-9	-1.2e-8
400.0	5.0	0.0	1.9e-8	-2.0e-8	-3.8e-8
369.9	5.0	2.4e-8	6.0e-8	0.0	-3.8e-8

It can be seen that in the specified range, the relative error between two models are very close to zero. This means if the change in propane properties does not fall behind the boundaries chosen for the surface-fitting, both models can be used interchangeably with minimal compromise in accuracy.

## 5.2 Simulation Speed Comparison

Since water is the main fluid used in different energy systems, simulations with water can be set as base simulations for comparison of the simulation time for the new fluid models. Here, the simulation speed of both fluid models are compared in identical simulation models with a reference model with the simple water model available in Modelica standard library as its medium. The results are shown in Figure 3.

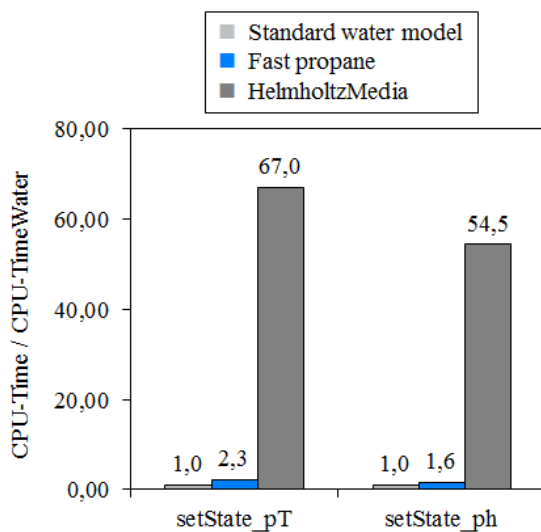

Figure 3: Simulation times for different propane models relative to water

The simulation speed of the fast propane is around 2 times slower than that of water but it is 30 times faster than the complete Propane model from the HelmholtzFluid library. This increase in simulation speed can ensure the possibility of simulating complete energy systems for a much longer period of time (monthly or yearly simulations).

## 6 Conclusions

To increase the stability and decrease the simulation time, HelmholtzMedia model for propane is modified for a certain region. The inverse calculation of the equations of states is done using several fitted surfaces instead of the actual EoS for the calculation of different variables.

It can be observed that the relative error between both models is almost zero, and on the other hand a significant increase in the simulation speed can be achieved, making the use of the fast propane model for larger simulations possible.

To conclude the differences between the two models, a simple comparison between the two models is shown in Table 3. This shows that although the HelmholtzMedia can be used for much wider range applications, for certain applications (ranges) it can be simplified so that much faster and more stable simulations are possible.

Table 3: Comparison between HelmholtzMedia and fast propane model

Property	Helmholtz Media	Fast Propane
Stability in complex systems	Not fully stable in complex energy systems with closed fluid circuits	Fully Stable between -10°C and 70°C and between 0.5 to 30 bars
Accuracy	100%	100% between -10°C and 70°C and between 0.5 to 30 bars
Simulation Speed / Simulation speed for simple water	60x	2x
Number of available media	9	1

The downside of the fast propane model is that it is only valid for a certain range of temperatures and pressures. Although this range is sufficient for many engineering applications in low temperature and low exergy heating and cooling systems, it is not sufficient for all the applications.

## Abstract

Systems engineers face the ever increasing chase for reduced time to market, while the systems to develop ever increase in complexity. Software systems design and integration processes have therefor evolved along the well-known V-cycle.

This paper will focus on the software integration for mechatronic systems as they develop fast due to high demands and challenging requirements in the automotive industry.

The development order of model in the loop (MIL), software in the loop (SIL), processor in the loop (PIL) and hardware in the loop (HIL) can be seen as state of the art practised by many systems engineers. Driver in the loop (DIL) may be in its infancy, but rapidly growing.

The novelty presented in this paper is the consistency of the plant models used in the integration chain supporting consistent model data propagation: Functional Mock-up Units (FMU) defined by the open standard of the Functional Mock-up Interface<sup>1</sup> (FMI).

*Keywords: FMI, FMU, MIL, SIL, PIL, HIL, plant models, Modelica*

## 1 Background

Volvo develops and calibrates its own engine control software. The model based design (MBD) process has been deployed for many years. The legislation on exhaust emissions and fuel consumption has become significantly stricter the past years. The change in legislation increases the burden of developing control software, calibration of parameters and validation of the mechatronic system. As a result efficiency improvements to the MBD process are required.

Experiences tell that the average development and project engineer does not feel comfortable with all aspects of MBD. It might simply be out of their comfort zone. Part of the project assignment was to bring MBD to the test and calibration engineer instead. These engineers shall be able to work with their de facto industry standard measurement, calibration and diagnostic (MCD) tools. The aim is to have a transparency for the software calibration tools as depicted in Figure 6.

## 2 Introduction

The FMI technology has been adapted fast by many modelling and simulation software vendors. This rapid adaptation of this open standard clearly is proof of an industry demand for (plant) model exchange. In the past the chain from MIL to HIL has been bridged by

many hours of manual labour to mix-and-match many, often for reasons of IP black-box, models from different sources and developed on different platforms. This was tedious work and error prone.

In the ideal case the plant model follows the entire integration process without any model modification. With the introduction of the FMI toolbox for MATLAB® Coder (FMIT-Coder) this vision is achieved.

Yet, the entire development chain from model in the loop to hardware in the loop can make use of one and the same source for a plant model exported as a Functional Mock-up Unit, FMU.

The main contributions of this paper are the use of consistent models throughout the integration workflow from desktop to test bed in the engine controller development, which by the introduction of the FMIT Coder has been made available. It is a solution to Volvo's mission to bring simulations to the test engineer. The engine test and calibration engineer can with help of industry standard protocols and tools, like the INCA<sup>9</sup> based product suite, do his/her calibration work against models or hardware.

The paper is outlined as follows. An introduction to the FMI technology is briefly drawn up, with emphasis on the toolbox available in MATLAB®. The engine and vehicle plant model based on commercially available Modelica libraries are introduced. This is to follow of a more detailed integration flow discussion with help of consistent use of FMU based plant models.

### 3 The Functional Mock-up Interface

#### 3.1 Introduction<sup>8</sup>

The FMI is a tool independent standard to support both model exchange (ME) and co-simulation (CS) of dynamic models using a combination of xml-files and compiled code.

The first version was published in 2010. The FMI development was initiated by Daimler AG with the goal to improve the exchange of simulation models between suppliers and OEMs. FMI is supported by many CAE tools and is used by automotive and non-automotive organizations throughout Europe, Asia and North America.

#### 3.2 FMI Toolbox for MATLAB

FMI Toolbox for MATLAB enables users to import FMUs into Simulink® models by means of a block-set supporting FMI for Model Exchange 1.0<sup>6</sup> and FMI for Co-simulation 1.0<sup>7</sup>. The FMU blocks can then be connected to native Simulink blocks, e.g., to support development of control systems and MIL scenarios. The FMU blocks offer a graphical user interface to parameterize the FMU, set initial conditions, configure outputs and to set the FMU log level, see Figure 1.

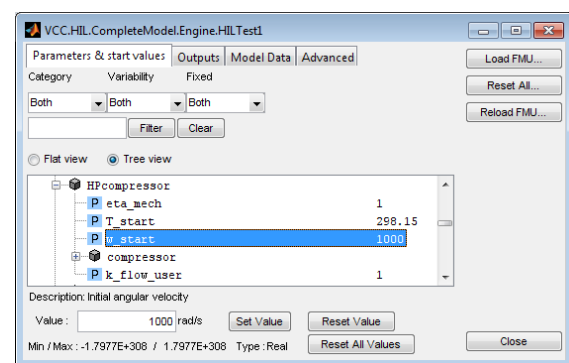

Figure 1 FMIT Dialog

#### 3.3 The FMI ME Calling Sequence

The option for co-simulation is a self-contained sampled system, but the model exchange alternative requires some tight interfacing with the master solver.

The FMI standard defines a calling sequence for simulating the FMU, see Figure 2. The FMI functions are executed in the appropriate order from the FMU block in the Simulink model. The FMU block is based upon an S-Function block which defines a list of call back functions. When the simulation loop is started, the S-function's call back functions are called which then calls the FMI functions.

For defining the engine load a vehicle model created with help of the Vehicle Dynamics Library<sup>®</sup> is deployed. The deployment of the vehicle model can either be in the same FMU as the engine model, because both used libraries are supported in Dymola, but may be two separate FMU's. The latter supports a transparent and consistent use of models all the way from desk top to an engine test bed.

Figure 3 Engine model diagram layer

## 5 Systems integration process

### 5.1 Introduction

For completeness many integration steps are outlined and discussed below, but a deployed development process does not necessarily include all presented steps in this document.

### 5.2 Model in the loop

The accessibility and quality of code generators has improved tremendously during the nineties. This has been an enabler for development of controllers in a simulation environment.

Developing control software in a simulation environment, like Simulink<sup>®</sup> in Figure 4, allows algorithm testing in a very early stage of development. The design iterations can be much faster, because the simulation environment allows the control engineer to

quickly change algorithms and instantly simulate and thus test.

Because the plant model is supplied as an FMU and run with help of the FMI Toolbox for MATLAB<sup>5</sup> (FMIT), the development engineer that actually masters the domain of the hardware can produce a plant model in his favourite and ideal modelling environment. In this case Dymola<sup>®</sup> Engine Dynamics Library<sup>®</sup>.

Figure 4 A MIL (blue block) example of a simple engine controller and an EDL based engine model exported as an FMU (white block)

### 5.3 Software in the loop

Once the algorithms in the MIL stage perform as designed the controller model can be transformed into c-code with a coder like Simulink Coder or TargetLink<sup>®</sup> including debug information. This exported software code can in its turn be linked with external sources of code or manual written code if desired.

The created code can firstly be tested in Simulink as shown in Figure 5. This solution mimics the MIL solution very closely.

The created code can also be hooked up to communicate with other systems and sub-systems in for instance Silver<sup>™</sup> by QTronic<sup>3</sup>. Silver supports virtual module integration and test automation. An important benefit for Volvo using Silver is the support it has for the already deployed engine calibration tools and protocols. The calibration engineer won't see the difference if s/he is calibrating a virtual or a real engine.

of using virtual vehicle models is that the environmental conditions are more controllable than in real vehicles tests.

The consistent usage of plant models across the different experimental domains allows propagation of parameters for the physical models and data for the empirical models for the plant models at different fidelity level all the way back to MIL.

(CSW) is interacting with the physical plant models.

Simulink Coder or TargetLink allow the CSW to be exported to Silver. This solution allows for SIL and VPIL. Silver supports standard CAN protocols and thus standard already available measurement, calibration and diagnostic (MCD) software can be used.

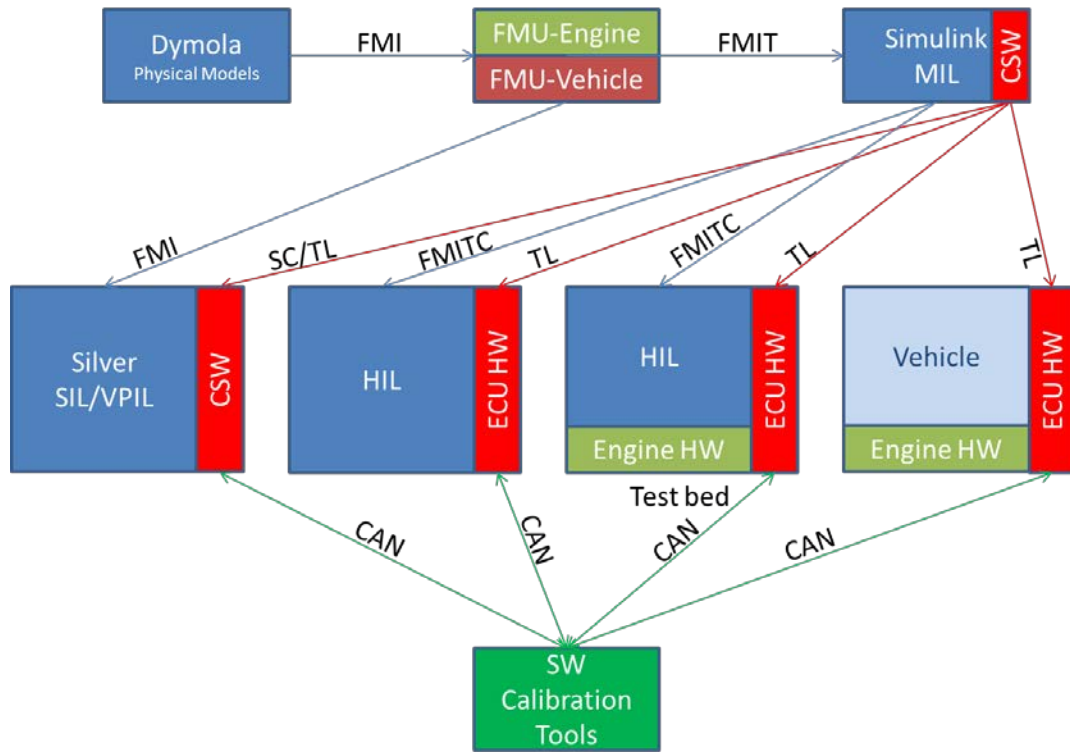

Figure 6 FMU’s central role in control system integration process. For sake of simplicity the PIL solutions are omitted. TL=TargetLink, SC=Simulink Coder, CSW=Control Software.

Data retrieved from tests will be part of data- and model regression and the process is thus improving quality of results over time.

### 6 Process summary

The process summary is depicted in Figure 6. Dymola is the environment where the plant models for the physical systems, engine and vehicle in this case, are created. These models are exported as FMU’s. On binary level these FMUs can with help of FMIT be used in Simulink and can also be natively imported to Silver. In Simulink the control software model

The next logical step is the export of plant models to the HIL environment with FMIT Coder. The model fidelity might be lower to account for the real time constraints this solution has. The CSW is in the real ECU hardware exported with TargetLink. Of course the standard MCD software can be invoked to alter the ECU calibration.

Currently the final stage will be the engine test bed that has its loads determined with an FMU for the vehicle with driveline. For the MCD software this is exactly the same use case as the HIL solution.

The test bed results can be fed back into the model parameters and data to evolve fidelity and quality of models. An iterative process is created to continuously improve model fidelity and quality.

At the end of the process of course, the engine and engine controllers are assembled in the vehicle. The same MCD-toolset can be used.

## 7 Conclusions

With the speed FMI technology is embraced in the industry is clear sign it has solved a long existing challenge for systems integration and validation engineers. Often tedious and error prone manual modifications to adopt the supplied models and data to different simulation environments have become a technology of the past with the introduction of FMI compliant FMUs.

With the FMIT-Coder the FMI based chain of FMU deployment is complete. Yet the entire suite of validation and verification development stages is covered by FMI technology.

The consistent use of FMI compliant models has been an enabler for improved work flow efficiency and model quality of the MBD process.

Part of the project assignment was to bring MBD to the test and calibration engineer. These engineers shall be able to work with their de facto industry standard measurement, calibration and diagnostic tools. The aim to have a transparency for the MCD tools is accomplished and depicted in Figure 6.

## Abstract

Matlab is a proprietary, interactive, dynamically-typed language for technical computing. It is widely used for prototyping algorithms and applications of scientific computations. Since it is a dynamically typed language, the execution of programs has to be analyzed and interpreted which results in lower computational performance. In order to increase the performance and integrate with Modelica applications it is useful to be able to translate Matlab programs to statically typed Modelica programs.

This paper presents the design and implementation of Matlab to Modelica translator. The Lexical and Syntax analysis is done with the help of the OMCCp (OpenModelica Compiler Compiler parser generator) tool which generates the Matlab AST, which is later used by the translator for generating readable and reusable Modelica code.

*Keywords: Modelica, MetaModelica, Matlab, OMCCp, translation.*

## 1 Introduction

The Matlab language is dynamically typed; it does not have explicit type declarations. A variable's type is implicit from the semantics of its operations and the type is allowed to dynamically change at runtime.

These features improves ease of use for prototyping and interactive use, but add heavy run-time overheads, such as runtime type checking, array bounds checking and dynamic resizing, to its interpretive execution. Therefore, Matlab programs often run slower than their counterparts which are written in conventional statically typed programming languages.

The main goal of this work is the development of a translator that accepts Matlab programs as input and

generates Modelica code as output which is suitable for static compilation. Due to the complexity of the Matlab language, a realistic goal is to develop a translator for a subset of Matlab.

The translation task of Matlab to Modelica code mainly involves the front-end implementation of the Matlab to Modelica compiler. The OMCC (OpenModelica Compiler Compiler) compiler generation tool, which has been developed as a part of the OpenModelica project, can be used as a parser and translator generator extended with advanced error handling facilities. The tool is implemented in MetaModelica and integrated with the MetaModelica semantics specification language based on operational semantics for generating executable compiler and interpreter modules.

The OMCCp part of the OMCC tool makes the implementation of the first two stages of a compiler much easier and saves time. We have to just write the lexer and parser rules for the Matlab language and input them to OMCCp to generate the appropriate lexer and parser modules in MetaModelica. The generated parser builds the Abstract Syntax Tree (AST) for the Matlab source code that is parsed.

The Matlab AST is later used by the second phase of the Matlab-to-Modelica translator which performs a series of internal transformations and finally generates the Modelica-AST which is unparsed to readable Modelica code.

There exists a large body of computational algorithms which are programmed in the Matlab language. The need to have an easy way of using and incorporating such algorithms within Modelica models, as well as achieving improved performance, motivated the development of the Matlab to Modelica translator in the OpenModelica project.

This paper is structured as follows: Section 2 presents some related approaches. Section 3 describes the different steps involved in generating a compiler from

specifications in different specification formalism. Section 4 explains the design and implementation of the Matlab to Modelica translator with main focus on the translator. The translator description is for the subset of the Matlab language grammar for which translation to Modelica code is supported. Section 5 explains the type inference approaches. Section 6 describes the Modelica unparser. Section 7 presents Test results and performance measurements. Finally, Section 8 concludes the paper with a short discussion of achieved results.

## 2 Related Work

In this section we discuss a few related approaches for the compilation of Matlab code to statically typed languages.

The Matlab tamer is an extensible object-oriented framework for generation of static programs from dynamic Matlab programs implemented in Java. The Matlab Tamer supports a large subset of Matlab. It builds a complete call graph, transforms every function into a reduced intermediate representation, and provides typing information to aid the generation of static code [15]. In an earlier student project we tried to use the Matlab tamer framework directly for a translator to Modelica. However, that project was not completed.

MCFOR: A Matlab to Fortran95 compiler is designed for translating Matlab code to Fortran95. It generates readable and reusable Fortran95 code. MCFOR had very limited support for built-in functions. It showed that the numerical and matrix features of Fortran95 are a good match for the compiled Matlab, and that the static nature of the language, together with powerful Fortran95 compilers provides the potential for high performance [16].

## 3 Background

### 3.1 Generating Compiler Phases

The different phases of the compiler can be generated from a formal specification in different formalisms, as depicted in Figure 1.

Generally a compiler is divided into two parts, the front-end and the back-end. The scanner and parser constitute the front end phase whereas the optimization and code generator constitute the back-end phase of the compiler. In this paper we focus on the front-end parts of the compiler [1] [2], and use the existing Modelica unparser to generate the Modelica code from the internal Modelica AST

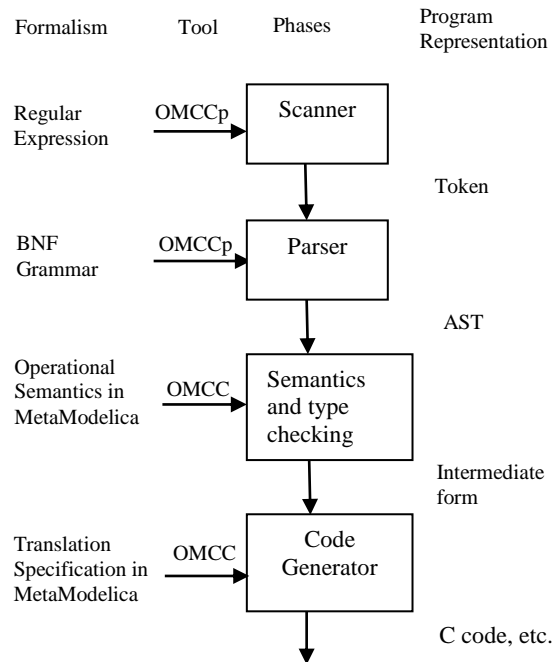

Figure 1. Structure of Compiler Generation using OMCC

### 3.2 Lexical Analysis

The Lexical analysis, performed by a scanner, is the first stage of the compilation process. It receives the source code as input and generates tokens. It also identifies the special tokens defined by the specified language making it simpler for the next phase of the compiler.

The structure of the tokens are usually specified by the use of regular expressions. There are several tools available that automate the labor of constructing the transition rules to identify the tokens for a scanner. We use the Flex tool for this purpose which generates C code; the generated C code containing tables is used by OMCCp to generate the appropriate lexer components in MetaModelica [1] [2].

### 3.3 Syntax Analysis

The syntax analysis, also called parsing, is the second stage of the compilation process. The parser takes the tokens generated by the lexer and determines whether the tokens are constructed according to the rules of the grammar. By doing this it creates the Abstract Syntax Tree (AST) if the input conforms to the defined grammar and otherwise reports an error message.

The AST is used as input to the back-end. The back-end uses the AST for type checking, optimization, and finally generates machine specific code. The grammar rules are usually specified in the form of BNF (Backus Normal Form). We use the BNF grammar rule format of the popular Bison tool for writing the grammar rules;

the generated C code contain parse tables that are used by OMCCp to generate appropriate parser components in MetaModelica [1][2].

### 3.4 Semantic Analysis

The semantic analysis is the phase in which the compiler adds semantic information to the parse tree and adds semantic information to the symbol table. This phase also performs semantic checks such as type checking (checking for type errors), or object binding (associating variable and function references with their definitions), or definite assignment (requiring all local variables to be initialized before use), rejecting incorrect programs or issuing warnings.

Semantic analysis usually requires a complete abstract syntax tree, meaning that this phase logically follows the parsing phase, and logically precedes the code generation phase, though it is often possible to fold multiple phases into one pass over the code in a compiler implementation.

The translator which takes the Matlab AST as input performs a series of internal transformation to produce the corresponding translated Modelica AST which can be unparsed to the generated textual Modelica code [1] [2].

## 4 Design

The design architecture of the Matlab to Modelica translator is depicted in Figure2.

Figure 2. Structure of Matlab to Modelica translator

The translator contains a scanner and a parser for the Matlab source code, which build the Matlab abstract syntax tree during parsing. The scanner and the parser are implemented using the OMCCp tool which generates appropriate lexer and parser components in MetaModelica. The result of the parser is used as input to the translator which performs a series of internal transformations and generates a Modelica AST. The last stage is the Unparser where the Modelica AST is unparsed to generate the Modelica source code. The scanner, parser and the translator are implemented in MetaModelica. In this paper we focus on the Matlab to Modelica translator; for detailed information about OMCCp see [1] [2].

### 4.1 LexerGenerator

The LexerGenerator is the main package of the lexer which generates the necessary lexer subsystems in MetaModelica. This module generates three packages in MetaModelica namely LexerModelica.mo, LextableModelica.mo and LexcodeModelica.mo. For more information about these packages see [1] [2].

#### 4.1.1 Lexer.mo

Lexer.mo is the main file which contains the calls to other functions in Lextable.mo and LexCode.mo that constitute the lexer. The main function of this package is to load the source code file and recognize all the tokens described by the grammar.

For recognizing a token the lexer.mo runs DFA (Deterministic Finite Automata) based on the transition arrays found in Lextable.mo. When it reaches an acceptance state it calls the function `action` in LexCode.mo which returns list of tokens that are input to the parser. The interface of the function which does this operation is given below.

```

function scan
  input String fileName "input source code file";
  input list<Integer> program "source code as a stream of Integers";
  input Boolean debug "flag to activate the debug mode";
  output list<OMCCTypes.Token> tokens
  "return list of tokens";
end scan
  
```

### 4.2 Parser Generator

The ParserGenerator package is the main package of OMCCp that generates the parser which performs the syntax analysis of the compiler. ParserGenerator generates four packages in MetaModelica namely TokenModelica.mo, ParserTable.mo, ParserCodeModeli

ca.mo and ParserModelica.mo. For more information about these packages see [1] [2].

#### 4.2.1 Parser.mo

The main function of this package is to efficiently convert the list of tokens received by the Lexer into Abstract Syntax Tree (AST). The package also contains the implementation of the LALR algorithm. For performing this task the package uses the parse table located in the package ParseTable.mo, to perform the shift-reduce action calls it uses the package ParserCodeModelica.mo. The interface of the function which starts the construction of AST is given below.

```
function parse "realize the syntax
  analysis over the list of tokens and
  generates the AST tree"
input list<OMCCTypes.Token> tokens "list
  of tokens from the lexer";
input String fileName "file name of the
  source code";
input Boolean debug "flag to output
  debug messages that explain the states
  of the machine while parsing";
output Boolean result "result of the
  parsing";
output ParseCode.AstTree ast "AST tree
  that is returned when the result
  output is true";
end parse;
```

### 4.3 Translator

The transformation *translator* is the third stage of the implementation which takes the Matlab AST as the input and performs a series of internal transformation and finally generates the Modelica AST. The translator package contains several functions which perform the above tasks by finding a possible mapping to a Modelica AST data structure. The implemented translator supports a particular subset of the Matlab language which is discussed in more detail in the following section.

### 4.4 Primary Function

A Matlab program consists of a list of files called M-files, which include a sequence of Matlab commands and statements. We can split the syntax of a Matlab function into three parts. First is the declaration part, which consists of the function name, the input and output formal parameters. The next part is the function body which consists of a list of statements which ends with the keyword `end`. A sample function in Matlab is given below.

```
function perfect = isperfect(value)
  sum = 0;
  for (divisor = 1 : value - 1)
    result = value / divisor;
```

```
    if (result == floor(result))
      sum = sum + divisor;
    end
  end
  if (sum == value)
    perfect = 1;
  else
    perfect = 0;
  end
end
```

The function name is `isperfect` which is defined in the declaration section. The input and output parameters are `value` and `perfect` respectively.

The body of function starts right after the declaration line and ends with keyword `end` which also ends the function. Due to the dynamic nature of the language there are no data type declarations in the Matlab code. All variables inside the function body are local to the `isperfect` function.

#### 4.4.1 Translation of Matlab to Modelica function

A Modelica function consists of three parts. The first part is similar to a Matlab function which contains function name, input, and output formal parameters. Since the Modelica language has static typing we have to define each function formal parameter with its proper data type as well as `input` and `output` keywords.

The next part is `protected`. All local variables apart from `input` and `output` formal parameters have to be declared in the `protected` section with proper data types. Finally the body of function starts with the keyword `algorithm` and ends with `end` keyword. An example of the Matlab function `isperfect` translated to Modelica is presented below.

```
function isperfect
  input Real value;
  output Real perfect;
protected
  Integer sum;
  Real result;
algorithm
  sum:=0;
  for divisor in 1:value - 1 loop
    result:=value / divisor;
    if result == floor(result) then
      sum:=sum + divisor;
    end if;
  end for;
  if sum == value then
    perfect:=1;
  else
    perfect:=0;
  end if;
end isperfect;
```

#### 4.5 Translation of function declaration statements

In the function declaration the translator assigns proper data types to the input and output formal parameters. The translator determines the data types of formal parameters once the whole function body has been traversed. An example of the translation is presented below.

##### Matlab

```
function perfect = isperfect(value)
```

##### Modelica

```
function isperfect
  input Real value;
  output Real perfect;
```

#### 4.6 Identification and Translation of Local identifiers

All variables defined inside the Matlab function body are local variables. Modelica declares all local variables in the translated function under the protected section. Therefore all those local variables have to be assigned proper data types before declaration in the protected section.

For translation of this phase we have to identify all local variables first since the function body contains input and output formal parameters and Modelica does not support re-declaration of variables. The translator then assigns the proper data types. The process of identifying the local variables is depicted in Figure 3.

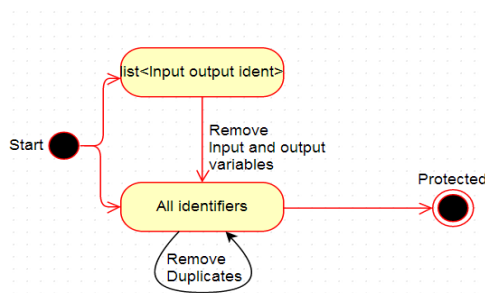

Figure 3. Declaration of variables

To perform this task we declare two lists of strings. Assume that there are two lists: a `param` and an `ident` list. The former contains input and output parameters and the latter contains all variables of the function including input and output parameters.

The translator compares both lists and removes all those variables from the `ident` list which were found in the `param` list. Now the `ident` list only contains local variables left but it might have duplicate variables.

To remove the duplicates compare the list with itself and remove all duplicates.

#### 4.7 Identification and Translation of constant variables

Matlab does not support constant declaration of variables as in Modelica with the prefix `constant` keyword. Here we mean identifiers whose right hand side is equal to any constant value, i.e., real, integer, logical or array not any variable. For example, `sum = 10` where 10 is an integer scalar. All these variables are declared under the `protected` heading with their relevant data types. Take a look at the following translation:

##### Matlab

```
function [sum] = add_scl_mat(scl1)
  real1 = 10.5;
  mat2 = [1,2,3;4,5,6];
  sum = mat2 + scl1 + real1;
end
```

##### Modelica

```
function add_scl_mat
  input Real scl1;
  output Real sum[:, :];
  protected
    Real real1;
    Integer mat2[:, :] = [1,2,3;4,5,6];
  algorithm
    real1:=10.5;
    sum:=mat2 .+ scl1 .+ real1;
  end add_scl_mat;
```

The translator identifies two local variables. First the variable `real1` whose right hand side is a real number, i.e., 10.5. The next one is `mat2` whose right hand side is a two dimensional integer array, i.e., [1,2,3;4,5,6].

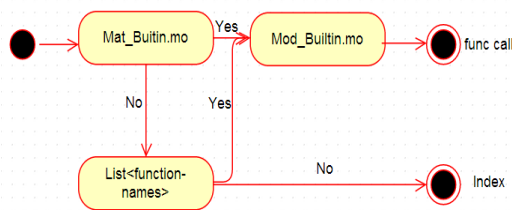

The translator identifies their respective data types from the right hand side value and then performs translation. The translated scalar identifiers only have type declarations in the protected section, the assignment of values is under the algorithm section whereas arrays have both declaration and assignment in the protected section.

#### 4.8 Translation of Function Body

The function body of the Matlab function is translated into a Modelica algorithm section. The body is composed of a list of statements where every statement is translated to the relevant Modelica statement.

#### 4.8.1 Identification and Translation of Function Call

The syntax for function call and array index operation is the same in Matlab using round parentheses, i.e. `sqrt(i)`. Thus `sqrt` can be a function call or an index operation. Matlab decides this during execution time. However, Modelica has different syntax for index operations. It uses brackets `[]` instead of parentheses `()`. Thus, `sqrt[i]` should be used if `sqrt` is an array that should be indexed. The function call has the same syntax as in Matlab, i.e., `sqrt(i)`.

**Figure 4.** Process of Identifying function call

Figure 4 presents the process where a function call is translated. For correct translation the translator must differentiate between function call and index operation.

The function call in the original Matlab code can either be a built-in function in Matlab, a sub-function, or a recursive function. For proper generation of translated code the translator copies the names of main functions and sub-functions into a list of strings.

Secondly, the mostly used Matlab built-in functions are collected and placed in the file `Mat_Builtin.mo`. This file works as a dictionary. If the translator finds any function call in input Matlab code it compares the name of the function in both the dictionary and the list of collected function names.

If there is a match in any list then the translator looks for a similar function in the other file `Mod_Builtin.mo` where Matlab and Modelica functions were placed which have a similar purpose but have different names.

For example, the `disp('text here')` function is used in Matlab for print/display purpose is replaced to a `print("text here")` function in OpenModelica because it has a similar purpose. Similarly `rdivide()` to `div()`, `diag()` to `diagonal()` etc. If the translator does not find it, it interprets the identifier as an array that should be indexed and the translator replaces parenthesis `()` by brackets `[]`.

#### 4.9 Identification and Translation of Anonymous function to sub-function

An anonymous function is just like a standard Matlab function. It is placed inside the body of a function and accepts inputs and return output as standard Matlab functions. However it contains only a single executable statement.

An example of a sub-function translation is presented below.

##### Matlab

```
function [result] = fnc(x)
    y = 2;
    sqrt = @(x) x^y;
    result = sqrt(x);
end
```

##### end

##### Modelica

```
function fnc //primary function
    input Real x;
    output Real result;
    protected
        Real y;
    algorithm
        y:=2;
        result:=sqrt(x, y);
    end fnc;

function sqrt //sub-function
    input Real x;
    input Real y;
    output Real sqrt;
    algorithm
        sqrt:=x ^ y;
    end sqrt;
```

Modelica does not support such functions. Therefore we handle them differently. The Translator converts an anonymous function to a sub-function in Modelica. The translator traverses the whole AST to find out whether the body of a function contains any anonymous function or not. If yes, then translator copies the whole anonymous expression from the original code and removes that node from the AST. Afterwards it converts it into a sub-function in Modelica. In a function call the translator replaces the input parameters with sub-function input formal parameters. As we see in the code `sqrt(x)` has only one formal parameter but in translated Modelica code we find two parameters, `x` and `y`.

#### 4.10 Translation of looping statements

Both languages use similar syntax in for- and while-loop header expressions. The translator only translates the `=` sign to the `in` keyword and the postfix `loop` keyword in an header expression.

Also, the square brackets `[]` replaces the braces or curly brackets `{}`. Matlab ends a for loop with an `end`

end for keywords. Therefore translator adds the end for keywords at the end. The same ending procedure is followed for while loops and if statements as end while, end if. An example of the translation is presented below.

#### .Matlab

```
for m = 1:14
end
```

#### Modelica

```
for m in 1:14 loop
end for;
```

#### Matlab

```
while nFactorial < 100
end
```

#### Modelica

```
while nFactorial < 100 loop
end while;
```

### 4.11 Translation of if statements

The if statement is also similar in both languages. The translator adds the then keyword in the headers of if expressions and the endif keyword to end the expressions. An example of the translation is presented below.

#### Matlab

```
if(result == floor(result))
    sum = sum + divisor;
end
```

#### Modelica

```
if result == floor(result) then
    sum:=sum + divisor;
end if;
```

### 4.12 Translation of Switch Statement

Modelica does not currently support the switch statement. When the translator finds a switch statement in the original Matlab code it translates it into if-else statements with possible elseif branches. An example of the translation is presented below.

#### Matlab

```
switch mynumber
case -1
    disp('negative one');
case 0
    disp('zero');
case 1
    disp('positive one');
otherwise
    disp('other value');
end
```

#### Modelica

```
if mynumber == -1 then
    print("negative one");
elseif mynumber == 0 then
    print("zero");
elseif mynumber == 1 then
    print("positive one");
end if;
```

### 4.13 Sub-function

A Matlab file can contain more than one function. If it contains multiple functions, then the first function is the primary function which can be accessed in other M files and the rest of the functions are secondary functions which are called as sub-functions.

A sub-function is only accessed by its primary function. All sub-functions are translated into sub-functions in Modelica and this process follows the same procedure for translation as for the main/primary function.

## 5 Type Inference

We have adopted the MCFOR "A Matlab To Fortran95 Compiler" approach for evaluating the types in our translator. It starts by analyzing each assignment statement on the right hand side (RHS) of the expression and assign types [16].

### 5.1 Statement where Right Hand Side is a constant

Constant values are very precise sources for assessing data types. They are the starting points for our type inference process. If the translator finds an assignment statement whose right hand side is a constant (e.g.) temp = 10, in Modelica such an expressions will be declared as an integer data type.

#### Example

```
temp = 10 => Integer temp
temp = 10.5 => Real temp
temp = [1,2,3,4] => Integer temp[1,4]
"size is 1x4"
temp = [1,2;3,4] => Integer temp[2,2]
"size is 2x2"
```

### 5.2 Statement where Right Hand Side is Built-in function

Built-in functions in Matlab are well defined therefore these functions also provide enough information for assessing data types. If an assignment statement contains built-in function on right hand side translator will easily assess its type from database where we have a list of all built-in functions supported by Modelica with their return type. (e.g.) zeros(n,m) is an n-by-m ma-

trix of zeros. If  $n$  and  $m$  is equal to 2 then translator will declare left hand side identifier as a two dimensional Integer array.

Example

```
temp = zeros(2,2) => Integer temp[2,2]
"size is 2x2"
temp = ones(1,3) => Integer temp[1,3]
"size is 1x3"
```

### 5.3 Statement where Right Hand Side is a computational expression and contains relational operator

Relational operators always return the results of the logical type. (e.g.)  $c = a < b$ .

### 5.4 Statement where Right Hand Side is a computational expression and contain arithmetic operator (array)

Matlab operators not only provide the shape and size information for the result but also provide constraints on the type and shape of operand. The assignment statement where right hand side is matrix computational expression,  $c = a*b$  where  $a$  &  $b$  are matrices.

In order to evaluate such an expression in Matlab the inner dimensions must agree. If  $a$  &  $b$  have a shape of  $n$ -by- $m$  and  $p$ -by- $q$ , then  $m$  must be equal to  $p$ . The generated result will have the shape of  $n$ -by- $q$ . For example if we have an expression  $temp = a * b$  where dimension size of  $a$  is  $1 \times 3$  and  $b$  is  $3 \times 3$  then  $temp$  have dimension  $1 \times 3$  and translator declares as an Integer  $temp[1,3]$ .

### 5.5 Statement where Right Hand Side is a computational expression and contain arithmetic operator (scalar)

Consider the following expression  $temp = a / b$  where  $a$  &  $b$  are Integer scalar variables. To avoid data loss the translator promotes the left hand side variable as real data type.

### 5.6 RHS is not equal to LHS

In Matlab we can re-create any variable with different type assignment and every assignment can create a type conflict where left hand side variable is different from the type of the right hand side expression. In such cases the translator performs typecasting on right hand side expression and defines it with proper data type.

## 6 Unparser

When translating the code to an abstract syntax tree in Modelica we need to unparse the AST to get a readable output, i.e., Modelica source code. The unparsing is performed by the package Dump which is already present in the OpenModelica Compiler. The interface of the function which starts the unparsing is given below.

```
public function unparseStr
  "Pretty prints the Program, i.e. the
   whole AST, to a string."
  input Absyn.Program inProgram;
  input Boolean markup
  output String outString;
end unparseStr;
```

## 7 Testing

We tested a number of Matlab programs to demonstrate that the translator was working properly.

A sample Matlab function to calculate the area is presented below

```
function area_sum = area_inside(radius,
num_boxes)
  box_length = (2.0*radius)/num_boxes;
  box_rad = box_length*0.5;
  box_area = box_length*box_length;

  area_sum = 0;
  for (xi = 1 : num_boxes)
    xc = - 1 + box_rad + box_length*(xi -
      1);
    for (yi = 1 : num_boxes)
      yc = 1 + box_rad + box_length*(yi -
        1);

      dist = sqrt((xc*xc) + (yc*yc));
      if (dist < radius)
        area_sum = area_sum + box_area;
      end
    end
  end
end
```

The above input is translated to the following Modelica source code which gives the same result..

```
function area_inside
  input Real radius;
  input Real num_boxes;
  output Real area_sum;
protected
  Real box_length;
  Real box_rad;
  Real box_area;
  Real xc;
  Real yc;
  Real dist;
algorithm
  box_length:=2.0 * radius / num_boxes;
  box_rad:=box_length * 0.5;
  box_area:=box_length * box_length;
  area_sum:=0;
```

```

for xi in 1:num_boxes loop
  xc:=-1 + box_rad + box_length *
    (xi - 1);
  for yi in 1:num_boxes loop
    yc:=1 + box_rad + box_length *
      (yi - 1);
    dist:=sqrt((xc * xc) + (yc * yc));
    if dist < radius then
      area_sum:=area_sum + box_area;
    end if;
  end for;
end for;
end area_inside;

```

## 7.1 Performance Evaluation

In this section we present the performance of the Modelica code generated by the translator which is compared to the execution time with the corresponding Matlab code in Matlab. Before the comparison we made sure that both codes generate same results. The measurements are listed in Table 1 below.

**Table 1.** Time measurement of Matlab with Modelica

Model	Scalar/Array	Matlab(ms)	Modelica(ms)
Closure	2D-array	185.90	26.49
IsPerfect	scalar	198.60	11.65
Finite	2D-array	69.98	55.25
AreaInside	scalar	180.05	16.72
MySort	1D-array	218.45	26.49
SwapVector	1D-array	80.67	18.02
BubbleSort	1D-array	109.34	81.96

From Table 1 we can clearly see that the generated Modelica code has better performance than the Matlab code.

## 8 Conclusion

In this paper we have presented a Matlab to Modelica translator that works for a specific subset of Matlab. The translator generates readable and reusable Modelica code. It can handle the following Matlab constructs:

- *Functions*: Simple, Nested and Sub-functions.
- *Loops*: For, Nested For, While, Nested While, and break.
- *Statements*: If, If else, If elseif else and Switch.
- *Program Termination*: return.
- *Arithmetic Operators*: Plus +, Unary plus ++, Minus -, Unary minus --, Matrix multiply \*, Array multiply .\*, Matrix power ^, Array power .^, Backslash or

left matrix divide \, Slash or right matrix divide /, Left array divide .\, and Right array divide ./.

- *Relational Operators*: Equal ==, Not equal ~=, Less than <, Greater than >, Less than or equal <= and greater than or equal >=.
- *Logical Operators*: Element-wise logical AND &, Element-wise logical OR | and Logical NOT ~.

The generated code can then be statically compiled by a Modelica compiler which usually result in better runtime performance.

## Abstract

A model predictive control framework for optimal heating of a residential building is proposed. The control inputs are applied to a virtual building emulator model using a limited amount of measurements. State estimation is implemented using moving horizon estimation to reinitialize the states of the controller model in every time step. To implement the moving horizon estimation, the Modelica equations had to be modified. A stochastic input is declared at the controller model state equations to represent the process noise (model error). The state estimation significantly improves the output matching between emulator and controller model. The JModelica optimization framework proves to be satisfactory for this first, limited case investigated here. Future work will focus on the extension to different models and prediction errors within the framework developed here.

*Keywords: Model Predictive Control; Moving Horizon Estimation; State estimation; JModelica; Modelica*

## 1 Introduction

Building heating systems are usually controlled using a heating curve that determines the supply water temperature based on the outside temperature. An increased interest in optimal control is encouraged by the widespread adoption of optimal control in other engineering domains. Model predictive control (MPC) is a general purpose control scheme that involves repeatedly solving a constrained optimization problem. Optimal control inputs are computed using a reduced order controller model and are applied to an emulator model or a real case. Measurements of (one or more) states in the emulator model or real case are used to reinitialize all states of the controller model.

This paper proposes a general framework for MPC with state estimation using Modelica models

and JModelica. The main focus lies on the implementation of moving horizon state estimation.

In the literature, often this step is either bypassed by using the controller model as an emulator model or by assuming all states can be measured and thus the controller model is updated perfectly. However, these assumptions do not hold when using MPC in real buildings where state estimation is thus needed to update all controller model states.

Because deterministic models cannot explain the differences between the system model output and the real system observations, stochastic models are needed. Therefore, the deterministic model equations are extended with a noise term, to overcome the simplifications in the model and the input uncertainty. State estimation computes this noise term based on statistical knowledge of this extra term and system observation.

For state estimation, often a Kalman filter is considered, which updates the states, by calculating a deterministic estimate, based on the covariance matrices of the noise. A classical Kalman filter can update the states of a linear time varying model. An extended Kalman filter can update the states of a non-linear time varying model, by linearizing the model equations in the working point. The framework described in the current paper uses Moving Horizon Estimation (MHE). MHE solves a least squares estimation that determines the optimal state estimates, based on covariance matrices of the noise.

The reason for choosing MHE over Kalman filter is twofold: first, the state estimation fits in a framework that is being developed for MPC with Modelica models to be used in real buildings. The MPC framework starts with parameter estimation of greybox controller models in Modelica using the greybox building models in a model library (*FastBuildings*) developed by De Coninck et al. [1]. MHE uses the Modelica-model differential algebraic equations (DAE) formulation directly and thus keeps the great flexibility of the greybox parameter estimation toolbox. In contrast, Kalman filter is applied to ordi-

nary differential equation (ODE) models. Second, the parameter estimation, the optimal control problem and the state estimation problem are all optimal control problems which are solved using JModelica [2]. JModelica allows solving non-linear problems using gradient-based optimization. The state estimation and optimal control problem encountered here, will always be initiated with an initial guess, based on a nearly equal former solution. This will ensure that the non-linear problem will be handled robustly. This is in contrast with often reported failing of an extended Kalman filter (EKF) when handling non-linear models [3].

In this study, the MPC is applied to a virtual, single zone residential building equipped with a floor heating system and fed by a heat pump. It is represented by a ‘detailed’ Modelica model, later called the emulator model which is presented in [4][4]. Only a limited number of states are measured. The next part of the paper explains the optimization framework step by step, after which the effects of state estimation are discussed.

## 2 Optimization framework

Figure 1 schematically shows one loop MPC, which is processed every ‘open loop’ time step. The disturbance inputs are ambient temperature, global horizontal solar irradiance and internal gains. The control input is the floor heating heatflux. Since a heatflux is not a physical decision variable, it is translated into a floor heating water supply temperature setpoint as a function of the measured return temperature. The temperature of the building zone is also measured, for feedback in the high level control.

The MHE problem looks at the past time window to estimate every new initial state variables of the controller model. The MHE optimization is initialized by a controller model simulation over that past period using observed control inputs. This initialization is an important part of solving the state estimation problem, especially when the model has nonlinearities.

The optimal control problem(OCP) problem looks at the future time window to optimize the control inputs over the prediction horizon The OCP optimization. is initialized using the solution of the OCP from the past MPC-step. The shorter the open loop horizon, the closer the optimal control inputs will be to the initial values. Optimization using linear models will always find the global optimum for the corresponding linear system.

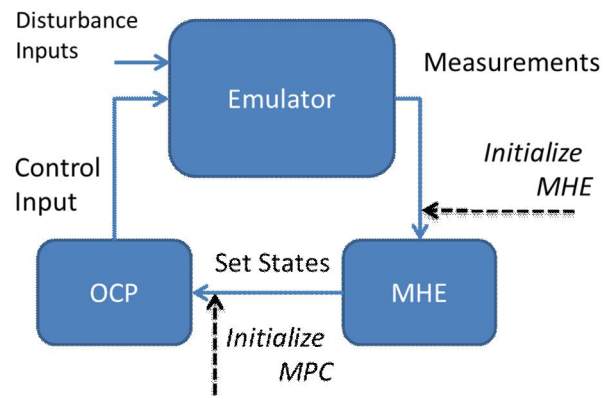

Figure 1: Outline of MPC

### 2.1 State estimation

Because of model mismatch and disturbance prediction errors, the controller model state values deviate from the emulator values. To prevent this, a moving horizon estimator is implemented to correct the states of the controller model based on measurements (or emulator model values). MHE can be seen as the dual of the MPC as it solves an optimal control problem over the past horizon to fit some measurement(s). The difference is that MHE takes the fixed past control inputs and optimizes the model error: it determines the process noise  $w$  over the optimization horizon for every state. To understand the concept of process noise, one must look at the model as a stochastic model. Take a look at the notation of a simple, explicit form of the model equations, with  $x$  the model states and  $y$  the output.  $w$  represents the model error (process disturbance/noise) and  $v$  the output error (measurement disturbance/noise):

$$\begin{aligned}\dot{x} &= f(x, u) + w \\ y &= g(x, u) + v\end{aligned}$$

The explicit formulation of the model error  $w$  means that a stochastic model allows for a difference between the state change according to a deterministic model:  $f(x, u)$ , and the state change in the real system:  $\dot{x}$ . Solving a state estimation problem means finding the difference  $w$  over the past time, such that the stochastic model accurately represents the real system behavior.

To solve the state estimation as an optimization problem, the following least squares problem should be solved by determining  $w_k$ .

$$\min_{x_0, \{w_k\}_{k=0}^{T-1}} \sum_{k=0}^{T-1} \|v_k\|_{R^{-1}}^2 + \|w_k\|_{Q^{-1}}^2 + \|x_0 - \bar{x}_0\|_{P_0^{-1}}^2$$

This is known as the ‘full information problem’, which minimizes the weighted sum of the output

noise  $v$  (on some measured outputs  $y$ ), the model noise  $w$  and the initial state  $x_0$  over the past time. The weights can be determined using the inverse covariance matrices of the model error ( $Q^{-1}$ ), the measurement noise ( $R^{-1}$ ) and the initial condition ( $P^{-1}$ ). A larger covariance of a model state thus leads to a smaller weight in the objective function and a larger value for  $w_k$  as optimal solution. A model state with large covariance will have larger deviations from the real system, which is to be expected from a larger covariance.

As time progresses, this full information problem becomes computationally infeasible. Moving horizon estimation removes this difficulty by considering only the most recent  $N$  measurements. An arrival cost is formulated to represent the information about the initial states and the measurements prior to  $N$ . The arrival cost cannot be calculated exactly (full information problem) and therefore approximations are used. For stability reasons often the prior measurements are disregarded. The initial value  $x_0$  is then set according to the solution of the last MHE update and the arrival cost is thus a constant value. Another approach is to calculate deterministic updates of the initial MHE states ( $k=T-N$ ) using an extended Kalman filter (EKF). The first approach is followed here and prior measurements are disregarded. The MHE problem translates to:

$$\min_{x_0, \{w_k\}_{k=T-N}^{T-1}} \sum_{k=T-N}^{T-1} \|v_k\|_{R^{-1}}^2 + \|w_k\|_{Q^{-1}}^2$$

or

$$\min_{\{w_k\}_{k=T-N}^{T-1}} \sum_{k=T-N}^{T-1} \|y_{meas_k} - g(x_k, u_k)\|_{R^{-1}}^2 + \|x_{k+1} - f(x_k, u_k)\|_{Q^{-1}}^2$$

With  $\|\cdot\|_A$  the 2-norm with weights  $A$ . As explained before, the weights are determined by the covariance matrices. The covariance matrix ( $Q$ ) for the is a diagonal matrix with covariance of each model state on its diagonal. The covariance matrices can be considered a tuning parameter. This is shown Figure 2 where the  $R^{-1}$  values (*weight\_meas* in the figure) takes three different values while keeping the  $Q^{-1}$  value constant. In order to get the stochastic model output to agree more with the measurements: increase  $R^{-1}$ /decrease  $Q^{-1}$ . And vice versa to agree more with the deterministic model state: decrease  $R^{-1}$ /increase  $Q^{-1}$ ). In this work, the weights are not related to the covariance matrices yet. However as we estimate the greybox models using a parameter estimation, it is mathematically possible to estimate the covariance matrices along with the model parameters [5].

Figure 2: State estimation influence of the different weighting factors

To implement the MHE optimization problem using Modelica models, the model equations need to be adapted. Modelica model equations are by design deterministic and not stochastic. The DAE system of equations in the general implicit form is:

$$F(\dot{x}, x, u, d, p)$$

In this equation  $d$  represents the disturbance input and  $p$  the model parameters. Each equation holds and simulating a Modelica model generates a deterministic solution for the variables. To use MHE with Modelica models, we decide to add a normalized, stochastic variable  $w$  to every state equation (here for a heat capacity, with  $C=m*c$ ). The stochastic Modelica model then looks like:

```
model Capacitor_stochastic_der_paper
  "Lumped thermal capacity, with stochastic model error"
  parameter SI.HeatCapacity C "Heat capacity of element";
  Modelica.Thermal.HeatTransfer.Interfaces.HeatPort_a port;
  input Real w;

```

Figure 3: Stochastic Modelica model heat capacity

The process noise  $w$  is modelled as an input to this capacity model. The inputs 'w' of all states are optimization variables in the MHE problem. The equation shows that  $C*w$  physically represents an extra heat flux, not included in the original deterministic equation. It can also be seen that  $delta_T$  is a temperature deviation, which is the model error for the temperature (state). Since the problem is continuous in Modelica, the variable  $w$  can be determined in the MHE over the past  $N$  steps, to find the deviation  $delta_T$  of the state  $T$ . The Modelica model can be reconverted into a deterministic model for simulation purposes by setting the process noise to zero.

### 2.2 Optimal control problem

The optimal control problem is solved using a reduced order controller model. This controller model is identified based on monitoring data by use of a grey-box modeling approach. This approach starts from the Modelica library FastBuildings which defines potential low-order model candidates. For each potential model, parameter estimation is carried out, and the resulting models are compared using cross-validation, confidence intervals and other residual analyses. The best model is selected as controller model. This grey-box modeling approach is described in more detail in [1][6]. For the case investigated in this paper the time series consists of simulation data of the building zone temperature obtained by the emulator model, but this could as well be measured data. A third order resistance-capacitance (RC) model for the building zone fed by a heat pump with constant COP of 3.58 gives a good fit (rmse of 0.08 °C) to the time series generated by the emulator model. Figure 5 shows a visual representation of the

selected RC model from the FastBuildings library. There are three heat capacitors which all have a different temperature (state): capEmb.T (heater), capWal.T (wall) en capZon.T (zone). The last state is an output as it is measured in the emulator model.

$$\min_{Q_{hea}} \alpha * J_s + J_d$$

$$J_s = \int_T^T \frac{Q_{hea}}{COP}$$

$$J_d = \int_0^T (\beta * \epsilon_h^2 + \epsilon_c^2), \quad \text{with } \begin{cases} \epsilon_h \geq T_z - T_{comf,max} \\ \epsilon_c \leq T_z - T_{comf,min} \end{cases}$$

s. t.

$$F(\dot{x}, x, u, d, p) = 0$$

$$Q_{hea} \leq Q_{HP,max}$$

$$Q_{hea} \geq 0$$

$$T_z(T) \geq T_z(0) - 10$$

$$T_z(T) \leq T_z(0) + 10$$

Figure 4: multi-objective optimal control problem formulation.

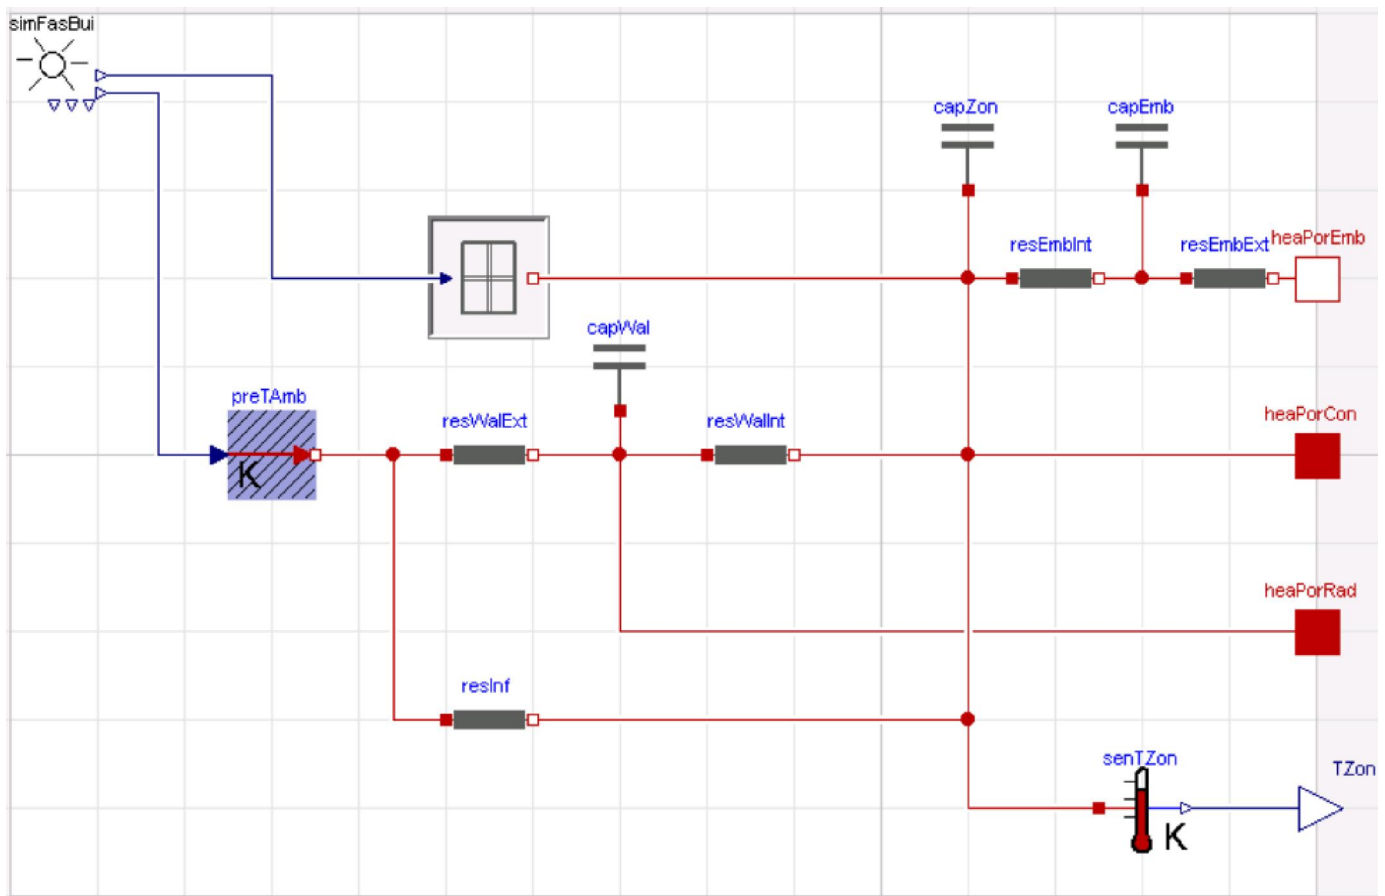

Figure 5: Visual representation of the third order greybox model in Modelica.

The optimal control problem is multi-objective. It minimizes both the energy use and the thermal discomfort and is based on a PhD regarding MPC in buildings [7]. The problem formulation is shown in Figure 4. The control input  $u$  (here:  $u=Q_{\text{hea}}$ ) determines the heat from the heating system to the zone to control the zone temperature  $T_z$ . The first term in the objective function  $J_e$  is the total electricity used by the heat pump, while the second term in the objective function  $J_d$  is the weighted sum of thermal discomfort (overheating and undercooling).

This multi-objective approach treats the discomfort boundaries  $T_{\text{comf},\text{min}/\text{max}}$  as soft, asymmetric (for  $\beta$  different from 1) constraints through the slack variables  $\epsilon$ . The external inputs (/disturbances)  $d$  are ambient temperature, solar irradiance, internal gains and the electricity price. The latter is kept constant. For the disturbances, perfect predictions are used. The optimal control input is applied to the emulator model and the building zone temperature is measured.

### 2.3 MPC

The MPC framework is written in Python, because JModelica is interfaced in Python. It is tested on an emulator model of a single zone residential building with floor heating emission system and a heat pump for heat production [4].

The future horizon over which the optimal control problem is repeatedly solved and thus over which it needs future predictions is chosen to be 2 days. It is called the ‘prediction horizon’. The past horizon over which the state estimation is repeatedly solved and thus over which it needs past measurements is chosen to be 2 days. It is called the ‘state estimation horizon’.

The future horizon over which the optimally determined control inputs are repeatedly applied to the emulator model can vary. It is called the ‘open loop horizon’. Choosing a shorter open loop horizon might improve the control, however it increases the number of optimization problems. In the example shown in Figure 6 it is chosen to be 1 day. This is a long period for control, but it is reasonable as we use perfect predictions. The figure also illustrates the horizons and the working principle by showing the zone temperature state.

First the state estimation (MHE) problem is solved to determine the initial state for the optimal control problem (OCP). The optimal control input determined in the OCP is then fed to the emulator model by translating the heat into a supply water temperature setpoint. The emulator is simulated with this heat input and the temperature of the building zone is measured. The measurement is the input to a new MHE problem.

This is shown in Figure 7, at March 2, 00:00h the states are updated. The temperatures in the controller model are discontinuously changed at every new iteration. The figure also illustrates the horizons and the working principle by showing the zone temperature state.

Figure 6: MPC framework, result for zone temperatures for 1 MPC iteration.

Figure 7: MPC framework, result for zone temperatures for 2 MPC iterations.

### 3 Results

The MPC is tested over a period of 10 days, with an open loop length of 6 hours. This means there will be four state updates throughout a day. As explained using Figure 6 and Figure 7, the initial values of the controller model states  $x_0$  for the MPC are determined by a first solution of the MHE. The initial values of the controller model states  $x_0$  for the MHE can be estimated freely to best capability. In order to evaluate the performance, some variations were made in the MPC formulation and settings: with and without state estimation, larger open loop (control) horizon, variation of the weighting in MHE formulation.

First a case without state estimation is solved. From is clear that the controller model would benefit from measurement feedback. The controller model (OCP) predicts a too high temperature for the states. It stays near its optimal temperature profile of around 295 K (21°C) while the emulator model (EMU) remains at a lower temperature. The third order RC model is not capable of modelling the steady state heat loss from the building zone to the soil. This third order RC model seems not appropriate for model predictive control without state estimation. The situation improves with state updates as can be seen in Figure 9. The controller model is still at its 295K (21°C), but due to the feedback of the state estimations, there is a better coupling with the emulator model. The red curve, which is in the middle of the two, represents the MHE-model state of the zone temperature. It is very close to the the measurements as the weights are chosen to be  $R^{-1} = \{10\}$ , and  $Q^{-1} = I^{3 \times 3}$ , the identity matrix. This means we assume a higher covariance on the model states than on the measurements ( $R < Q$ ). Remember that the inverse of the covariance determines the weighting and not the covariance matrix itself. If we change the values of these covariance matrices, we get a different result, which is visible in Figure 10.

The corrections made by the state estimator are visible in the optimal control problem. At every new control time step, the optimal control problem is solved again starting from the new (in this case lower) initial conditions. The lower temperature is immediately compensated by a control input determined heatflux from the heat pump to the building to regain thermal comfort.

The temperature change in the emulator does not quite follow the OCP. Firstly, this is because of a steady state heat loss to the soil and secondly because of the slow thermal response of the floor heating. A control input of 3kW does not spread as fast to the building zone as it would in the heater model.

Figure 8: MPC over 10 days with no state updates.

Figure 9: MPC over 10 days with 6 hourly state updates

Figure 10: MPC over 10 days with 6 hourly state updates and a higher covariance for the measurements (less trustworthy)

These are two important controller model deficiencies. The first one is not so much a problem, as it can be overcome by the use of a state estimator. The second one can be misinterpreted by the state estimator as the heat to the emulator lags behind. It is therefore important to take into account the dynamics of the thermal system. If the controller time step is too small, the system might overheat as a reaction to the zone temperature measurements.

A comparison is made to MPC with a larger control time step of 1 hour update. As expected, an improved coupling pulls the emulator model building zone temperature towards the optimal values from the OCP.

In Figure 11 the coupling to the emulator model is not as would be expected. The building zone temperature of controller model is hourly updated to a higher value, and the emulator model does not seem able to catch up. One cause to this problem is found by examining the translation of the optimal control input to a physical temperature setpoint.

Figure 11: MPC over 1 day with 1 hourly state updates

Figure 12: Optimal (HH.QHea) vs real (d1.nzeb...) heat flux

Since the floor heating system supply temperature setpoint and the heat pump setpoint are calculated using a measurement of the outlet temperature of the floor heating, a problem always arises at startup. As the outlet temperature is low when the heating starts, the first heatflux through the floor heating is always lower than the optimal control heat flux from the OCP. This effect can be seen in Figure 12. This stresses the importance of good low level control. A PID controller could help overcome this discrepancy.

To conclude we study the result of the MHE optimization for temperature difference for the states. These temperature differences are the errors of the controller model compared to the observations. In parameter estimation processes, the model errors are studied to decide whether the estimated model is 'good enough'. The decision criterium identifying a good model is whether the model error (or process noise) is white noise. The process noise produced by state estimation represents the same error of the model. This means that the controller models accuracy could be analyzed by looking at the error. The noise for the last MHE optimization problem is shown in Figure 13 for the three states.

The error is not white noise. This means there are phenomena which are not modelled. From the figure, it can be seen that the heater temperature has a steady state error with a periodic variation. This error might arise from a heat loss to the ground, which is not modelled in the controller model. The third order RC model cannot represent this loss through a model. A different RC model should thus be selected for parameter estimation. This would render a new better controller model, which will improved predictions allow better use of the optimal control horizon to improve energy savings.

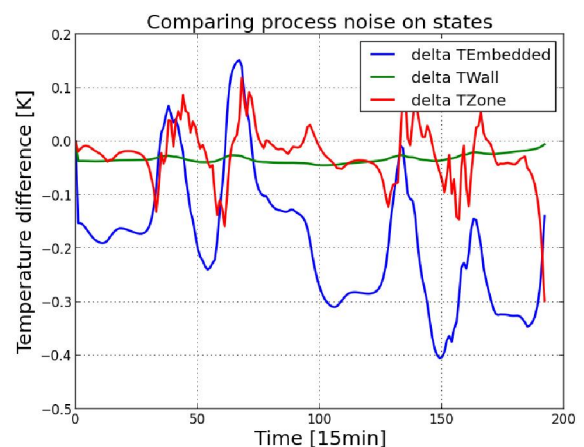

Figure 13: Process noise on states

It is also worth noting that the model error (temperature difference) in Figure 13 changes rapidly near the end. This is the case for most of the state updates of the MPC analyses with state estimation that were studied in this work. The process error on *capEmb* (state) is always high, but decreases rapidly in the end. The zone *capZon* state undergoes the inverse transition. This can be seen on Figure 14, where this last part of the results of repeated MHE solutions are shown.

**Figure 14: Process noise of the last steps in repeated solutions of the MHE problem.**

This means that in the MHE model a high noise-heatflux is present towards the embedded state (*capEmb.T*) and a high negative noise-heatflux is present to the zone state (*TZon*) near the end of the interval. This seems to mean that the temperature of the Zone is kept high until the end, and is then lowered due to a non-physical heatflux. The question rises whether this behavior is to be avoided, although it seems to be mathematically correct. Since altering the weights  $R^{-1}$  and  $Q^{-1}$  changes the behavior of the process noise for the states (and thus the timeseries in Figure 13 and Figure 14), the adoption of covariances for every states might mitigate this problem. Another solution might be to better initiate the MHE problem. This can be done by not disregarding the arrival cost, as is done now.

## 4 Conclusions

In this work, it is shown that stochastic models can be implemented in Modelica. This is an important step for optimal control framework using MPC. The MPC framework uses greybox models, which will produce an output which is different from the real building. Because not all the states in the controller model are measured states, the moving horizon estimator estimates the new initial states of the controller model. This feedback is shown in the fact that the measured state in the emulator model will be closer to the output state of the controller model. The feedback of the measurements in the emulator can be tuned by changing the weights in the objective function of the state estimator. These weights are mathematically the covariance matrices of the model states and the measurements, but since they are not always known, they can be fine-tuned to give state estimation results.

The results from the state estimation can be used to detect modeling errors or deficiencies in the controller model in the same way the residuals are checked in a parameter estimation problem. If the residuals are white noise, the controller model accurately models the system. In case the residuals are not white noise the controller model does not model the system very accurately. The state estimator can prevent the controller model from diverging from the real situation (observations).

## Exhibitors

### **BAUSCH-GALL GmbH**

BAUSCH-GALL GmbH (LLC) is an engineering company based in Munich, Germany, which sells and supports Modelica Libraries, works on simulation projects, organizes training courses and does consulting based on specific technical know-how. BAUSCH-GALL GmbH also offers special design services, devices and products for radio frequency (RF) applications. Based on a broad range of expertise in the solution of practical problems by effective computer application, BAUSCH-GALL GmbH serves the market for simulation and computer-aided engineering.

### **cenit**

*DRIVEN BY YOUR VISION.*

CENIT has been successfully active for more than 20 years as a leading consulting and software specialist for optimizing business processes in product lifecycle management (PLM), enterprise information management (EIM), business optimization & analytics (BOA) and application management services (AMS). The enterprise focuses chiefly on proprietary software development and on marketing standard solutions by market leaders such as Dassault Systèmes, SAP and IBM. CENIT employs about 700 staff world-wide, serving customers from the automotive, aerospace, mechanical engineering, tool and mold construction, financial services, commercial and consumer goods industries.

Claytex is an engineering consultancy and software distributor that specialises in Systems Engineering. Our expertise is in the modelling and simulation of complex multi-domain systems using Dymola and Modelica. We are based in Leamington Spa (UK) and work with Modelica and FMI on a wide variety of projects. Most recently these include the modelling of Low Carbon Vehicles, Formula 1 and Nascar Sprint Cup racing cars. These projects apply the models in a wide range of tasks including energy usage calculations, control system development, powertrain design and driving simulators. We develop a number of application libraries for Dymola include the Engines, Powertrain Dynamics, SystemID, FlexBody, VDLMotorsports and XMLReader libraries.

Concurrent Real-Time is the industry's foremost provider of high-performance real-time computer systems and software solutions. With nearly 50 years of experience in the real-time market, we deliver hard real-time performance in support of the world's most sophisticated hardware-in-the-loop and man-in-the-loop simulation, data acquisition and process control applications. With a reputation for reliability and performance, our optimized hardware and software products ensure the success of commercial and government programs worldwide. Products include the RedHawk Linux real-time operating system with guaranteed response; NightStar tools for advanced Linux debugging and analysis; iHawk real-time multiprocessors; and Simulation Workbench modeling environment. Simulation Workbench is currently used by major corporations in a variety of simulation applications including automotive component testing, vehicle driving systems, engine test stands, aircraft subsystem testing and maritime control systems. Concurrent Real-Time is based in Pompano Beach, FL, and has offices throughout North America, Europe and Asia.

CyDesign Labs was founded in late 2011 to develop a cloud platform for model-based product engineering. At CyDesign, we believe that the cloud is the future of engineering design. Our product architecture is designed from the ground up to be deployed and operated in a cloud environment – public or private, open or classified, big or small. Our primary goal is to allow engineers to configure, model, and analyze a vast array of design alternatives and to optimize their designs based on requirements.

In October 2013, CyDesign Labs was acquired by ESI Group SA, a leader in virtual product engineering. Under ESI's leadership, CyDesign is focusing on the development and deployment of model-based product engineering solutions for the global automotive and aerospace communities. CyDesign solutions are powered by CyModelica, a proprietary high-performance Modelica compiler and solver.

CyDesign Labs is based in San Jose, CA, with a subsidiary in Coventry, UK

D2T is a worldwide supplier for powertrain development and calibration, test bed engineering and equipment. With our state of the art automation, simulation and calibration tools, developed in cooperation with major OEMs, D2T is strongly involved in hybrid and electric powertrain design and validation. D2T is a subsidiary of IFPEN.

D2T is your experienced partner for:

- Modeling, simulation and design
- Control, overall supervision and calibration
- Optimization, characterization and validation

Dassault Systèmes, the 3DEXPERIENCE Company, provides business and people with virtual universes to imagine sustainable innovations. Its world-leading solutions transform the way products are designed, produced, and supported. Dassault Systèmes' collaborative solutions foster social innovation, expanding possibilities for the virtual world to improve the real world. The group brings value to over 150,000 customers of all sizes in all industries in more than 80 countries.

Dassault Systèmes' CATIA provides a fully integrated systems modeling environment that enables systems engineers to execute and analyze system or sub-systems models, while mixing dynamic and state logic behaviors, using the open source Modelica language.

IPG Automotive GmbH is one of the world's leading suppliers of simulation solutions, test systems and engineering services. Apart from vehicle dynamics simulation the simulation tools CarMaker, TruckMaker and MotorcycleMaker assist in the development of chassis control systems, driver assistance systems, hybrid technologies as well as fuel consumption analysis.

*Supporting your vision*

In the realm of system simulation, ITI is a leading developer of innovative software solutions and offers a vast range of engineering services that help to reduce time-to-market significantly. Our interdisciplinary software application SimulationX allows for comprehensive physical modeling of complex systems. Amongst others we support our customers in virtual prototyping, result interpretation and optimization of energy-efficient design. SimulationX supports the Modelica® language with open and complete CAx interfaces. The software is applied by more than 700 well-known companies, such as Audi, BMW, Bureau Veritas, Daimler, Fraunhofer-Gesellschaft, Germanischer Lloyd, Honda, Nikon, Robert Bosch, Siemens, ThyssenKrupp und Veolia.

### A Siemens Business

Since the 2010 conference, LMS considerably increased its effort to make Imagine.Lab the best-of-breed platform for system simulation. LMS' will is to deliver a combined structured approach (C-based and Modelica-based) to best serve the engineering needs, from full system to detailed component modeling over most of the mechatronics applications. LMS continues to support the establishment of Modelica as an industrial reference through its dedicated commercial support team as well as its involvement in European research projects and its support of the FMI. LMS's position in the Model Based System Engineering software market is considerably increasing to the benefit of the industry and the recognition of Modelica.

Maplesoft, a subsidiary of Cybernet Systems Co., Ltd. in Japan, is the leading provider of high-performance software tools for engineering, science, and mathematics. Its product suite reflects the philosophy that given great tools, people can do great things. Maplesoft's core technologies include Maple, the world's most advanced symbolic computation engine, and MapleSim, a Modelica-based physical modeling and simulation tool. With MapleSim, you can leverage the growing collection of industry-tested Modelica components in your own projects. Maplesoft's customers include Ford, BMW, Bosch, Boeing, NASA, CSA, Canon, Motorola, Microsoft, Bloomberg, and DreamWorks, covering sectors such as automotive, aerospace, electronics, defense, and energy.

Modelon provides industry solutions, services and technology for analytical model-based systems engineering based on the Modelica and FMI open standards. We offer unique know-how in industrial physical modeling, simulation and optimization, and model-based control design. Our customers are found all over the world and represent a variety of application areas with some emphasis on the automotive, energy and process industries. We are proud to have some of the world's best renowned technology companies among our customers. We serve our customers from our locations in Sweden, Germany, USA, and Japan.

## OpenModelica

OpenModelica is an open-source Modelica-based modeling and simulation environment intended for industrial and academic usage. Its long-term development is supported by a non-profit organization – the Open Source Modelica Consortium (OSMC). The goal with the OpenModelica effort is to create a comprehensive Open Source Modelica modeling, compilation and simulation environment based on free software distributed in binary and source code form for research, teaching, and industrial usage. We invite researchers and students, or any interested developer to participate in the project and cooperate around OpenModelica, tools, and applications.

Schlegel Simulation GmbH is an engineering company and software distributor based in Munich, Germany. Our expertise is modeling and simulation of mechatronic systems using Dymola / Modelica and other tools. We develop simulation models, work on simulation projects, realtime and hardware-in-the-loop simulations, we develop customer specific simulators and software, and provide consultancy and training. Schlegel Simulation distributes and supports Dymola.

# WOLFRAM

## COMPUTATION MEETS KNOWLEDGE

Founded by Stephen Wolfram in 1987, Wolfram is one of the world's most respected software companies. At the center is Mathematica: the world's most powerful global computation system. In 2011, Wolfram acquired MathCore Engineering AB - a founding member of the Modelica Association and an active influence in the Modelica language design since 1997. Through this, SystemModeler was released in 2012 - the most complete physical modeling and simulation tool. Unlike other systems, SystemModeler requires no add-ons, fully supports the standard Modelica model language and is designed to connect perfectly with Mathematica for the ultimate integrated modeling, simulation, and analysis workflow.

XRG Simulation GmbH

XRG Simulation has extended expertise in thermal energy system simulations in the automotive and building services field, for the aerospace and shipping industry and for power plants. We are specialized in energy engineering and support industry and research institutions in research, development and improvement of products and projects. Our excellence is:

- Modelling and simulation of thermodynamic systems
- Mathematical optimization
- Validation of models
- Software development for optimization as well as pre- and post-processing of system simulations
